Received 1 October 2002; revised 10 February 2003; accepted 7 April 2003; published 13 September 2003.

[1] We report the first in situ measurements of hydrogen cyanide (HCN) and methyl cyanide (CH₃CN, acetonitrile) from the Pacific troposphere (0–12 km) obtained during the NASA Transport and Chemical Evolution over the Pacific (TRACE-P) airborne mission (February–April 2001). Mean HCN and CH₃CN mixing ratios of 243 ± 118 (median 218) ppt and 149 ± 56 (median 138) ppt, respectively, were measured. These in situ observations correspond to a mean tropospheric HCN column of 4.2×10^{15} molecules cm⁻² and a CH₃CN column of 2.5×10^{15} molecules cm⁻². This is in good agreement with the 0–12 km HCN column of $4.4 (\pm 0.6) \times 10^{15}$ molecules cm⁻² derived from infrared solar spectroscopic observations over Japan. Mixing ratios of HCN and CH₃CN were greatly enhanced in pollution outflow from Asia and were well correlated with each other as well as with known tracers of biomass combustion (e.g., CH₃Cl, CO). Volumetric enhancement (or emission) ratios (ERs) relative to CO in free tropospheric plumes, likely originating from fires, were 0.34% for HCN and 0.17% for CH₃CN. ERs with respect to CH₃Cl and CO in selected biomass burning (BB) plumes in the free troposphere and in boundary layer pollution episodes are used to estimate a global BB source of 0.8 ± 0.4 Tg (N) yr⁻¹ for HCN and 0.4 ± 0.1 Tg (N) yr⁻¹ for CH₃CN. In comparison, emissions from industry and fossil fuel combustion are quite small (<0.05 Tg (N) yr⁻¹). The vertical structure of HCN and CH₃CN indicated reduced mixing ratios in the marine boundary layer (MBL). Using a simple box model, the observed gradients across the top of the MBL are used to derive an oceanic loss rate of 8.8×10^{-15} g (N) cm⁻² s⁻¹ for HCN and 3.4×10^{-15} g (N) cm⁻² s⁻¹ for CH₃CN. An air-sea exchange model is used to conclude that this flux can be maintained if the oceans are undersaturated in HCN and CH₃CN by 27% and 6%, respectively. These observations also correspond to an open ocean mean deposition velocity (v_d) of 0.12 cm s⁻¹ for HCN and 0.06 cm s⁻¹ for CH₃CN. It is inferred that oceanic loss is a dominant sink for these cyanides and that they deposit some 1.4 Tg (N) of nitrogen annually to the oceans. Assuming loss to the oceans and reaction with OH radicals as the major removal processes, a mean atmospheric residence time of 5.0 months for HCN and 6.6 months for CH₃CN is calculated. A global budget analysis shows that the sources and sinks of HCN and CH₃CN are roughly in balance but large uncertainties remain in part due to a lack of observational data from the atmosphere and the oceans. Pathways leading to the oceanic (and soil) degradation of these cyanides are poorly known but are expected to be biological in nature.

1. Introduction

[2] Hydrogen cyanide (HCN) and methyl cyanide (CH₃CN, acetonitrile) are two of the most abundant cyanides present in the global atmosphere. Following the first spectroscopic detection of HCN in the stratosphere [Coffey *et al.*, 1981], a number of ground and space based observations of its total atmospheric column have been made [Mahieu *et al.*, 1995; Rinsland *et al.*, 1998, 1999, 2000; Notholt *et al.*, 2000; Zhao *et al.*, 2000, 2002]. The presence of methyl cyanide was first inferred from the composition of its positive ions in the stratosphere [Arnold *et al.*, 1978]. Limited in situ measurements of HCN and CH₃CN have been reported from the lower stratosphere [Schneider *et al.*, 1997]. In the stratosphere, vertical profiles of CH₃CN have also been retrieved from satellite data [Livesey *et al.*, 2001]. Sporadic and often conflicting in situ measurements of CH₃CN from the surface air in urban/rural environments have been published [Becker and Ionescu, 1982; Snider and Dawson, 1984; Hamm and Warneck, 1990]. More recently a proton transfer mass spectrometric technique has been used to measure CH₃CN in tropical environments [Crutzen *et al.*, 2000; Reiner *et al.*, 2001; Williams *et al.*, 2001]. There is promise of future space-based tropospheric observations of HCN (and possibly CH₃CN) with some vertical resolution [Singh and Jacob, 2000].

[3] Controlled studies of laboratory fires have been used to suggest that biomass burning (BB) results in significant emissions of HCN and CH₃CN into the atmosphere [Lobert *et al.*, 1991; Holzinger *et al.*, 1999]. Estimates of their global sources are highly uncertain in part due to extremely limited and often conflicting field observational data [Andreae and Merlet, 2001]. Although large quantities of HCN {~0.40 Tg (N) yr⁻¹} and smaller amounts of CH₃CN {~0.01 Tg (N) yr⁻¹} are also manufactured for applications as fumigants and chemical intermediates, their release is stringently controlled due to their known toxicity. Extremely high HCN concentrations (1–2 parts per thousand) have been reported in cigarette smoke [Verschueren, 1996]. These cyanides are expected to be slowly removed from the atmosphere by reaction with OH radicals [Cicerone and Zellner, 1983; Hamm and Warneck, 1990]. It has also been speculated that oceans may provide an important sink for CH₃CN [Hamm and Warneck, 1990; Lobert *et al.*, 1990; Bange and Williams, 2000], although no direct evidence of this sink is presently available. A recent modeling study by Li *et al.* [2000] concludes that the seasonal behavior of the total column of HCN can be reconciled with an exclusive BB source and a relatively short lifetime attributable to an oceanic sink. Measurements of cyanides in the troposphere are extremely sparse, and our present knowledge of their sources, sinks, and role in atmospheric chemistry and biogeochemistry is highly uncertain.

