Key words: Environmental pollution Food contamination Methylmercury compounds
Polychlorinated biphenyls Prenatal exposure delayed effects

Abstract

Objective: To determine whether neonatal neurological function is adversely affected by seafood contaminants from maternal diet during pregnancy.

Study design: A cohort of 182 singleton term births was established in the Faroe Islands, where marine food includes pilot whale. Maternal serum, hair, and milk, and umbilical cord blood were analyzed for contaminants. Essential fatty acids, selenium, and thyroid function parameters were determined in cord blood. The infant's neurological optimality score was determined at two weeks of age adjusted for gestational age, and predictors were assessed by regression analysis.

Results: Exposures to methylmercury and polychlorinated biphenyls were increased in relation to maternal seafood intake, as were $\omega 3$ fatty acid concentrations in cord serum. Thyroid function showed no abnormalities. After adjustment for confounders, a 10-fold increase of the cord-blood mercury concentration was associated a decreased neurological optimality score of 2.0 ($p = 0.03$). This effect corresponds to the one caused by a decrease in gestational age of about three weeks. Other seafood diet parameters had no effect on this outcome.

Conclusions: Prenatal exposure to methylmercury from contaminated seafood was associated with an increased risk of neurodevelopmental deficit. Thus, in this North Atlantic population, methylmercury constituted an important neurological risk factor, while effects of other seafood components were not detectable.

Abbreviations:

DDE: dichlorodiphenyldichloroethene

DDT: dichlorodiphenyltrichloroethane

DHA: docosahexaenoic acid

EPA: eicosapentaenoic acid

NOS: neurological optimality score

PCB: polychlorinated biphenyl

Σ PCB: sum of polychlorinated biphenyl congeners

Methylmercury is a seafood contaminant which has raised concern regarding the safety for pregnant women (1). Seafood seriously contaminated with methylmercury in Minamata, Japan, caused many cases of a congenital poisoning that, at first, resembled spastic paresis (2). In a later incident in Iraq, an increased number of neurological abnormalities was observed in infants when the maternal hair-mercury concentration had exceeded approximately 10 µg/g (50 nmol/g) (1,3). Prenatal exposures below this level were associated with neurobehavioral delays detectable at age seven years (4), but equivocal findings on developmental tests have been reported from other studies of younger children (5,6). Other seafood contaminants include polychlorinated biphenyls (PCBs), and prenatal PCB exposures have also been linked to delays in neurobehavioral development (7-9). However, the nature of these deficits and their detailed relation to specific organochlorine compounds is unclear, although some PCBs may act via interference with thyroid function (10).

Major essential nutrients in seafood include ω3 polyunsaturated fatty acids (11) and selenium (12). Essential fatty acids are necessary for optimal neurological development (13), and they could potentially modify the effects of neurotoxicants (14). In experimental models, selenium in seafood may attenuate methylmercury toxicity (15). Thus, seafood diets during pregnancy must be considered as a balance between the beneficial effects of essential nutrients and the adverse effects caused by toxicants.

We have examined these issues in the Faroe Islands, a North Atlantic fishing community of about 42,000 inhabitants, where the marine diet may also include pilot whale meat and blubber. Whale meat contains increased mercury concentrations, and blubber has a high PCB content, thus contributing to neurotoxicant exposures (4). The lipid phase of marine fish often contains about 10-15% eicosapentaenoic acid (C20:5ω3, EPA) and 10-25% docosahexaenoic acid (C22:6ω3, DHA) (11), while pilot whale blubber contains somewhat lower levels of these two ω3 polyunsaturated fatty acids (Marita Poulsen, pers. comm.). Apart from lamb, potatoes and some dairy

products, the majority of the Faroese food is otherwise imported from other countries, and the lifestyle is Scandinavian.

