AVERAGE RANKS OF ELLIPTIC CURVES

BAUR BEKTEMIROV, BARRY MAZUR, WILLIAM STEIN AND MARK WATKINS

Abstract. Rational points on elliptic curves are the gems of the arithmetic theory: they are, to diophantine geometry, what units in rings of integers are to algebraic number theory, what algebraic cycles are to algebraic geometry. A rational point in just the right context, at one place in the theory, can inhibit and control—thanks to ideas of Kolyvagin [Kol88]—the existence of rational points and other mathematical structures elsewhere. Despite all that we know about these objects, the initial mystery and excitement that drew mathematicians to this arena in the first place remains in full force today.

We have a network of heuristics and conjectures regarding rational points, and we have massive data accumulated to exhibit instances of the phenomena. Generally, we would expect that our data support our conjectures; and if not, we lose faith in our conjectures. But here there is a somewhat more surprising interrelation between data and conjecture: they are not exactly in open conflict one with the other, but they are no great comfort to each other either. We discuss various aspects of this story, including recent heuristics and data that attempt to resolve this mystery.

1. Introduction

Suppose you are given an algebraic curve $C$ defined, let us say, as the locus of zeroes of a polynomial $f(x, y)$ in two variables with rational coefficients. Suppose you are told that $C$ has at least one rational point, i.e., there is a pair of rational numbers $(a, b)$ such that $f(a, b) = 0$. How likely is it that $C$ will have infinitely many rational points?

Such a question, on the one hand, clearly touches on a fundamental issue in diophantine geometry, and on the other, is somewhat meaningless until it is made more precise and appropriately organized. The question we have just asked has distinctly different features when considered for each of the three basic “types” of algebraic curves: curves of (geometric) genus 0, 1, and $> 1$. Curves of genus 0 possessing a rational point always have infinitely many rational points (an easy fact; indeed, even known to the ancient Greeks, since our curve can be written as a conic in this case); curves of genus $> 1$ never do (a hard fact; indeed a theorem of Faltings [Fal86], for which he received the Fields Medal).

This leaves curves of genus 1 as the unresolved, and thus most interesting, case of the problem we posed, since some elliptic curves, like

$$x^3 + y^3 = 1,$$

only have finitely many rational points (two, in this instance) and others of them, like

$$y^2 + y = x^3 - x,$$

have infinitely many, starting with $(0, 0), (1, 0), (-1, -1), (2, -3), (1/4, -5/8), (6, 14), (-5/9, 8/27), (21/25, -69/125), (-20/49, -435/343), \ldots$
If we are to try to extract an actual number between 0 and 1 that will describe “the” probability that a curve of genus 1 possessing at least one rational point has infinitely many, we have to be precise about exactly which curves we want to count, and how we propose to “sort” them. Let us agree, then (with details later):

- to deal only with the smooth projective models of the curves of genus 1 possessing a rational point (these being precisely the elliptic curves defined over \( \mathbb{Q} \)),
- to count their isomorphism classes over \( \mathbb{Q} \), and
- to list them in order of increasing conductor, banking on the theorem that tells us that there are only finitely many isomorphism classes of elliptic curves over \( \mathbb{Q} \) with any given conductor.

We can now pose our question. Does

\[
P(X) = \frac{\# \{ \text{elliptic curves of conductor } \leq X \text{ with infinitely many rational points} \}}{\# \{ \text{elliptic curves of conductor } \leq X \}}
\]

converge as \( X \) tends to \( \infty \), and if so, what is the limit

\[
P = \lim_{X \to \infty} P(X).
\]

In this way we have made our initial question precise:

What is the probability \( P \) that an elliptic curve has infinitely many rational points?

It is extraordinary how much vacillation there has been in the past three decades, in the various guesses about the answer to this—clearly basic—question. The subject of this paper is to discuss aspects of this drama. Its see-saw history, involving a network of heuristics and conjectures and massive data that seemed not to offer much comfort to the conjecturers, comes in four parts.