[4] The NASA Transport and Chemical Evolution over the Pacific (TRACE-P) airborne experiment was performed in the spring (February–April) of 2001 to study the composition and chemistry of the outflow of pollution from Asia to the Pacific troposphere. This experiment provided a first opportunity to utilize a recently developed technique to perform real time in situ airborne measurements of HCN and CH₃CN. Complementing these were measurements of a large number of unique trace chemicals that are helpful in

the identification of sources. Further details on the instrument payload, flight patterns, and prevailing meteorology can be found in the overview papers of Jacob *et al.* [2003] and Fuelberg *et al.* [2003]. Here we describe the atmospheric distribution of HCN and CH₃CN over the Pacific and use the relationship of their observed concentrations with other selected tracers to construct a first picture of their sources and sinks. We also note that these data have been further investigated by Li *et al.* [2003] with the help of a global 3-D model.

2. Experiments

[5] A gas chromatographic (GC) instrument, previously used to measure PAN and oxygenated organics [Singh *et al.*, 2001, and references therein], was expanded to measure HCN and CH₃CN. This instrument was integrated aboard the DC-8 aircraft and all measurements discussed in this paper were performed on this platform. A volume of 5.0 L min⁻¹ (0°C, 1 atm) of ambient air was drawn through a heated Teflon-lined sampling probe using a low pressure drop mass flow controller (MKS Model 1559A). An aliquot of 200 mL of air (80 mL min⁻¹) was passed through a water dryer held at -35°C, and then cryogenically trapped in a sample loop held at -140°C. Extensive laboratory tests were performed to ensure that the water trap removed moisture without measurable loss of other constituents of interest. After cryogenic concentration, the sample loop was heated to 70°C and switched in line with the GC columns. A 50-m “analytical” and a 15-m “stripper” DB wax (0.85 µm) quartz capillary column of 0.45 mm ID were used for constituent separation. The “stripper column” was used to back flush high boiling constituents from the system. Chemicals were detected with a photo ionization detector (PID) placed in series with a reduction gas detector (RGD). Only the RGD was capable of detecting cyanides while both PID and RGD were suitable for detecting oxygenates. All calibrations were performed using standard addition techniques and in a manner that mimicked ambient air sampling. Primary standards for HCN and CH₃CN were referred to a series of permeation tubes held at 30°C and 0°C. A 1-ppm compressed mixture of CH₃CN in nitrogen was also used for this purpose. The detector response for CH₃CN and HCN was linear over a wide concentration range. A precision of ±5% could be obtained on the ground in dry air. Precision under the highly variable atmospheric conditions during airborne operation was of the order of ±15% in the free troposphere and was somewhat poorer in the moist marine boundary layer (MBL). Overall measurement accuracy is expected to be ±25% with a limit of detection of 30 ppt.

[6] A chromatogram showing the separation and detection of HCN and CH₃CN from ambient air is shown in Figure 1. The tailing of peaks in Figure 1 occurs in the mercuric oxide bed and is a known difficulty with the RGD detector but is not a source of additional error. This was the first time that this instrument was used to measure ambient HCN and CH₃CN. There were some instances, usually in the early stages of sampling, when the sensitivity of the instrument appeared to be poor. This loss of sensitivity could be easily confirmed from the analysis of calibration standards. Although the causes of this loss of sensitivity are not fully understood, we have chosen to disregard data collected under such

Figure 1. A sample chromatogram of the atmospheric detection of HCN and CH₃CN using a reduction gas detector (RGD). Sample size is 200 mL.

conditions. Further improvements in instrument sensitivity and precision should be possible in the future.

3. Results and Discussion

[7] In the following sections we provide an analysis of the observations of HCN and CH₃CN during TRACE-P (25 February to 10 April 2001). All measurements discussed in this paper were performed aboard the NASA DC-8 aircraft. The Pacific troposphere was sampled from 0.1 to 12 km over a region that extended from 10 to 45°N latitude and 100°E to 120°W longitude. More details on flight profiles and sampling density are provided by *Jacob et al.* [2003]. When appropriate, this region has been divided into areas representing the western Pacific (longitude 100–160°E) and central/eastern Pacific (longitude 160°E–130°W). To relate these data with other key chemicals, which were measured at differing frequencies, merged data files were created. In much of the analysis that follows, a 5-min merged data set has been used. Unless noted otherwise, only data from the troposphere are considered. A convenient filter ($O_3 > 100$ ppb and $z > 10$ km or $CO < 50$ ppb) was used to remove stratospheric influences. We used methyl chloride and potas-

sium as tracers of biomass combustion, and CO as a more generic tracer of pollution. Although CH₃Cl is known to have a diffuse oceanic and possibly biogenic source [*Butler*, 2000], it was possible to use it as a tracer of biomass/biofuel combustion in air masses downwind of its terrestrial sources. Tetrachloroethylene (C₂Cl₄), a synthetic organic chemical, was employed as a tracer of urban pollution. When appropriate, a pollution filter was used to mitigate the effect of pollution ($CO < 120$ ppb; $C_2Cl_4 < 10$ ppt). This filter resulted in mixing ratios of $96(\pm 15)$ ppb/CO and $3(\pm 1)$ ppt/C₂Cl₄, and is assumed to represent near-background conditions. Utilizing meteorological and tracer information, we are able to draw important conclusions about the sources and sinks of HCN and CH₃CN.

