Abstract

Background: Breakdown of the gut mucosal barrier during chronic HIV infection allows translocation of bacterial products such as lipopolysaccharides (LPS) from the gut into the circulation. Microbial translocation also occurs in inflammatory bowel disease (IBD). IBD serological markers are useful in the diagnosis of IBD and to differentiate between Crohn’s disease (CD) and ulcerative colitis (UC). Here, we evaluate detection of IBD serological markers in HIV-infected patients with advanced disease and their relationship to HIV disease markers.

Methods: IBD serological markers (ASCA, pANCA, anti-OmpC, and anti-CBIr1) were measured by ELISA in plasma from AIDS patients (n = 26) with low CD4 counts (<300 cells/mL) and high plasma LPS levels, and results correlated with clinical data. For meta-analysis, relevant data were abstracted from 20 articles.

Results: IBD serological markers were detected in approximately 65% of AIDS patients with evidence of microbial translocation. An antibody pattern consistent with IBD was detected in 46%; of these, 75% had a CD-like pattern. Meta-analysis of data from 20 published studies on IBD serological markers in CD, UC, and non-IBD control subjects indicated that IBD serological markers are detected more frequently in AIDS patients than in non-IBD disease controls and healthy controls, but less frequently than in CD patients. There was no association between IBD serological markers and HIV disease markers (plasma viral load and CD4 counts) in the study cohort.

Conclusions: IBD serological markers may provide a non-invasive approach to monitor HIV-related inflammatory gut disease. Further studies to investigate their clinical significance in HIV-infected individuals are warranted.

Introduction

CD4 T-cells in gut-associated lymphoid tissue (GALT) are primary target cells of HIV, and GALT is an important site for HIV replication and pathogenesis [1–4]. Significant CD4 T cell loss occurs in the gastrointestinal tract within the first few weeks of infection [3–7]. Later on, during chronic HIV infection, loss of GALT integrity and breaching of the gut mucosal barrier leads to microbial translocation [8–10], which is evidenced by the release of microbial products such as bacterial endotoxins (lipopolysaccharides (LPS), a component of gram negative bacteria) into the circulation (endotoxemia) [11]. Microbial translocation from a leaky gut may contribute to immune activation during chronic HIV infection [11–13]. Elevated levels of plasma LPS and bacterial 16S rDNA have been used to measure translocation of microbial products from the gastrointestinal tract [11,16].

Microbial translocation is also a noted feature in inflammatory bowel disease (IBD) [17–20]. IBD comprises a group of intestinal diseases characterized by chronic inflammation of the bowel; Crohn’s disease (CD) and ulcerative colitis (UC) are the common clinical subtypes of IBD. The intestinal bacterial flora triggers and drives an aberrant immune response in a genetically susceptible host, resulting in chronic inflammation of the gut [21,22]. Low level endotoxemia has pathogenic significance in IBD; it occurs in 31%–48% of CD patients and 17%–28% of UC patients [18,23], with a higher incidence in patients with active IBD (94% in CD, 88% in UC) [19].

The role of enteric microflora in IBD pathophysiology is highlighted by the presence of antibody reactivity to microbial antigens. These serological markers can be helpful to distinguish between CD and UC as well as aiding in the diagnosis of IBD along with clinical history, endoscopy, and physical examination [24]. The currently available IBD serological markers are: ASCA (anti-Saccharomyces cerevisiae antibody) [25–31], pANCA (perinuclear anti-neutrophil antibody) [25–30,32], and anti-OmpC (antibody against outer membrane porin C of E.coli) [28,33–37]. ASCA, which is directed against a mannose epitope in the phospholipid mannan of the Saccharomyces cerevisiae cell wall [30–32], is
associated with CD [23–27,37–41]. The sensitivity and specificity for detection of ASCA antibodies in CD are 50%–70% and 80%–90%, respectively [25,27,29,30,32,33,42,43]. pANCA is an antibody directed against cytoplasmic constituents of neutrophils with a perinuclear staining pattern [25,44,45]. pANCA is detected in 40%–80% of UC patients, but also in 6%–20% of CD patients who can be classified as having a UC-like phenotype [30,32,37,46,47], with sensitivity and specificity between 55%–70% and 80%–95% in UC patients [27,29,30,32,37,43,45–47]. Anti-OmpC antibodies are detected in 40%–55% of CD patients [25,48–51], with sensitivity and specificity ranging between 20%–55% and 75%–95%, respectively [25,34,37,50,32]. Anti-CBir1 (antibodies against bacterial flagellin) is a new serological marker associated with IBD [28,35,53–58]. CBir1 flagellin is an immunodominant and colitogenic antigen of enteric microbial flora [58]. Anti-CBir1 is detected in approximately 50% of CD patients [28,35,53,55–58], and is independently associated with complicated CD [25,33,35,59].