(1) **The minimalist conjecture.** The “classical” Birch and Swinnerton-Dyer conjecture (see Section 2) suggests that the probability \( P \) described by our question is at least 1/2. The reason for this is the phenomenon of parity: elliptic curves can be sorted into two classes, those of **even parity**, where the “sign in the functional equation of the \( L \)-function” is +1, and those of **odd parity**, where the “sign” is −1. The probability that an elliptic curve is of even parity is 1/2, and the same—of course—for odd parity. A consequence of the Birch and Swinnerton-Dyer conjecture is that all elliptic curves of odd parity have infinitely many rational points. This is why no one doubts that the probability \( P \) described above is \( \geq 1/2 \).

It has long been a folk conjecture that \( P \) is exactly 1/2—let us call this the **minimalist conjecture**. Given the Birch and Swinnerton-Dyer conjecture, an equivalent, and cleaner, way of stating it is as follows:

**Conjecture 1.1.** An elliptic curve of even parity has probability 0 of having infinitely many rational points.

This minimalist conjecture might seem appealing purely on the grounds that rational points of elliptic curves are accidental gems of mathematics, and it is hard to imagine that there could be bulk occurrence of these precious accidents—or at least substantially more bulk than is already predicted.
It seems that one cannot find such a minimalist conjecture explicitly in the literature until very recently (see [Wat06] and Conjecture 3.4). Nevertheless, for some particular families of elliptic curves (the “quadratic twist” families—see Section 3.3 below) the conjecture is much older. Over a quarter of a century ago, Dorian Goldfeld conjectured that for any elliptic curve $E$, the probability

$$G(D) = \frac{\#\{\text{quadratic twists up to } D \text{ of } E \text{ with infinitely many rational points}\}}{\#\{\text{quadratic twists up to } D \text{ of } E\}}$$

has $G = 1/2$ as its limit as $D \to \infty$.

(2) **Contrary numerical data.** The next phase of our story involves the accumulation of numerical data regarding this probability $P$ taken over the entirety of elliptic curves, and also over various selected families of elliptic curves. The short description of this data (but see the detailed discussion in the body of our article) is the following. Over every data set accumulated so far, about $2/3$ (or sometimes more) of the curves in the families being considered have had infinitely many rational points, and rather flatly so over the range of conductors involved in the computations; these now include a large (over 100 million curves) set of elliptic curves of conductor $< 10^8$.

(3) **A gross heuristic, for special families.** To get the most precise results we change the data set, and restrict attention to the probability that a member of even parity of a quadratic twist family of elliptic curves has infinitely many rational points. As a refinement to Goldfeld’s conjecture, Peter Sarnak gave a heuristic that predicts that among the first $D$ members of such a quadratic twist family (essentially arranged in order of increasing conductor) the number of those with even parity and infinitely many rational points is caught between $D^{3/4-\epsilon}$ and $D^{3/4+\epsilon}$ for any positive $\epsilon$ and $D$ sufficiently large. This guess, based on consideration of the size of Fourier coefficients of modular forms of half-integral weight, revived the minimalist conjecture: if Sarnak’s estimate is correct, we would indeed have $G = 1/2$ in Goldfeld’s conjecture, and even-parity members of a quadratic twist family would have probability 0 of having infinitely many rational points.

At this point in our story, there is decided friction between accumulated data which suggests something like $2/3$ as the probability for the general member to have infinitely many rational points, and a reasoned theoretical expectation, which suggests exactly $1/2$ for that probability. Generally, the least we would expect of our data is that they either support our conjectures, or overthrow them. Here there was a somewhat more surprising interrelation between data and conjecture: a kind of truce between them: we believed our guesses, we believed the data, and acknowledged the apparent gap between them.

(4) **A refined heuristic, for special families.** More recently, another twist to this story has developed. The work of Katz and Sarnak [KaSa99] regarding symmetry groups of the analogous families of curves over function fields\(^1\) gave impetus to the random matrix theory calculations of Keating.

\(^1\)More recently, Kowalski [KowB] has used monodromy results of Katz to prove upper bounds for average ranks in the function field analogues.
and Snaith [KeSu00] regarding moments of $L$-functions and their value distribution. This was then combined with a discretization process by Conrey, Keating, Rubinstein, and Snaith in [CKRS02] to give a more precise guess for the (asymptotic) number of curves of even parity in a quadratic twist family with infinitely many rational points. For example, for the quadratic twist family $y^2 = x^3 - d^2x$, the prediction is that among the first $D$ members of this family, the number of those with even parity and infinitely many rational points is asymptotic to

$$F(D) = c \cdot D^{3/4} \log(D)^{11/8}$$

for some (positive) constant $c$.