3.1. Atmospheric Distribution

[8] Figure 2 shows the vertical distribution of HCN and CH₃CN in the troposphere based on all TRACE-P data. Superimposed on the data are mean ($\pm\sigma$) mixing ratios based on 2-km bins. Mean concentrations of these and key tracer species are presented in Table 1. It is evident that substantial concentrations of cyanides are present throughout the atmosphere and that there is significant variability. These mixing ratios correspond to a 0–12 km grand average of 243 ± 118 ppt (median 218 ppt) HCN and 149 ± 56 ppt (median 138 ppt) CH₃CN. Comparable in situ HCN data from the troposphere are not available. However, our measured values in the upper troposphere (UT) are not inconsistent with the $164 (\pm 25\%)$ ppt lower stratospheric mixing ratios reported by *Schneider et al.* [1997] for February 1995. Unlike HCN, a more extensive tropospheric database for CH₃CN has become available. Following the TRACE-P deployment, Pacific region measurements of CH₃CN were made at the Mauna Loa observatory (April 2001) and over the eastern Pacific (April–May 2002). These studies report mixing ratios in the vicinity of 100–200 ppt in good agreement with our results [*Karl et al.*, 2003; *De Gouw et al.*, 2003]. Background CH₃CN mixing ratios reported from the Indian Ocean and Surinam [*Crutzen et al.*, 2000; *Lelieveld et al.*, 2000; *Reiner et al.*, 2001; *Wisthaler et al.*, 2002] were generally in the range of 100–300 ppt. It is noted that strong seasonal variations in the atmospheric abundance of HCN (and likely CH₃CN) are present [*Zhao et al.*, 2002], and any comparison of observations must take this factor into account.

[9] The variability in the mixing ratios of cyanides is substantial and largely associated with the outflow of pollution from the Asian continent. Maximum concentrations of 1610 ppt and 320 ppt were measured for HCN and CH₃CN, respectively. It is instructive to normalize these data with respect to a common tracer of pollution to minimize the observed scatter. Figure 3 shows the altitude profile when the mixing ratios of HCN and CH₃CN are normalized with respect to CO. An evident feature is that relative to CO, the mixing ratios of HCN and CH₃CN decline rapidly toward the surface of the ocean. A nearly identical vertical structure can also be seen when mixing ratios are normalized to a more specific tracer of BB such as CH₃Cl. This behavior is also seen directly in the vertical structure of HCN and CH₃CN (Table 2) when the data are further filtered for relatively clean atmospheric conditions ($CO < 120$ ppb; $C_2Cl_4 < 10$ ppt). As we show in section 3.5, these reduced lower tropospheric concentrations are a first indication of their surface sink.

Figure 2. Vertical structure of HCN and CH₃CN over the Pacific as measured during TRACE-P.

[10] On limited occasions and at midlatitudes, it was possible to penetrate the lowermost part of the stratosphere. Ozone concentrations as large as 600 ppb were measured during these episodes. Figure 4 shows the distribution of CH₃CN plotted as a function of O₃. The decline in CH₃CN concentrations above the tropopause is very similar to that observed by *Schneider et al.* [1997]. It was not possible to collect sufficient HCN data in the stratosphere due to an instrument artifact.

3.2. Atmospheric Columns

[11] For the sampled latitudes and season, our in situ measurements (Table 1) correspond to a 0–12 km tropospheric HCN column of $3.7\text{--}4.2 \times 10^{15}$ molecules cm⁻² and a CH₃CN column of $2.4\text{--}2.5 \times 10^{15}$ molecules cm⁻². The lower end of this range is based on median mixing ratios while the upper end is based on means. This result can be best compared with the Japanese ground-based infrared solar spectroscopic observations of the column of HCN over Tsukuba (36.2°N), Rikubetsu (43.5°N), and Moshiri (44.4°N) during the TRACE-P period. Mean 0–12 km column densities (in units of 10^{15} molecules cm⁻²) of 4.8 ± 0.7 , 4.1 ± 0.4 , 4.4 ± 0.6 respectively, were derived. The daily HCN columns from these sites are shown in Figure 5. These mean column densities of $4.1\text{--}4.8 \times 10^{15}$ molecules cm⁻² are in reasonably good agreement with the derived mean HCN column of 4.2×10^{15} molecules cm⁻² deduced from in

situ measurements (Figure 5). Although there can be substantial year to year variability, typical spring time column densities of $4\text{--}5 \times 10^{15}$ molecules cm⁻² have been reported from 1996 to 2000 over Japan [*Zhao et al.*, 2000, 2002]. HCN columns have also been derived from spectra collected at high altitude observatories located at Mauna Loa, Hawaii (19.5°N, 3.4 km altitude) and Jungfraujoch, Switzerland (46.6°N; 3.6 km altitude) [*Rinsland et al.*, 1999, 2000]. Mean springtime HCN columns from these locations are found to be in the range of $2\text{--}3 \times 10^{15}$ molecules cm⁻². Once again, this is in reasonable agreement with the 3.5–12 km mean column density of 2.4×10^{15} molecules cm⁻² derived from the present in situ measurements (Table 1). We note that the ground-based spectroscopic observations do not have sufficient vertical resolution to determine the boundary layer HCN column. Long-term spectroscopic observations are inconclusive about any possible trend in the atmospheric HCN [*Mahieu et al.*, 1997; *Rinsland et al.*, 2001]. Similar spectroscopic data for CH₃CN are not available possibly because its strongest absorption in the 6-μm region is obscured by water vapor.

