New Evidence for Early Silk in the Indus Civilization

Irene L. Good,[†] J. Mark Kenoyer, and Richard H. Meadow

Summary

Silk is an important economic fiber, and is generally considered to have been the exclusive cultural heritage of China. Silk weaving is evident from the Shang period, though the earliest evidence for silk textiles in ancient China dates to more than a millennium earlier. New study of fibers from Harappan bronze artifacts reveals surprising early evidence for knowledge of silkworking in South Asia, the earliest evidence in the world for any silk outside China, and roughly contemporaneous with the earliest Chinese evidence for silk. This important new finding brings into question the traditional historical notion of sericulture as being an exclusively Chinese invention.

Background

The Indus Civilization, c. 2800–1500 BCE, was one of the great river civilizations of the ancient world. Current understanding of this urban culture is that it was generated out of earlier diverse, regional cultures that interacted with each other economically and socially. Thus within a very large area around the Indus river valley (in Sindh, Pakistan), the Indus Civilization extended from the Himalaya and Hindu Kush to the coastal regions of Kutch and Gujarat; westward into Baluchistan and eastward into northwestern India; covering an area larger than that of Mesopotamia or of Egypt. Harappa was the first of the Indus cities to be discovered. For nearly a century excavations have taken place in the eponymous city. The florescence of the Indus culture (2600–1900 BCE) is known as the *Mature Harappan*.

More than a few enigmas concerning the Indus Civilization still vex archaeologists, not least of which is the lack of substantive evidence for reciprocal exchange of commodities with Mesopotamia, where Indus-produced luxury materials are found in such places as the royal graves at Ur. Yet to date, no Mesopotamian materials have ever been recovered from Indus sites. Recent microscopic analysis of archaeological thread fragments found inside bronze and chlorite beads from two important Indus sites, Harappa and Chanudaro (ca. 2600–2200 BC) have yielded silk fibers. Could this be evidence for sericulture in the Indus civilization that developed independently from that of early China?

Recent work at Harappa has been jointly carried out by a team from the University of Wisconsin at Madison, New York University and Harvard University, under the auspices of Harvard's Harappa Archaeological Research Project (HARP). New study of artifacts recovered from the one of the last seasons of excavation at Harappa (1999) has revealed the presence of silk. The silk is not degummed but contains sericin-coated twinned *brins*, or filaments, of fibroin. Micromorphological study indicates wild silkmoth species rather than *Bombyx mori*. To assess the culture-historical significance of these new silk finds we take into account several wild silkmoth species known to South Asia, understanding that the real nature and extent of sericulture in antiquity is at present unknown. It has been assumed that *Bombyx mandarina* (Moore) was domesticated in China into the well-known (and only domesticated) insect *B. mori* (Chang 1986; Kuhn 1982). The earliest

[†] Author to whom correspondence should be addressed

evidence dates to ca. 2700 BCE from Qianshanyang (Zhou 1980). However *B. mandarina* (Moore) is also native to South Asia.

Not only has early evidence for silk been assumed to be Chinese, but the techniques of degumming and reeling are also considered exclusively Chinese silk industry ‘secrets’. The process of de-gumming, is where the sericin gum is removed from the silk, by submerging the cocoons into a weak alkaline solution. Reeling silk is a process by which the long silk strands (gummed or not) are collected onto a bobbin rather than needing to be twisted as short segments into a spun thread. These two important silkworking processes have been thought to be part of a ‘package’ of Chinese technology known only to China until well into the early centuries AD, although the evidence presented here indicates that wild *Antheraea* silks were also known and used in the Indus as early as the mid-third millennium BCE, and that reeling was practiced. The implication of evidence for silk reeling is that the silkmoth was stifled, leaving the cocoon intact in order to be unraveled. When wild silk cocoons are collected on the ground, usually after the silkmoth has eaten its way out, the remaining silk fibers must be spun rather than reeled, as they are short.

This new discovery of silk in the Indus Valley pushes back the earliest date of silk outside of China by a millennium. Specific contributions of the present paper include discussion of new silk finds from Harappa and Chanudaro along with SEM imaging of modern wild specimens of *Antheraea assamensis* and *A. mylitta* silk.

Methods

Thread samples were first investigated under a low-power binocular microscope for possible fiber identification. The samples were then examined and imaged under a high-power polarizing microscope using auxillary fiber optics and high depth of field, allowing optimal view of extant fiber surface structures. After this, samples were coated with a 5-angstrom coating of Ag and examined under a LEO A FESEM scanning electron microscope at 15 and 20 *kV* at Harvard University’s Center for Imaging and Mesoscale Structures. Determinations were based on comparative silk specimens, viewed under SEM, collected from cocoons sampled from the Entomology Departments of the British Museum of Natural History and the Philadelphia Academy of Natural Sciences.

Results

Harappa

A thread sample was removed from a copper bead excavated at Harappa in 1999 (H 99/8863-2 [168]; lab 99:4488). It is comprised of two fragments: one disintegrated (designated ‘A’) and the other still retaining some thread structure (‘B’). These two samples are of the same thread, and are comprised uniformly of the same type of fiber. Partial mineralization and fiber disintegration hampered a simple and straightforward identification of thread sample H99/8863-2. The thread itself is a slightly ‘S’ twisted (at about 10°), two-ply thread with approximately 60-75 ‘Z’-spun strands in each ply.