METHODS

Cohort Establishment

During a 12-month period in 1994-1995, a cohort of 182 singleton term births was generated from consecutive births at the National Hospital in Tórshavn, Faroe Islands. Maternal residence was required in the central and northwestern region of the primary catchment area, i.e., away from the capital area of Tórshavn. About one-third of the Faroese population resides in this area, where the mercury exposure was expected to vary the most. About 64% of all births were included, incomplete sampling being mainly due to logistic problems in the busy ward. In addition, four children were excluded because they were born before the 36th week of gestation, and two children because they had congenital neurological disease; none of the children had a birth weight below 2500 g. The overall participation rate is slightly below the one obtained in a previous Faroese cohort (4), but the average birth weight was almost the same in the two cohorts and similar to the Faroese average. Relevant obstetric data were obtained by standardized procedures (16) and supplemented by a brief nutrition questionnaire (4,17). The study design and methodology were approved by the Faroese Ethical Review Committee. The main characteristics of the cohort are shown in Table I.

Maternal serum was obtained in connection with the last antenatal consultation at week 34. Blood from the umbilical cord was taken by the midwife in heparinized syringes with teflon-lined pistons. In connection with the parturition, a hair sample of at least 100 mg was cut with a pair of scissors close to the root in the occipital area of the mother. Transition milk was obtained at days 4 or 5 after parturition.

Outcome Measures

For the neurological examination of the newborn infant, the technique described by Prechtl (18) was used at approximately two weeks of age adjusted for gestational age. This schedule includes items to assess functional abilities, most reflexes and responses, as well as the stability of behavioral status during the examination. All items are classified as clinically optimal, questionable, or suboptimal. The neurological optimality score (NOS) is the number of main items rated optimal (out of 60). Also, two subscores are formed, one for muscle tone and one for reflexes. This highly standardized test has a substantial degree of predictive validity (19). The examiner had training in Groningen, the Netherlands, under supervision by Professor Bert Touwen; the NOS scores were also calculated in Groningen. Examiner and scorer were blinded with regard to exposure variables.

Thyroid stimulating hormone was measured in maternal serum and in cord serum by a time-resolved fluoroimmuno assay, and thyroxin and resin-triiodothyronine uptake were determined by radioimmuno assay. Free thyroxin and free triiodothyronine were measured by the radioimmuno assay after dialysis to equilibrium.

Exposure Biomarkers

Mercury analysis: Maternal hair (the first 3 cm from the root), and cord whole-blood and serum were analyzed in duplicate by flow-injection cold-vapor atomic absorption spectrometry after digestion of the sample in a microwave oven (4,20). Mercury results in μg may be converted to nmol by multiplying by 5.0.

Serum organochlorine analysis: Two milliliters of all maternal serum samples and 10% of the cord-serum samples were analyzed at the National Center for Environmental Health at CDC in Atlanta (21): Eighteen parent pesticides or their metabolites and twenty-eight persistent PCB congeners were quantified by a two-stage solid-

phase extraction method followed by gas chromatography analysis with electron capture detection. The results were adjusted for total serum lipid content and reported as ng/g lipid. The limit of detection varied from 0.08 ng/g to 0.66 ng/ml. For maternal serum with an average lipid content of about 9 g/l, these limits correspond to 9 ng/g and 70 ng/g lipid.

Milk organochlorine analysis: As an additional measure of perinatal exposure, 5 ml of human milk were analyzed at the Institute of Environmental Toxicology, Kiel, Germany (22) for a similar array of organochlorine compounds. Following solid-liquid-phase extraction, analyses were performed by gas chromatography with electron capture detection. At a 5% fat content, the detection limits were 2 and 5 ng/g lipid for pesticides and PCBs, respectively.

Selenium analysis: Selenium in cord whole-blood was determined by electrothermal atomic absorption spectrometry with Zeeman background correction (23). Selenium results in μg may be converted to μmol by dividing by 79.

Fatty acid analysis: Cord-serum phospholipids were extracted and transmethylated before analysis on a gas chromatograph with a flame ionization detector (24). All results were reported as relative concentrations in percent of total phospholipid fatty acids.