A number of parallels are observed between HIV and IBD in terms of gut disease [60–62]. Small intestinal villous atrophy and enterocyte defects have been described in HIV-infected patients. Because these defects usually occur in the absence of enteric pathogens, the term HIV enteropathy has been used [60,62,63]. Characteristic features of HIV enteropathy are diarrhea, gastrointestinal inflammation, increased intestinal permeability, and decreased mucosal repair and regeneration [1,2,60,64]. Previous studies reported infrequent cases of IBD in HIV-infected patients [61,65–67]. To our knowledge, however, no reports have examined the prevalence of ASCA, OmpC, and CBir1 antibodies in HIV infection.

We previously demonstrated that elevated circulating LPS levels correlate with monocyte activation during HIV infection, and may thereby contribute to chronic immune activation [12]. In the present study, we evaluated detection of IBD serological markers in AIDS patients with low CD4 counts (<300 cells/µl) and high plasma LPS levels. We detected IBD serological antibodies in approximately 65% of subjects. A serological pattern consistent with IBD was detected in 46% of AIDS patients; of these, 75% showed a CD-like pattern, while 25% had a UC pattern. IBD serological markers may provide a non-invasive approach to monitor HIV-related gut disease. Further studies to determine their prognostic significance in HIV-infected individuals are warranted.

Methods

Subjects

AIDS patients with CD4 counts <300 cells/µl were recruited at the Lemuel Shattuck Hospital (n = 20), or at 3 sites in the National NeuroAIDS Tissue Consortium (NTNTC) (Manhattan HIV Brain Bank, National Neurological AIDS Bank, Texas NeuroAIDS Research Center) (n = 6) with written informed consent and IRB approval at each study site. Subjects with active bacterial or opportunistic infections were excluded. There was no available radiographic, endoscopic, or histopathologic data for the gut. All plasma samples were stored at −80°C until analyzed.

Laboratory assays

Frozen plasma samples were shipped on dry ice to Prometheus Laboratories (San Diego, CA) and analyzed in a blinded fashion; Prometheus staff did not have access to clinical information except for HIV/HCV status. Prometheus IBD Serology 7 is the most comprehensive IBD test available, utilizing several proprietary markers and incorporating computer-based Smart Diagnostic Algorithm pattern recognition technology to aid in the diagnosis of IBD as well as differentiate between CD and UC. Prometheus IBD Serology 7 tests include the following assays: ASCA IgA and IgG, anti-OmpC IgA antibodies, IgG anti-CBir1, and pANCA autoantibody by ELISA, and immunofluorescence assay (IFA) to determine the perinuclear pattern of neutrophils and DNase sensitivity. The reference cut-off for each assay was defined by Prometheus laboratories (ASCA IgA <20 EU/ml, ASCA IgG <40 EU/ml, anti-OmpC <1.5 EU/ml, anti-CBir1 <21 EU/ml, and pANCA autoantibody <12.1 EU/ml). Positive samples showing patterns consistent with IBD were reported based on analysis by Prometheus Smart Diagnostic Algorithm Technology.