3.3. Tracer Relationships

[12] Despite a high degree of variability, mixing ratios of HCN and CH₃CN are related suggesting common sources. Figure 6 shows this relationship in the free troposphere (>2.5 km) over the entire Pacific. A linear relationship

Table 1. Atmospheric Mixing Ratios of HCN, CH₃CN, and Selected Tracers in the Pacific Troposphere Based on All TRACE-P Tropospheric Data

Altitude, km	HCN, ppt	CH ₃ CN, ppt	CO, ppb	CH ₃ Cl, ppt	C ₂ Cl ₄ , ppt
0–2	233.5 ± 160.6 (196.6, 244) ^a	115.3 ± 50.7 (105.6, 242)	194.2 ± 88.8 (173.5, 428)	580.7 ± 101.3 (554.3, 393)	10.2 ± 8.9 (9.2, 393)
2–4	248.2 ± 116.7 (208.9, 156)	148.4 ± 65.1 (128.7, 175)	150.8 ± 54.6 (131.0, 281)	572.9 ± 37.4 (559.2, 264)	6.6 ± 6.0 (5.5, 264)
4–6	243.8 ± 70.3 (226.3, 94)	146.4 ± 47.5 (137.4, 125)	130.6 ± 46.3 (116.3, 218)	565.1 ± 26.0 (556.9, 203)	5.3 ± 3.5 (4.4, 200)
6–8	246.6 ± 66.1 (232.0, 99)	153.2 ± 43.6 (142.5, 144)	118.9 ± 40.3 (110.6, 229)	564.7 ± 28.6 (559.1, 220)	4.1 ± 2.3 (3.6, 220)
8–10	254.0 ± 91.6 (225.3, 108)	177.9 ± 48.7 (162.7, 201)	122.1 ± 42.8 (108.9, 308)	580.0 ± 32.0 (578.0, 293)	3.2 ± 1.5 (2.7, 288)
10–12	235.9 ± 77.0 (227.6, 45)	166.0 ± 49.1 (152.7, 128)	102.0 ± 35.8 (85.8, 206)	573.5 ± 31.8 (569.0, 200)	2.2 ± 1.1 (2.1, 199)
0–12	242.7 ± 118.4 (218.4, 746)	149.0 ± 55.9 (138.0, 1015)	143.6 ± 67.7 (127.2, 1670)	574.1 ± 57.9 (561.0, 1573)	5.8 ± 6.1 (4.4, 1564)

^aMean ±1 standard deviation (median, number of data points).

Figure 3. Vertical structure of the relative abundance of HCN and CH₃CN with respect to CO in the troposphere.

provides a reasonable fit to these data ($R = 0.70$) which is somewhat improved with a second order best fit ($R = 0.77$). The latter suggests that under certain conditions emissions of HCN increase more rapidly than CH₃CN. While there is insufficient data to draw firm conclusions, there is an indication that these mixing ratios are nonlinearly related. A likely cause is that emission factors of HCN and CH₃CN vary differently with the nature of fuel and combustion temperature. There is insufficient knowledge about the pyrogenic formation mechanisms of cyanides to quantitatively understand the nonlinear behavior. There exists a linear relation between CH₃Cl, a tracer of biomass combustion, and HCN, CH₃CN, and CO in the free troposphere over the western Pacific as well as the central/eastern Pacific regions (Figure 7). These linear relationships are maintained over the entire Pacific troposphere. Figure 8 demonstrates the persistence of this linear relationship between cyanides and tracer (CO and CH₃Cl) mixing ratios in the UT (8–12 km). The somewhat improved linear correlations over the central/eastern Pacific as well as the UT are attributable to the greater homogeneity of the air masses farther away from their sources. In their entirety, these relationships provide broad support for the view that the atmospheric burden of cyanides is strongly associated with BB sources. Nonvolatile aerosols also behaved in a manner similar to gas phase tracers such as CO.

[13] The linear relationships typically observed in the free troposphere frequently broke down in the boundary layer in part due to the high complexity of the Asian anthropogenic sources and the proximity of the oceanic sink. We sampled two distinct outflow events when low level outflow (<1 km) of pollution was encountered in the Taiwan Straits (Mission 12) and the Yellow Sea (Mission 13). Trajectory analysis showed that the Taiwan Straits episode was impacted by source regions from the Fujian province of China, while the Yellow Sea episode was a direct outflow from the Shanghai urban complex. Figure 9 shows the relationship of CH₃Cl with cyanides and CO for these missions. Extremely large concentrations of CH₃Cl were associated with virtually no elevation in CH₃CN and only a modest increase in HCN. A very large fraction ($\approx 30\%$) of fuel consumed in China is from the use of biofuels/coal. We interpret the boundary layer outflow data to infer that such fuels are inefficient producers of cyanides. A low fuel nitrogen content and a high halogen content is implied.

3.4. Source Estimates of HCN and CH₃CN From Biomass Burning

[14] To assess the sources of cyanides, we investigated their atmospheric behavior relative to known tracers of combustion and urban pollution. As a first step, we looked

at the enhancement ratios (ERs) of HCN and CH₃CN relative to CH₃Cl and CO in 12 plumes sampled in the free troposphere (>3 km) and in episodes of pollution outflow in the MBL (0–1 km). These data are summarized in Table 3. All these chemicals are long-lived (several months), and the plumes are sufficiently fresh (<5 days), so that chemical changes during transport should have a negligible effect on these ERs. Therefore these enhancement ratios are effectively the same as emission ratios defined by *Andreae and Merlet* [2001]. Five-day back trajectory analysis [*Fuelberg*

Figure 5. A comparison of the HCN columns (0–12 km) derived from spectroscopic observations over Japan with in situ measurements over the Pacific. Shaded area represents the mean value derived from in situ data. The HCN column is known to show a spring maximum attributable to biomass burning emissions. Circles, Moshiri; squares, Rikubetsu; diamonds, Tsukuba.