![Figure 1. Plots of $D^{3/4} \log(D)^{11/8}$ (upper) and $\Delta^{19/24}(\log \Delta)^{3/8}$ (lower) up to $10^8$](image)

On the one hand, this is a sharpening of the prior heuristic, for $F(D)$ is comfortably sandwiched between $D^{3/4+\epsilon}$. On the other hand, we may be in for a surprise when we actually plot the graph of the function $F(D)$. See Figure 1. The striking aspect of the graph in Figure 1 is how "linear" it looks. Indeed, if $F(D)$ were replaced by a linear function with roughly the slope that appears in Figure 1, it would predict something closer to $2/3$ than $1/2$ for the proportion of curves in the family with infinitely many rational points.

Similarly—cf. Section 3.5 below—if we order all elliptic curves by discriminant $\Delta$, one of us (see [Wat06]) has conjectured that the number of even parity elliptic curves with infinitely many rational points and absolute discriminant less than $\Delta$ is asymptotically given by

$$\Phi(\Delta) = c\Delta^{19/24}(\log \Delta)^{3/8}.$$ 

See Figure 1.
Here, roughly speaking, is where the story is at present, as we will explain in detail in the body of this article. The curious last phase of it, focussing on special families, makes it seem now that data for these families is (a) more closely adhering to the refined guess than one might expect, even for relatively small values of the conductor, and (b) a refined guess predicts an asymptotic behavior that is far from linear, but within the currently attainable range is so close to linear, that the numerical evidence elucidating these phenomena (even the very large data sets that computers have amassed) seem indecisive when it comes to distinguishing convincingly between such gross questions as: is the probability closer to $1/2$ or to $2/3$?

It may very well be that until we actually demonstrate our conjectures, no data that we can accumulate, however massive it may appear, will give even lukewarm comfort to the conjecturers. This conflict raises the question of whether we as mathematicians may, at times, face a situation where the substance we study has one shape asymptotically, and yet all computational evidence elucidating this substance, even up to the very large numbers that computers today, or in our lifetime, can compute, seems consistent with the possibility that the data have a different asymptotic shape.

But, of course, our story will continue. We would hope for

- a refined heuristic that covers the full set of elliptic curves, and not just quadratic twist families,
- an extension of the numerical computation to conductors $< 10^{10}$, which is a range where we may begin to see some significant differences between the graph of $F(D)$ and a linear function,
- a conceptual understanding of how to obtain—by more unified means—this impressive bulk of rational points that we see occurring for even parity elliptic curves, at least for curves of “small” conductor.

We find it useful to compare our question what is the probability that an elliptic curve has infinitely many points with some of the other counting problems of current interest. Specifically, consider the problem of counting quartic fields and sorting them into classes corresponding to the isomorphy type of the Galois group of their Galois closure. We have to be exceedingly careful when choosing the coefficients of a degree 4 polynomial if we want a root of that polynomial to generate anything other than a field whose Galois group is $S_4$. Hilbert’s irreducibility theorem provides corroboration of this with a proof that if you rank algebraic numbers of degree 4 by the size of the coefficients of their minimal polynomial (monic, over $\mathbb{Q}$) then 100% of them have Galois group $S_4$. But consider the problem of counting quartic fields (rather than the algebraic numbers that generate them) listed by the size (absolute value) of their discriminant. Counting field extensions of a given field whose Galois closure has its Galois group of a particular isomorphy type has been the subject of a number of precise conjectures (initially [CDO], and then successively refined in [Mal02, Mal04]). Bhargava’s remarkable paper [Bha05], which is further

---

2 We are reminded of the challenge of Shanks [Sha85, §69] regarding Carmichael numbers; with respect to the conjecture of Erdős that, for every $\epsilon > 0$, there were, for sufficiently large $X$, at least $X^{1-\epsilon}$ Carmichael numbers up to $X$, Shanks (essentially) noted that the data for small $X$ did not remotely conform to this, and proposed giving an explicit $X$ for which there were at least (say) $\sqrt[3]{X}$ Carmichael numbers up to $X$, suspecting that exhibiting such an $X$ would be much beyond the capabilities of computers.
evidence for these conjectures, proves that when we count quartic fields, nested by absolute discriminant, we do not get that 100% of them have Galois group $S_4$.