Quantification of cytokines and chemokines

A multiplex immunoassay (Bio-source 25-plex Human Cytokine Assay; Invitrogen., CA, USA), consisting of fluorescent microspheres conjugated with a monoclonal antibody specific for a target protein, was used according to the manufacturer’s instructions to measure levels of the following cytokines IL-1β, IL-2, IL-4, IL-5, IL-6, IL-7, IL-8, IL-10, IL-12, IL-17, IFN-α, IFN-γ, TNF-α granulocyte-monocyte colony stimulating factor (GM-CSF), monocyte chemoattractant protein (MCP-1/CCL2), macrophage inflammatory protein (MIP-1β/MIP-1α), IP-10, MIG, Eotaxin and RANTES. Briefly, plasma was diluted 1:2 and incubated with antibody-coupled beads. Complexes were washed and then incubated with biotinylated detection antibody followed by streptavidin-phycocerythrin prior to assessing titers of cytokine concentration. Recombinant cytokines were used to establish standard curves. Cytokine levels were determined using a multiplex array reader from LumineX™ Instrumentation System (Bio-Plex Workstation from Bio-Rad Laboratories, USA). Analyte concentration was calculated using Bioplex Manager Software.

Statistical analysis

Data were analyzed using the Mann-Whitney U test and Spearman rank correlation coefficient. Differences were considered significant at p<0.05.

Results

IBD serological markers in AIDS

To investigate the frequency and pattern of IBD serological markers in AIDS patients, we used the Prometheus IBD Serology 7 test to detect IBD serological markers in plasma samples. Subjects were selected from a larger cohort of 119 AIDS subjects with CD4 counts <300 cells/µl described in a previous study [12] on the basis of high plasma LPS above the median value for AIDS patients in the study cohort (>80 pg/ml); LPS levels were determined in the previous study using the Diazo-coupled Limulus amebocyte lysate (LAL) assay. The study cohort consisted of 26 AIDS patients with relatively high plasma viral loads (median 10,935 copies/ml, range <50–2,210,000) and low CD4 counts (median 80 cells/µl, range 3–261), together with a high frequency of intravenous drug abuse (IVDU) (65%), HCV co-infection (50%), and HIV-associated dementia (HAD) (50%). Eleven subjects were both IVDU and HCV positive. Demographic and clinical characteristics of the study cohort are shown in Table 1. All subjects were on HAART, but only 23% were virologically suppressed (<400 plasma HIV RNA copies/ml).

In the study cohort (n = 26), ASCA IgA, pANCA, and anti-OmpC were detected in 31% (8/26), while ASCA IgG and anti-CBir1 were detected in 15% (4/26) (Table 2). Prometheus laboratories classified subjects as having a CD- or UC-like pattern according to Smart Diagnostic Algorithm Technology. According
to this classification, 46% (12/26) of the subjects showed a pattern consistent with IBD, with 75% (9/12) having a CD-like pattern and 25% (3/12) having a UC-like pattern. In subjects with a positive IBD pattern, ASCA IgA and IgG antibodies were detected in 50% and 33%, while anti-OmpC, anti-CBir1, and pANCA were detected in 67%, 33%, and 42%, respectively (Table 2). Three patients with a pANCA (+) anti-OmpC (+) pattern and 1 with a pANCA (+) anti-CBir1 (+) pattern (n = 1) could also be classified as having a pattern consistent with UC-like CD [25,29,48,68,69,70]. Thus, IBD serological markers were detected in approximately 65% of AIDS patients with high plasma LPS levels, with 46% having an IBD-like pattern and the majority of these having a CD-like pattern.

IBD serological markers in subgroups with IV heroin use, HCV co-infection, or HIV-associated dementia (HAD)

Previous studies reported that AIDS patients with heroin IVDU, HCV co-infection or HAD have higher plasma LPS levels compared to respective control groups [12,71]. Furthermore, substance abuse and HCV co-infection are associated with an increased incidence of bacterial infections [72]. We therefore examined the pattern of ASCA, pANCA, anti-OmpC, and anti-CBir1 in AIDS patients classified according to these subgroups (Table 2 and data not shown). There was no significant difference in the frequency or magnitude of IBD serological markers between IVDU heroin users compared to patients with no substance abuse, HCV-positive compared to HCV-negative subjects, or HAD compared to non-HAD subjects (Table 2 and data not shown).

Thus, there was no difference in magnitude or frequency of IBD serological markers in these clinical subgroups.