Figure 6. Relationship between the atmospheric mixing ratios of HCN and CH₃CN in the free troposphere.

et al., 2003], indicated that the free tropospheric plumes generally originated over regions of southern China, Southeast Asia, and northern Africa. Satellite observations showed that fires were prevalent in these regions. It is common knowledge that BB air masses are easily advected into the free troposphere. All of the relevant tracers of biomass combustion (e.g., HCN, CH₃CN, CO, CH₃Cl, and potassium) were significantly elevated in these plumes. Additionally, the elevation in C₂Cl₄ (Table 3) was quite small (0–10 ppt). In contrast, trajectories associated with the 9 boundary layer pollution episodes (Table 3) showed that nearly all of them had crossed the eastern China coastal areas at relatively low altitudes within the last two days. These episodes were also associated with high concentrations of C₂Cl₄ and other anthropogenic tracers.

[15] Fossil fuel combustion is not a known source of either CH₃Cl or cyanides. Because of this specificity, we will first use ERs with respect to CH₃Cl to assess BB emissions of HCN and CH₃CN. In large east Asian cities, most of the BB emissions are due to biofuels [*Streets and Waldhoff*, 1998; *Yevich and Logan*, 2003], and thus boundary layer ERs provide an indicator of cyanide emissions from this source. In the following analysis we use both free tropospheric and MBL ERs to estimate the total BB source of HCN and CH₃CN. The former represents relative emissions from plumes due to fires, and the latter indicates biofuel/coal emissions. We adopt a global BB CH₃Cl source of 0.9 Tg yr⁻¹ (87% biomass fires; 13% biofuels/charcoal) based on the most recent evaluations [*Lobert et al.*, 1999; *Andreae and Merlet*, 2001]. To obtain global BB source of HCN and CH₃CN (S_{HCN,CH₃CN}, Tg (N) yr⁻¹), we scale ERs in Table 1 (ppt/ppt) according to

$$[S_{HCN,CH_3CN}]_{CH_3Cl} = 0.9 \times \{14/50.5\} \times \{0.87ER_{ft} + 0.13ER_{bl}\}_{CH_3Cl}, \quad (1)$$

where ER_{ft} and ER_{bl} are the respective ERs (ppt/ppt) with respect to CH₃Cl in the free troposphere and the MBL

Figure 7. Relationships between the mixing ratios of methyl chloride with CH₃CN, HCN, and CO in the free troposphere over the (a) western Pacific and (b) eastern/central Pacific. For the entire ensemble of data, best fit slopes are $\Delta\text{HCN}/\Delta\text{CH}_3\text{Cl}$ -1.80; $\Delta\text{CH}_3\text{CN}/\Delta\text{CH}_3\text{Cl}$ -1.19; and $\Delta\text{CO}/\Delta\text{CH}_3\text{Cl}$ -1.00.

(Table 1). To minimize errors due to urban influences, only ER_{fit} associated with minimal C₂Cl₄ enhancements (<5 ppt) are used in these calculations. Using equation (1), we calculate a global BB source of $0.8 \pm 0.4 \text{ Tg (N) yr}^{-1}$ for HCN and $0.4 \pm 0.1 \text{ Tg (N) yr}^{-1}$ for CH₃CN. Equation (1) also leads to the conclusion that most of these emissions are due to fires (first term) and biofuels/charcoal (second term) contribute only a small fraction (10% HCN and 5% of CH₃CN) to the total BB source of cyanides.

[16] A similar analysis was also carried out by using ERs with respect to CO. The presence of non-BB sources of CO may make these estimates somewhat less reliable. However,

by using ER_{fit} values (ppt/ppb) associated with minimal C₂Cl₄ enhancements (<5 ppt), it is possible to obtain a reasonable estimate by using

$$[S_{\text{HCN,CH}_3\text{CN}}]_{\text{CO}} = 600 \times \{14/28\} \times 10^{-3} \{0.74\text{ER}_{\text{fit}} + 0.26\text{ER}_{\text{bi}}/f\}_{\text{CO}}. \quad (2)$$

For this purpose, we adopted a global BB CO source of 600 Tg yr^{-1} (74% biomass fires; 26% biofuels/charcoal), based on the most recent evaluations of BB sources [Duncan *et al.*, 2003; Yevich and Logan, 2003]. The factor f is the CO

Figure 8. Relationship of HCN and CH₃CN with select tracers in the upper troposphere (8–12 km).

fraction from biofuel/charcoal use in regions of eastern Asia and attempts to correct for the impact of fossil fuel CO sources on the MBL. On the basis of the inventory developed by *Streets et al.* [2003], a value of 0.55 is adopted for f . As we have seen from equation (1), the biofuel component of HCN/CH₃CN emissions is small (<10%), so errors due to uncertainty in f are relatively modest. Using equation 2 and ERs with respect to CO from Table 1 results in a BB source estimate of 0.9 ± 0.4 Tg (N) yr⁻¹ for HCN and 0.4 ± 0.1 Tg (N) yr⁻¹ for CH₃CN, in good agreement with results from equation (1). We caution that these estimates are relative and would be directly affected by the uncertainties in the global BB emissions of CO and CH₃Cl [Andreae and Merlet, 2001; Yevich and Logan, 2003].

[17] In Table 4, we summarize BB source estimates of HCN and CH₃CN from published laboratory and field studies. Nearly all these estimates have been derived from measured ERs with respect to CO in controlled laboratory fires, in prescribed burns, and in real forest and savanna fires. In some instances [e.g., *Lobert et al.*, 1991], emission factors relative to fuel nitrogen have been employed. These derived estimates typically lie in the range of 0.5–1.5 Tg (N) yr⁻¹ for HCN and 0.3–0.6 Tg (N) yr⁻¹ for CH₃CN. Recent measurements of comparatively large HCN ERs relative to CO in African fires by *Yokelson et al.* [2003] suggest that the HCN global BB source may be near the upper limit of this range (R. Yokelson, private communication, 2003). Our ERs, based on direct atmospheric measurements, and BB source estimates (Tables 3 and 4) are within the broad ranges that have been previously reported.