Data Analysis

Parameters which deviated substantially from a Gaussian distribution, especially the exposure biomarkers, were normalized by logarithmic transformation. For some organochlorine results, transformations and calculation of geometric means and correlation coefficients were performed with the actual measured values even when they were below the detection limit. Parametric methods were used whenever applicable. However, the dietary

questionnaire data required the use of Spearman's correlation coefficient (r_s). Regression analyses were carried out with the NOS as the dependent variable and with potential predictors selected a priori. Individual exposure parameters were then entered as continuous variables, using covariates that were significant at $p < 0.1$ for confounder adjustment. For the sake of uniformity, two-tailed p-values were used.

RESULTS

The questionnaire data regarding dietary habits during pregnancy confirmed that this population is highly dependent on seafood, including pilot whale; summary data are shown in Table I. Most of the pregnant women were nonsmokers, with only 19 (10.4%) smoking more than 10 cigarettes per day. Likewise, only 5 women (2.7%) drank alcoholic beverages at least once per month during pregnancy. Six mothers (3.3%) were less than 18 years

The average mercury exposure was elevated, but varied widely (Table II). Fifteen hair samples (10.4 %) exceeded a mercury concentration limit of 10 $\mu\text{g/g}$ (50 nmol/g). The three mercury exposure biomarkers were highly interrelated, with correlation coefficients of 0.76-0.82 after logarithmic transformation. Exposures to organochlorine compounds were also increased (Table II). The ΣPCB concentration was calculated as 2.0 times the sum of the most prevalent congeners 138, 153 and 180 (IUPAC numbers) (25). Lipid-based concentrations of the same analyte in serum and milk correlated well, but were generally higher in milk. The lipid-based ΣPCB concentrations in the 19 cord serum samples were similar to those in maternal serum ($r = 0.97$). However, volume-based serum concentrations correlated less well and reflected the 3-to-4-fold difference in lipid content (means, 2.5 g/l and 9.0 g/l in cord and maternal serum, respectively). Other organochlorine compounds in the same sample correlated well with ΣPCB and p,p' -DDE.

The frequency of whale meat dinners was the best predictor for the mercury concentrations, while the

frequency of blubber dinners during pregnancy was the best predictor for the organochlorine concentrations (Table II). The Σ PCB concentration in maternal serum correlated significantly with mercury concentrations in maternal hair and cord blood ($r = 0.53$ and 0.43 , respectively).

Maternal seafood intake was also associated with increased concentrations of $\omega 3$ fatty acids and selenium in cord blood (Table III). EPA and selenium concentrations also showed highly significant associations with the seafood contaminants.

Thyroid function parameters revealed no clear association with contaminant concentrations, except that the resin-triiodothyronine uptake in cord serum seemed to decrease at increasing Σ PCB concentrations ($r = -0.21$, $p = 0.01$). The thyroid stimulating hormone concentration in cord blood and maternal serum showed a weak negative association with Σ PCB ($r = -0.04$; $p = 0.66$; and $r = -0.13$; $p = 0.09$).

The infants had an average NOS of 49.8, with 77 (43.8%) below 50. The score was significantly associated with gestational age, but not with birth weight. Maternal age, parity and education were not associated with the NOS. Diabetes mellitus or signs of gestational diabetes ($N = 11$) were associated with a higher birth weight, a shorter gestation and, at the same time, a lower NOS ($p = 0.001$). The average NOS score was higher in girls (50.5 ± 4.1) than in boys (49.1 ± 4.8) ($p = 0.04$). Other potential risk factors recorded as part of the obstetric optimality schedule (24) were not associated with a decreased NOS.

The cord-blood mercury concentration showed a negative association with the NOS, and results for quartile exposure groups are shown in Fig. 1. The unadjusted regression coefficient was -2.0 ($p = 0.03$). Thus, a 10-fold increase in mercury was associated with a NOS decrease of 2. After confounder adjustment and exclusion of the 11 children of diabetic mothers, the adjusted coefficient was nearly unchanged (-2.1 ; $p = 0.03$). A shortening of gestational age by 3 weeks was associated with a decrease in NOS similar to the one related to a 10-fold increase

in mercury exposure. The mercury/selenium ratio showed only a slightly improved association with the outcome variable. Removal of the child with the lowest NOS (the most influential observation) also had only a small effect on these associations. The mercury concentration in cord serum was also a significant predictor in the regression analyses, while the maternal hair concentration was not.