Higher ASCA IgG, anti-OmpC, and anti-CBir1 levels but similar plasma viral load and CD4 counts in AIDS patients with IBD-like serological pattern

Higher levels of ASCA IgG (median 31.4 EU/ml, range 12–120 compared to 12 EU/ml, 12–27.9, p = 0.027), anti-OmpC (25.9 EU/ml, 4.7–111, compared to 7.1 EU/ml, 1–15.3, p = 0.005), and anti-CBir1 (18.6 EU/ml, 8–37.7, compared to 9.1 EU/ml, 5.3–15.6, p = 0.001) were detected in subjects with a positive IBD pattern as compared to those with a negative pattern (Table 3 and Figure S1). In contrast, there was no significant difference in ASCA IgA and pANCA antibody levels between these two groups (p = 0.135 and p = 0.540). We then investigated the relationship of IBD serological markers to HIV disease markers, plasma LPS, and EndoCaB levels. HIV RNA levels, CD4 cell counts, plasma sCD14, plasma LPS, and IgM EndoCaB levels were similar in the 2 groups (Table 5). Furthermore, there were no significant correlations (Spearman correlation) between levels of individual IBD serological markers and HIV RNA levels, CD4 cell counts, plasma sCD14, or plasma LPS levels (data not shown). Thus, we found no association between IBD serological markers and HIV disease markers or plasma LPS levels in the study cohort.

No association of IBD serological markers with plasma cytokines and chemokines in AIDS patients

In IBD, the dysregulated inflammatory response is associated with upregulation of mucosal and systemic levels of cytokines (i.e., IL-1, IL-6, IL-8, IL-12, and TNF) [73]. We used a multiplex assay to measure levels of 25 cytokines and chemokines in plasma samples from 20 AIDS patients in the study cohort and explore their relationship to individual IBD serological markers. We detected higher levels of IL-2R, CXCL9, CXCL10, CCL2, and their relationship to individual IBD serological markers. We measured levels of 25 cytokines and chemokines in plasma samples from 20 AIDS patients in the study cohort and explore their relationship to individual IBD serological markers. We detected higher levels of IL-2R, CXCL9, CXCL10, CCL2, and MCP-1, and found a positive correlation only between anti-CBir1 antibody and IL-6 (r = 0.447, p = 0.048, Figure S2). Together with previous studies demonstrating that CBir1 antigen can induce IL-6 and other proinflammatory cytokines [56,58], this finding raises the possibility that translocation of flagellin into the circulation may be a factor that contributes to immune activation in AIDS.

Magnitude of IBD serological antibody response in AIDS

Previous data suggested that the magnitude of antibody responses to microbial antigens is associated with increased risk

[58x125] HCV co-infection, or HIV-associated dementia (HAD)
[58x211] Three patients with a pANCA (+) pattern (n = 1) could also be classified as having a pattern consistent with UC-like CD [25,29,48,68,69,70]. Thus, IBD serological markers were detected in approximately 65% of AIDS patients with high plasma LPS levels, with 46% having an IBD-like pattern and the majority of these having a CD-like pattern.

IBD serological markers in subgroups with IV heroin use, HCV co-infection, or HIV-associated dementia (HAD)

Previous studies reported that AIDS patients with heroin IVDU, HCV co-infection or HAD have higher plasma LPS levels compared to respective control groups [12,71]. Furthermore, substance abuse and HCV co-infection are associated with an increased incidence of bacterial infections [72]. We therefore examined the pattern of ASCA, pANCA, anti-OmpC, and anti-CBir1 in AIDS patients classified according to these subgroups (Table 2 and data not shown). There was no significant difference in the frequency or magnitude of IBD serological markers between IVDU heroin users compared to patients with no substance abuse, HCV-positive compared to HCV-negative subjects, or HAD compared to non-HAD subjects (Table 2 and data not shown).

Thus, there was no difference in magnitude or frequency of IBD serological markers in these clinical subgroups.