[18] The source of variability in individual ERs in Table 3 is likely due to the dependence of ERs on the type of fuel burned and its nitrogen content. The outflow of Asian pollution represents an extremely complex mixture resulting from the heterogeneity of the fuel sources [Kato, 1996; Streets and Waldhoff, 1998]. There were instances when CO was elevated but cyanides as well as

CH₃Cl were not, as may be expected from a typical industrialized urban source. There were also instances when a large elevation in CH₃Cl coexisted with little increase in CH₃CN. In a study involving a variety of burns, *Yokelson et al.* [1997] find that relative to CO organic fuels produce the largest HCN, grasses less so, and woody fuels produce the least.

3.5. Air-Sea Exchange and Oceanic Sink

[19] It is evident from Figure 3 that the atmospheric mixing ratios of HCN and CH₃CN declined toward the surface over open oceans. This is easily seen in Table 3, where statistical distributions of data filtered to remove pollution episodes (CO < 120 ppb; C₂Cl₄ < 10 ppt) are summarized. All other indicators of pollution (CO, C₂H₆, C₂H₂, etc.) show the opposite behavior with increasing mixing ratios near the surface. We have assessed the significance of these reduced boundary layer mixing ratios using a simple steady state box model [Singh et al., 1996]. In this model the marine boundary layer (MBL) mixing ratios are maintained by entrainment from the free troposphere, loss due to reaction with OH radicals, and exchange with the ocean. As we shall see later, soils are not a likely important sink for cyanides and this gradient is mainly due to the oceanic sink.

[20] The total flux into the MBL (F_t) was calculated by using a mean entrainment velocity (V_e) of 0.4 cm s^{-1} [Kawa and Pearson, 1989; Paluch et al., 1994; Singh et al., 1996; I. Faloon et al., Observations of entrainment in eastern Pacific marine stratocumulus using three conserved scalars, submitted to *Journal of Atmospheric Science*, 2003] and a concentration gradient (ΔC) across the top of the MBL derived from measurements filtered for clean atmospheric conditions (Table 3):

$$F_t = V_e \Delta C. \quad (3)$$

^aSources are generally derived from measured emission ratios (ERs) with respect to CO in controlled laboratory fires, in prescribed burns, and in real forest and savanna fires.

^bDerived from mean ERs in Table 3 based on a global BB source of 600 Tg yr⁻¹ for CO and 0.9 Tg yr⁻¹ for CH₃Cl. It is assumed that enhancement ratios are effectively the same as emission ratios. See text for details.

To avoid biases due to scatter in the data, ΔC was determined by using median concentration differences between the free troposphere above the MBL (2–4 km) and within the MBL (0–2 km). A median gradient of 47 ppt for HCN and 20 ppt for CH₃CN from Table 2 is employed to determine F_t . A second method that normalized mixing ratios to CO was also used with comparable results. The loss in the MBL due to OH reaction (F_{OH}) was estimated by using an OH concentration of 1.5×10^6 molecules cm⁻³ and an MBL depth of 2 km, consistent with historic knowledge and actual observations during TRACE-P. Losses due to other radical reactions (Cl, NO₃ etc.) are small and are presently neglected. Choice of a somewhat lower MBL depth (1.5 km) did not perceptibly change results. The CH₃CN + OH rate constant ($k_{OH-CH_3CN} = 7.8 \times 10^{-13} e^{-1050/T}$ cm³ molecule⁻¹ s⁻¹) was based on the recommendation of *DeMore et al.* [1997]. The HCN + OH rate constant ($k_{OH-HCN} = 1.0 \times 10^{-13} e^{-773/T}$ cm³ molecule⁻¹ s⁻¹ at 600 torr) was from the recent study of *Wine et al.* [2002], who find this rate to be substantially slower than the *DeMore et al.* [1997] recommendation. Although this reaction is pressure-dependent, this effect is small under tropospheric conditions. A net oceanic deposition flux ($F_o = F_t - F_{OH}$) of 8.8×10^{-15} g (N) cm⁻² s⁻¹ and 3.4×10^{-15} g (N) cm⁻² s⁻¹ could be calculated for HCN and CH₃CN, respectively (Table 5).

[21] The air-sea exchange model of *Liss and Slater* [1974], with newly recommended parameters [*Liss and Merlivat*, 1986; *Nightingale et al.*, 2000; *Donelan and Wanninkhof*, 2001], was adapted to derive the undersaturation (S) necessary to maintain the oceanic deposition flux, F_o :

$$F_o = F_t - F_{OH} = K_l(C_g/H - C_l) \quad (4)$$

$$K_l = [1/k_l + 1/Hk_g]^{-1} \quad (5)$$

$$S = 1 - HC_l/C_g = H F_o/K_l C_g \quad (6)$$

$$v_d = F_o/C_g = S K_l/H \quad (7)$$

where C_l and C_g are concentrations in the bulk liquid and gas phases, respectively, H (C_{sg}/C_{sl}) is the dimensionless Henry's law constant, k_l and k_g are transfer constants for liquid and gas phases, and v_d is the corresponding deposition velocity. The temperature-dependent Henry's law constants for HCN and CH₃CN have been measured in water and best values of 3.4×10^{-3} ($\Delta H_{298} = -40.0$ kJ mol⁻¹) and 7.5×10^{-4} ($\Delta H_{298} = -50.0$ kJ mol⁻¹), respectively, were

^aOn the basis of a mean entrainment velocity of 0.4 cm s⁻¹ and an OH value of 1.5×10^6 molecules cm⁻³ in MBL (0–2 km).

^bCalculated using an air-sea exchange model (see text for detail).