Concentrations of Σ PCB and *p,p'*-DDE showed weak, positive associations with the NOS (Table II), and adjustment for covariates and mercury exposure caused only minor changes. The fatty acids (Table III) and thyroid parameters were also poorly associated with the overall NOS, and no clear association with dietary questionnaire parameters was found. Adjustment for Σ PCB and ω 3 fatty acid concentrations also did not have a discernible effect on the mercury regression coefficient.

The NOS subscores for muscle tone and reflexes showed no clear associations with any of the risk indicators studied. A review of individual tasks showed no clear pattern, except that slight or marked opisthotonus was present in 20 infants and absent in 157 infants (geometric means of cord-blood mercury concentrations, 34.3 μ g/l and 19.5 μ g/l; $p = 0.005$).

DISCUSSION

In the present study, increased exposures to methylmercury from maternal seafood intake were associated with a significant decrease in the neonatal neurological optimality score (Fig. 1). Methylmercury is a well documented developmental neurotoxicant (1,2,4), but neonatal function was not examined in previous cohort studies (4,6). Although previous studies have linked prenatal exposure to PCBs and other organochlorine compounds to neurotoxic effects in children (7-9), PCBs had no discernible effect on neurological function in the present study.

The neonatal neurodevelopmental scale used in this study has been developed to ascertain the integrity of the neonatal nervous system in a reproducible way (18). The NOS has been useful in epidemiological studies to determine subsequent risks for major or minor neurological dysfunctions (19). Recently, the Dutch researchers (9) reported that a decreased neonatal NOS was associated with biomarkers of increased dioxin exposure, and PCB congeners showed a significant association with a decreased muscle tone score. While the same outcome parameter was used in the Faroes, the different outcomes of these studies must be interpreted in the light of the exposure settings.

The average mercury concentrations (Table II) are similar to those seen in a previous Faroese cohort study (4,17). The cord-blood mercury concentration indicates the amount of methylmercury that has reached the fetal circulation. The maternal hair concentration may be a less precise risk indicator (4,26). Sources of imprecision for hair-mercury concentrations include external contamination during hair growth (27), and studies that have relied solely on maternal hair-mercury concentrations (5,6) may therefore involve exposure misclassification. Although mercury exposure levels have not been reported from the Dutch study, they are likely to be similar to those seen in populations that eat seafood infrequently (1,23), i.e., with averages of about one-tenth of those seen in the Faroes. Because even small increases in methylmercury exposure may be associated with a decreased neonatal NOS (Fig.1), an undetected mercury effect in the Dutch study cannot be ruled out.

The milk PCB concentrations are similar to results from Faroese samples collected in 1987, where the overall average for four pooled samples was slightly above 2 µg/g lipid (25). Similarly, ΣPCB in cord tissue from the same cohort (4) showed an arithmetic average of 1.6 ng/g lipid, as calculated from concentrations of congeners 138, 153 and 180. However, the Dutch study showed a median of 2 µg/l for the sum of PCB congeners 118, 138, 153, and 180 in maternal plasma (9,28). In the present study, the median for the same congeners in maternal serum

was 0.64 µg/g lipid; with an average lipid concentration of 9 g/l, this concentration corresponds to 5.8 ng/l serum i.e., about 3-fold higher than the average in the Dutch cohort.