Higher ASCA IgG, anti-OmpC, and anti-CBir1 levels but similar plasma viral load and CD4 counts in AIDS patients with IBD-like serological pattern

Higher levels of ASCA IgG (median 31.4 EU/ml, range 12–120 compared to 12 EU/ml, 12–27.9, p = 0.027), anti-OmpC (25.9 EU/ml, 4.7–111, compared to 7.1 EU/ml, 1–15.3, p = 0.005), and anti-CBir1 (18.6 EU/ml, 8–37.7, compared to 9.1 EU/ml, 5.3–15.6, p = 0.001) were detected in subjects with a positive IBD pattern as compared to those with a negative pattern (Table 3 and Figure S1). In contrast, there was no significant difference in ASCA IgA and pANCA antibody levels between these two groups (p = 0.135 and p = 0.540). We then investigated the relationship of IBD serological markers to HIV disease markers, plasma LPS, and EndoCaB levels. HIV RNA levels, CD4 cell counts, plasma sCD14, plasma LPS, and IgM EndoCaB levels were similar in the 2 groups (Table 5). Furthermore, there were no significant correlations (Spearman correlation) between levels of individual IBD serological markers and HIV RNA levels, CD4 cell counts, plasma sCD14, or plasma LPS levels (data not shown). Thus, we found no association between IBD serological markers and HIV disease markers or plasma LPS levels in the study cohort.

No association of IBD serological markers with plasma cytokines and chemokines in AIDS patients

In IBD, the dysregulated inflammatory response is associated with upregulation of mucosal and systemic levels of cytokines (i.e., IL-1, IL-6, IL-8, IL-12, and TNF) [73]. We used a multiplex assay to measure levels of 25 cytokines and chemokines in plasma samples from 20 AIDS patients in the study cohort and explore their relationship to individual IBD serological markers. We detected higher levels of IL-2R, CXCL9, CXCL10, CCL2, and MCP-1, and found a positive correlation only between anti-CBir1 antibody and IL-6 (r = 0.447, p = 0.048, Figure S2). Together with previous studies demonstrating that CBir1 antigen can induce IL-6 and other proinflammatory cytokines [56,58], this finding raises the possibility that translocation of flagellin into the circulation may be a factor that contributes to immune activation in AIDS.

Magnitude of IBD serological antibody response in AIDS

Previous data suggested that the magnitude of antibody responses to microbial antigens is associated with increased risk
of complicated CD [25,42,59]. We tested this hypothesis with respect to HIV disease progression by counting the number of positive antibodies (ASCA, pANCA, anti-OmpC, and anti-CBir1) and scoring these from 0–3 (Table 4). None of the subjects showed a positive response for all 4 antibodies; 26.9% (7/26) had a score of 1, 30.7% (8/26) had a score of 2, 7.6% (2/26) had a score of 3, and 34.6% (9/26) had a score of zero. Forty-two percent (6/14) of subjects with CD4 T-cell counts, 100 cells/ml versus 27% (3/11) with .100 cells/ml had antibody responses to 2 antigens, but this difference did not reach statistical significance (p = 0.676). Subjects grouped according to HIV RNA levels, 10,000 versus .10,000 copies/ml, heroin use versus no heroin use, HAD versus non-HAD, or LPS, median value of 109 pg/ml versus .109 pg/ml had no difference in the magnitude of antibody response. Thus, the magnitude of IBD serological antibody responses was not associated with HIV disease markers, high LPS levels, or clinical subgroups in the study cohort.

Discussion

In this study, we examined IBD serological markers in AIDS patients with high plasma LPS levels and detected an IBD-like serological pattern in 46%. Among subjects with a positive IBD pattern, 75% had a CD-like pattern and 25% had a UC-like pattern. The association of pANCA with CD markers has been described as a UC-like Crohn’s pattern [25,29,43,69,70]. Based on this classification, 15% of the study cohort had a UC-like CD pattern. These findings are consistent with the frequent occurrence of HIV-related gut disease involving the small and large intestine in AIDS patients [1,2,3,4]. Antibodies to microbial antigens (ASCA IgA/IgG, anti-Saccharomyces cerevisiae antibodies; Anti-OmpC IgA- Anti-Outer membrane porin C on E.coli; Anti-CB1r)-recognizes bacterial flagellin antigen associated with IBD; pANCA autoantibody- IBD-specific pANCA autoantibody (NSNA, Neutrophil-specific nuclear autoantibody);

*p represents cut-off above the median value for the study cohort.