^cExtrapolations to the globe are carried out by scaling to the seasonal and latitudinal behavior of the remotely sensed total column of HCN (see text for detail).

^dCalculated by normalizing to a CH₃CCl₃ lifetime of 5 years (OH $\approx 1 \times 10^6$ molecules cm⁻³).

adopted for 295°K (R. Sander, Compilation of Henry's law constants for inorganic and organic species of potential importance in environmental chemistry, version 3, 1999, available at <http://www.mpch-mainz.mpg.de/~sander/res/henry.html>). These were increased by 20% to correct for the salting out effect of seawater which reduces solubility [Donelan and Wanninkhof, 2001]. A liquid phase transfer constant (k_l) of 11 cm h^{-1} and a gas phase transfer constant (k_g) of $6912 (18/\text{MW})^{1/2} \text{ cm h}^{-1}$ were used based on recommended values for a mean surface wind speed of 6 m s^{-1} [Asher, 1997; Donelan and Wanninkhof, 2001]. HCN and CH₃CN are moderately soluble in water and both liquid phase ($1/k_l$) and gas phase ($1/Hk_g$) resistances are important in controlling their air-sea flux. Using the parameters described above along with equations (4)–(6), we determine that HCN and CH₃CN are undersaturated in the oceans by 27% and 6%, respectively (Table 5). An uncertainty of the order of $\pm 20\%$ can be placed on the calculated mean oceanic flux and undersaturation due solely to the choice of entrainment velocity.

[22] On the basis of the present observations, a deposition velocity (v_d) of 0.12 cm s^{-1} for HCN and 0.06 cm s^{-1} for CH₃CN is calculated from equation (7). These values are appropriate for deposition over open oceans. Using a different set of assumptions, Li *et al.* [2003] find that a v_d of 0.13 cm s^{-1} for both HCN and CH₃CN provides a reasonable fit to the present data. We were unable to uncover independent studies of HCN dry deposition. However, several estimates of CH₃CN deposition velocity have been made [de Laat *et al.*, 2001; de Gouw *et al.*, 2003; Karl *et al.*, 2003]. These estimates have been typically in the range of 0.01 to 0.2 cm s^{-1} . In a recent study performed in the upwelling south Atlantic regions off of the Namibian and Angolan coasts, Jost *et al.* [2003] find that a much higher dry deposition velocity of the order of 0.4 cm s^{-1} best fits their observations. It is possible that deposition velocities over coastal regions are larger than over open oceans. Clearly, additional HCN and CH₃CN studies are needed for an accurate assessment of the oceanic sink.

[23] For seawater undersaturation to persist, a removal mechanism within the oceans is necessary. Chemical reaction pathways for HCN and CH₃CN degradation (e.g., hydrolysis, Cl^-) are too slow to be a significant process. In polluted streams, bioremediation of HCN has been a common industrial practice. Enzymatic reactions in aerobic conditions can relatively quickly deplete HCN to ammonia $\{\text{HCN} + 1/2\text{O}_2 \rightarrow \text{HOCN} (+\text{H}_2\text{O}) \rightarrow \text{NH}_3 + \text{CO}_2\}$. Similar removal is also known to occur for CH₃CN. In one study of river streams, unaided biodegradation was sufficient to remove these cyanides with a half-life of about two weeks [Environmental Protection Agency (EPA), 1985, 1992]. By analogy, we believe that oceanic removal via biological degradation is a likely possibility. Although bacteria present in soils could also destroy cyanides, there is no evidence to support that this is an important loss mechanism, in part because cyanides are rapidly and preferentially exchanged to the air medium. It should be noted that the presence of a net sink does not imply that there are no additional oceanic sources. These sources, if present, could be masked by the oceanic degradation. We were unable to find any direct seawater

observations to confirm the hypothesis of undersaturation or to ascertain the rate of loss of HCN and CH₃CN.

3.6. Atmospheric Lifetimes and Global Budgets

[24] Development of an accurate global budget for HCN and CH₃CN requires far more extensive observational data than are currently available. As a first step, we attempt to use our measurements over the Pacific for this purpose by relying on reasonable extrapolations and assumptions. We extrapolate the TRACE-P observations of HCN and CH₃CN in time and space by scaling them to the seasonal and latitudinal profile of the column of HCN which has been extensively derived from spectroscopic observations and also modeled [Zhao *et al.*, 2000, 2002; Notholt *et al.*, 2000; Li *et al.*, 2000; Rinsland *et al.*, 2001, 2002]. In the absence of direct observations and given the presumed commonality of sources, we consider this extrapolation to be a reasonable first step for both HCN and CH₃CN. The seasonal cycle of HCN reported by Zhao *et al.* [2000] over Japan indicated that the annual average mixing ratios at midlatitudes are 1.08 times those in spring. Latitudinal extrapolation to the globe, based on the work by Notholt *et al.* [2000] and Rinsland *et al.* [2002], resulted in a scaling factor of 0.92. Fortuitously, these two factors (seasonal and latitudinal) result in a net scaling factor of 1.0. Thus the springtime midlatitude measurements of HCN made during TRACE-P closely resemble the global annual average. For extrapolation to global scales, median concentrations under relatively clean conditions (Table 2) are utilized. We also assume that the oceanic fluxes estimated for the TRACE-P region are representative of global oceans.