The power of a study with regard to separating effects of different components of a complex exposure depends on the association between those components. In the Faroe Islands, methylmercury exposure mainly originates from pilot whale meat, while organochlorine exposure predominantly comes from whale blubber (4). The scattered correlation between mercury and PCB exposure parameters mirrors the one previously reported between cord-blood mercury and cord tissue PCB (4) and suggests that the Faroese are unlikely to eat equal proportions of whale meat and blubber. Although confounding between mercury and PCB may therefore be limited, unmeasured pollutants must also be considered, e.g., dioxins and related compounds. Exposures to these compounds are probably not elevated in the Faroes, as analyses of milk samples from 1987 (25) showed total dioxin equivalent exposure levels similar to the average reported from the Dutch cohorts generated in 1990-1992 (9). However, as increasing dioxin equivalent concentrations in human milk were associated with a lower NOS in the Dutch study, the question should be considered whether a dioxin effect on NOS could explain the mercury association observed (Fig. 1). If that were to be true, then the dioxin exposure level would have to be more closely associated with the mercury concentration in cord blood than with the PCB concentration. That possibility would appear to be rather remote. Further, while thyroid function data may offer an independent indication of possible organochlorine effects (10,28), the results of the present study were within expected ranges and failed to show a clear association with PCB exposure.

The validity of the NOS assessment must also be critically considered. The NOS results of the present study are lower than those obtained in the Netherlands. Significant differences also occurred between two Dutch centers and were attributed to observer differences (28). Thus, while such differences may be unavoidable, the fa

that all Faroese children were examined by the same pediatrician who was blinded with regard to exposure parameters, offers confidence that the results are unbiased. Under controlled circumstances, the NOS may therefore possess sufficient sensitivity, precision, and predictive validity to reveal subtle contaminant-associated neurobehavioral deficits in population studies. Other developmental tests used in young children have shown equivocal associations with hair-mercury concentrations (5,6), perhaps affected both by imprecise exposure assessment and by uncertain validity of response assessments in different cultures. More detailed neuropsychological tests that can be applied at school age have revealed mercury-associated deficits in several domains of brain function (4).

Essential fatty acids from seafood may contribute certain advantages to the infant (13) and may perhaps counteract or protect against adverse effects (14). In agreement with previous studies in adults (29), especially EL showed a clear association with seafood intake (Table III). Analyses in the Netherlands of relative concentrations in cord serum (30) have shown similar averages for arachidonic acid, while those for DHA were about one-half of the level seen in the present study (Table III). These findings emphasize the high average Faroese intake of $\omega 3$ fatty acids from seafood. Although associated with increased neurotoxicant exposures (Table III), the ample supply of essential nutrients did not provide any detectable beneficial or protective effect on the NOS.

The increased selenium concentrations (Table III) are in accordance with the previous study in the Faroe (17), which showed an overall median of 110 $\mu\text{g/l}$ (1.40 $\mu\text{mol/l}$). These levels are higher than those seen in populations not dependent on marine food (23). Although selenium was present in cord blood in an average molar excess of about 10-fold above methylmercury, no evidence was found that it offered any important protection against a mercury-associated decrease in the NOS.

Because the neurotoxicant may readily pass the placenta, and because the fetal brain must be regarded

particularly sensitively to neurotoxicant exposures and endocrine disruption, safety considerations for contaminated seafood must focus on early development. The present study examined several potentially beneficial and detrimental factors, thus allowing a detailed assessment of possible confounding. The detailed assessment of neonatal neurological function showed a negative association only with the cord-blood mercury concentration. The seafood contaminant therefore deserves increased attention.

We are indebted to members of the Faroese health care system for assistance in generating this cohort and in conducting the examinations of the children, to Brita Andersen and Sylvia Nome Kvam for laboratory assistance and to Dr. Nynke Weisglas-Kuperus and Professor Pieter Sauer (Erasmus University, Rotterdam), Dr. Caren Lanting, Professor Rudi Boersma, and Professor Bert Touwen (University of Groningen) and to Jens Walkowiak and Professor Gerhard Winneke (University of Düsseldorf) for sharing unpublished information and for assistance in coordination and quality assurance. This study is part of the European project on ‘Neonatal PCB Exposure and Neurodevelopmental Deficit’ coordinated by Dr. Winneke.