Abbreviations used: HAD- HIV-associated dementia; Heroin IVDU- heroin intravenous drug users; LPS- Lipopolysaccharide; Antibodies tested: ASCA IgA/IgG- Anti-Saccharomyces cerevisiae antibodies; Anti-OmpC IgA- Anti-Outer membrane porin C on E.coli; Anti-CB1r- recognizes bacterial flagellin antigen associated with IBD; pANCA autoantibody- IBD-specific pANCA autoantibody (NSNA, Neutrophil-specific nuclear autoantibody);

To assess the diagnostic precision of IBD serological antibodies and their ability to distinguish between CD, UC, inflammatory and non-inflammatory non-IBD disease subjects, and healthy controls, we performed meta-analysis of serological data from 20 published studies [25,27–30,33–35,37,42,49,52,53,55,57,58,78–81]. Extensive meta-analysis was previously reported for ASCA and pANCA antibodies [43]. To our knowledge, however, the present study is the first meta-analysis for all available IBD serological markers. Consistent with previous reports [25,27,29,30,34,37,79,81], our meta-analysis demonstrated that the prevalence of ASCA IgA/IgG was 45% in CD subjects as compared to 7.9% and 3.7% in non-IBD and healthy controls, respectively, and pANCA was prevalent in 42.4% of UC subjects (Table 5) [26,27,29,32,37,44,82]. Anti-OmpC and anti-CB1r were prevalent in 29.4% and 55.2% of CD subjects, respectively, compared to 17.6% and 25.5% in non-IBD and healthy disease controls, and 10.7% and 6.3% in healthy controls. A separate meta-analysis of 10 published studies that used Prometheus Laboratories IBD Serological Markers (Table S1) demonstrated similar findings, with ASCA, anti-OmpC, and anti-CB1r more prevalent in CD (48.5%, 32.2%, and 53.8%, respectively), pANCA more prevalent in UC (67.9%), and ASCA, pANCA, and anti-OmpC prevalent in HIV disease biomarkers. We also cannot exclude the possibility that the absence of antibody responses to microbial antigens in 35% (9/26) of AIDS patients with high LPS levels reflects weakened humoral immune responses. Another limitation of our study is the lack of endoscopy or gut pathology data for the study cohort. Viazis et al [66] examined IBD outcomes in HIV-infected subjects who had an IBD diagnosis and found that these patients have a better disease course with lower probability of IBD relapse as compared to HIV-negative IBD patients. This was attributed to lower CD4 T-cell counts in HIV-infected individuals suppressing disease activity in CD. If true, low CD4 counts in our study cohort might influence relationships between HIV disease markers or LPS levels and IBD serological antibodies. The Th17 subset of CD4+ T-cells play an important role in the pathogenesis of IBD; HIV preferentially infects and depletes these cells in GALT, which may also help to explain the better disease course observed in patients with an IBD diagnosis who are HIV-positive compared to those who are HIV-negative. Larger prospective studies are needed to determine the clinical significance of IBD serological markers in HIV-infected patients and their relationship to HIV-related gut disease.
The meta-analysis highlights the utility of IBD serological markers in peripheral blood samples as novel markers of gut disease in HIV infection. In summary, we detected at least one IBD serological marker in approximately 65% of AIDS patients with high LPS levels, and an IBD-like serological pattern in 46%. Detection of these markers, particularly ASCA, anti-OmpC, and anti-CBir1, could provide a potential non-invasive approach to monitor HIV-related gut disease. Further studies are warranted to understand the clinical significance of IBD serological markers in HIV infection and their utility as tools for studies of HIV-related gut disease and monitoring therapeutic responses.

Supporting Information

**Figure S1** Differences in levels of IBD serological markers (A-ASCA IgA, B-ASCA IgG, C- Anti-OmpC and D- Anti-CBir1) in subjects with versus without IBD pattern are shown. Lines indicate median levels for each group. Mann Whitney test was used to assess the difference in antibody levels between the two groups, *p*<0.05 was considered statistically significant. (EPS)

**Figure S2** IL-6 levels correlated positively with levels of anti-CBir1 (*n* = 20 AIDS patients, Spearman correlation). (EPS)

**Table S1** Meta-analysis of 10 studies using Prometheus laboratories IBD Serology 7 (DOC)

Acknowledgments

We thank investigators at NNTC sites and Dr. David Stone (Shattuck Hospital) for providing plasma samples from AIDS patients and clinical data.