[25] Table 5 summarizes the global budget of HCN and CH₃CN based on the present observations and noted assumption. The calculated oceanic deposition flux is equivalent to a deposition of $1.0 \text{ Tg (N) yr}^{-1}$ of HCN and $0.4 \text{ Tg (N) yr}^{-1}$ of CH₃CN to the global oceans. This nitrogen deposition of $1.4 \text{ Tg (N) yr}^{-1}$ is only a small fraction of the total nitrogen deposition into the oceans of $30 \text{ Tg (N) yr}^{-1}$ [Duce, 1998]. However, this nearly uniform global nutrient source may still play an important role in remote oceans. The total annual tropospheric burden of HCN and CH₃CN is determined to be 0.44 Tg (N) and 0.30 Tg (N) , respectively. The oceanic removal rate thus corresponds to an atmospheric residence time of 5.3 months for HCN and 9.2 months for CH₃CN. Using the OH reaction rates (in units of $\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) noted earlier ($k_{\text{OH-CH}_3\text{CN}} = 7.8 \times 10^{-13} e^{-1050/T}$; $k_{\text{OH-HCN}} = 1.0 \times 10^{-13} e^{-773/T}$) and a CH₃CCl₃ lifetime of 5 years corresponding to a global mean OH of $\sim 1 \times 10^6 \text{ molecules cm}^{-3}$ [Montzka *et al.*, 2000], we derive a mean residence time of 63 months for HCN and 23 months for CH₃CN due to removal by reaction with OH radicals. We note that this HCN residence time is nearly 4 times longer than that inferred from the DeMore *et al.* [1997] recommendation. Clearly, there is much uncertainty associated with these OH rate constants. Given the extremely low solubility of these cyanides, we expect removal by processes such as rain out and wash out to be unimportant in comparison [Crutzen and Lawrence, 2000]. Loss due to reactions with Cl , $\text{O}(^1\text{D})$, and NO_3 radicals is calculated to be negligibly small. Although soil bacteria could destroy cyanides,

limited studies have shown that cyanides are quickly released after deposition to soil and this sink [EPA, 1985, 1992], although poorly studied, is expected to be minor. The mean atmospheric residence time, based on OH and oceanic loss, is 5.0 months for HCN and 6.6 months for CH₃CN (Table 5). The calculated burden and residence times imply that a global source of some 1.1 Tg (N) yr⁻¹ for HCN and 0.5 Tg (N) yr⁻¹ for CH₃CN is present. The 5 month mean lifetime of HCN can be compared with a range of 2–4 months derived by Li *et al.* [2000]. Similarly, the 7 month lifetime of CH₃CN can be compared with estimates of 3–11 months by Hamm and Warneck [1990], 1 month by Bange and Williams [2000], and ~5 months by Karl *et al.* [2003].

[26] It is evident from Tables 4 and 5 that our estimates of the BB sources can account for most of the needed source for HCN and CH₃CN. Nevertheless, the possibility of additional sources is not ruled out. According to the Toxics Release Inventory of U.S. EPA <http://www.epa.gov/tri>, the 1999 total U.S. emissions for HCN and CH₃CN were 1.6×10^9 g (N) yr⁻¹ (55% air discharge) and 3.2×10^9 g (N) yr⁻¹ (5% air discharge), respectively. Thus direct industrial releases of HCN and CH₃CN are extremely small (<0.02 Tg (N) yr⁻¹). Measurements over urban Los Angeles during TRACE-P (Mission 20 and test flights) along with the direct measurements of CH₃CN in automobile exhaust by Holzinger *et al.* [2001] are consistent with the view that fossil fuel combustion is a miniscule source (<0.02 Tg (N) yr⁻¹). We note here that cyanides are easily formed during processes of high temperature fuel combustion ($\text{CH} + \text{N}_2 \rightarrow \text{HCN} + \text{N}$) but are instantly converted to NO resulting in nearly zero net emissions. There is also the possibility that biogenic sources of HCN (and CH₃CN) may be present. In several studies cut leaves are found to have significant levels of HCN (1 mg g⁻¹ dry weight). High amounts of cyanogenic glycosides (1–30 mg kg⁻¹), which are quickly converted to HCN upon maceration, are found in common foods such as almonds and lima beans. A mechanism for the formation and release of HCN from linamarin (a cyanogenic glycoside) has been discussed by Fall *et al.* [2001]. Tyndall *et al.* [2001] also suggest that CH₃CN oxidation by OH could also yield some HCN. The budget analysis presented in Table 5 does not rule out the possibility that primary biogenic or secondary sources of <0.2 Tg (N) yr⁻¹ may be present.

[27] The budget presented in Table 5 must be considered a somewhat rough estimate in large part because of the extreme paucity of available data. Many of the assumptions and extrapolations (e.g., uniform oceanic loss) have not yet been tested in varied geographical locations and seasons. We should expect losses in coastal, open, and upwelling oceanic regions to vary. Detailed studies of soil deposition and loss have also not been performed. At the present time, there are insufficient data to quantify the uncertainties associated with estimates in Table 5. Substantial additional atmospheric and oceanic data are required to refine these estimates.

4. Conclusions

[28] In situ measurements of HCN and CH₃CN are consistent with the view that biomass burning is the

largest source and oceanic loss the largest sink. The global budget of these cyanides is in rough balance but the possibility of small additional sources and sinks is not ruled out. While these chemicals are convenient tracers of biomass burning pollution, their atmospheric and biogeochemical cycles are poorly understood. There are few in situ data currently available on the atmospheric distribution of cyanides from the Northern Hemisphere and virtually none from the Southern Hemisphere. The paucity of oceanic data is even more glaring. While bacterial loss in the oceans is postulated as the main loss process, no chemical or biological data from the oceans are currently available. The assumption that soils are a minor sink is poorly validated. There is a need to better quantify the global budget of cyanides, including a better mechanistic understanding of combustion sources and biological sinks. The potential of upcoming satellite instruments to measure of HCN and possibly CH₃CN in the troposphere hold great promise.

[29] **Acknowledgments.** This research was funded by the NASA Global Tropospheric Experiment. We thank all TRACE-P participants for their support. Comments and suggestions by R. Yokelson of the University of Montana are much appreciated.