Scanning electron micrographic survey of various sites on both sample fragments ‘A’ and ‘B’ produced a reasonably secure morphological determination of silk, and possible further determination of silk from the *A. assamensis* species (see table I and figures 1-2).

HARP ID#	Locus	Material	Context	Level	Date (cal)	description
H 99/8863-2 lab 99:4488 A	inside copper bead	silk thread fibers	Trench 11	IIIB	2200 BCE	S plied Z twist cf. <i>A. assamensis</i>
H 99/8863-2 lab 99:4488 B	inside copper bead	silk thread intact fragment	Trench 11	IIIB	2220 BCE	S plied Z twist cf. <i>A. assamensis</i>
H2000/2242- 1 lab 2000- 1955	inside copper wire ornament	silk thread	Trench 54	IIIC	2450 BCE	Z twist single ply cf. <i>A. mylitta</i>

A second thread sample from Harappa (H2000/2242-1 lab 2000-1955), was recovered in the 2000 field season. This sample also came from within a copper bead, and is also of a wild *Antheraea* silk, but appears to be from a different species, *A. Mylitta*, as it has a distinctive striated fiber (figures 3-5). The particular shape of each type of silk is due to the unique shape of the silkworm's orifice when ejecting fibroin during cocooning. In this case, striations are characteristic of *A. Mylitta* silk. These two species are indigenous to South Asia. *A. assamensis* is found in the high altitudes of the northeastern subcontinent, and *A. mylitta* is found along the tropical west coastal region.

Chanudaro

Chanudaro is another important early urban site of the Indus Civilization which thrived during the third millennium BCE in the Indus Valley. It was excavated in the 1930s by Ernest Mackay through the sponsorship of the Boston Museum of Fine Arts. Recent survey of excavated small finds (principally bronze artifacts such as razors and bowls) currently in the Boston MFA collections revealed several objects with either textile ‘pesudomorph’ or actual extant textile adhering to surfaces of objects. One object, a heat-

fused cluster of microbeads from a bronze bowl, had been published in Mackay's catalogue (#2391B). The microbeads contained therein were noted to include intact thread remains. (see figures 6 and 7).

Figure 6. Microbead from Chanudaro showing slightly 'S' twisted single ply thread. Photomicrograph by I. Good and R. Newman.

Microbead and thread samples from this object from Chanudaro were removed and analyzed. The thread consists of a single ply of approximately 40-50 strands, with a slight 'S' twist (approximately 12-15 degrees). Fibers from the thread were studied under SEM at 20 *kV* without sputtercoating. They appear partially gummed and partially twinned, characteristic of a reeled (but not degummed) silk. The fibers are from *A. assamensis*.

Discussion

The formal exportation of silk from China took place around 119-115 BCE, during the reign of Han Emperor Wu-ti who sought the fabulous blood-sweating 'celestial horses' of Ferghana (in modern day Uzbekistan), yet archaeologists have puzzled over the early presence of silk in a late prehistoric Celtic site in Germany ca. 700 BCE, as well as silk finds from several other sites in Europe, the Mediterranean, Egypt and Central Asia (see, for example, Lubec *et. al* 1993; Braun 1987; Wild 1984; Askarov 1973; Hundt 1971; Richter 1929). For decades, archaeologists have cited these findings as evidence of early contact between China and the West (for full discussion see Good 1995; see also Good forthcoming). What has not been adequately considered in the literature, however, is the possibility that a non-Chinese (and *de facto* wild) species of silkworm which produced workable silk was known and used in antiquity, and that the rare instances of silk that have been discovered far outside of China before Wu-ti's trade relationship with the West began may have in fact been produced indigenously. The evidence presented here now suggests that early sericulture existed in South Asia, and was roughly contemporaneous with the earliest known silk use in China.

Conclusions

This research offers new insight on the extent and antiquity of sericulture. Specifically, these finds suggest the use of wild indigenous silkmoth species in South Asia during the mid-third millennium BCE. Careful morphological study of highly degraded fibers through images derived from scanning electron microscopy allows subtle but distinct and diagnostic features of fiber surface and fiber shaft morphology to aid in species identification. At least two if not three species of silk were utilized in the Indus in the mid-third millennium BCE. There are two distinct thread forms in the samples from Harappa, and they appear to be from two different species of silkmoth (*Antheraea* sp.), based on SEM image analysis. The silk from Chanudaro is of another (yet unidentified) species, possibly an Eri silk (*Philosamia* spp.). It appears to be reeled.

Author Contributions

R. H. Meadow and J.M. Kenoyer excavated the Harappa materials. R. H. Meadow and J.M. Kenoyer recovered samples and brought them to I.L. Good. I.L. Good analysed the thread samples, including the one from Chanudaro. I.L. Good wrote the article and produced the images and figures, except figures 3 and 4.