Bhargava regards the problem of counting quartic fields as a problem purely in the Geometry of Numbers, and proves the following theorem:

**Theorem 1.2.** [Bhargava]. When ordered by absolute discriminant, a positive proportion (approximately 0.09356) of quartic fields have associated Galois group $D_4$ (the dihedral group). The remaining approximately 0.90644 of quartic fields have Galois group $S_4$, and the other three transitive subgroups occur with probability 0 asymptotically.

We would be more than delighted to see unconditional results of this precision established for questions such as the one motivating this survey article.

**Acknowledgment.** We thank Armand Brumer, Frank Calegari, Noam Elkies and Oisin McGuinness for stimulating conversations. We used PARI [ABCRZ] and SAGE [SJ05] to compute and analyze the data, and matplotlib [Mpl05] to draw the graphs. We thank Bob Guralnik for references to work about distributions of Galois groups. Similar surveys to this are those of Rubin and Silverberg [RS02] and Kowalski [KowA], the latter of which also relates random matrix theory to the theory of elliptic curves, and then discusses questions related to the inability of reconciling experimental data with theoretical asymptotics, particularly with respect to the work of Heath-Brown on the 2-Selmer rank of the congruent number curves.

2. **Elliptic Curves**

An elliptic curve $E$ over $\mathbb{Q}$ is a projective nonsingular curve defined as the projective closure of the zero locus of an equation of the form

$$y^2 + a_1 xy + a_3 y = x^3 + a_2 x^2 + a_4 x + a_6,$$

with the $a_i$ in $\mathbb{Q}$. The set $E(\mathbb{Q})$ of rational points on $E$ is equipped with an abelian group structure (see [Sil92]).

The equation (2) is rationally equivalent to exactly one of the form

$$y^2 = x^3 - 27c_4 x - 54c_6,$$

with $c_4, c_6, \Delta = (c_4^3 - c_6^2)/1728 \in \mathbb{Z}$ and for which there is no prime $p$ with $p^4 \mid c_4$ and $p^{12} \mid \Delta$. We call $\Delta$ the minimal discriminant of $E$. (For example, the minimal discriminant of the curve $y^2 + y = x^3$ mentioned in Section 1 is $\Delta = 37$; also $c_4 = 48$ and $c_6 = -216$ for this curve.)

The conductor of an elliptic curve $E$ over $\mathbb{Q}$ is a positive integer $N = N_E$ that is a measure of the nature of the reduction of the elliptic curve modulo the prime divisors of $\Delta$. For example, a prime $p \geq 5$ divides the conductor $N$ only if there is no way of finding another defining equation (2) of $E$ so that when reduced modulo $p$ we obtain an equation over the field $\mathbb{F}_p$ without multiple roots; the maximal power of such a prime $p$ dividing $N$ is 2 and whether it is 1 or 2 is determined by the nature of the best reduction of $E$ modulo $p$, i.e., whether its defining cubic polynomial has a double or a triple root. There is a slightly more involved, but elementary, recipe to give the power of the primes 2 and 3 dividing the conductor (see [Tat75]).

Mordell proved in 1922 (see [Mor22]) that the Mordell-Weil group $E(\mathbb{Q})$ of rational points on $E$ is a finitely generated abelian group, so $E(\mathbb{Q}) \approx \mathbb{Z}^r \oplus E(\mathbb{Q})_{\text{tor}}$. 
The integer $r$ is the rank of $E$, and is the main statistic that we will discuss below; in contrast, the torsion group is rather well-understood, and is thus of less interest.

Let $\Delta$ be the minimal discriminant of $E$. The $L$-function $L(E,s)$ of $E$ is a Dirichlet series given by a simple recipe in terms of the number of points $N_p$ of the reduction of $E$ over $\mathbb{F}_p$ for all primes $p$. Specifically,

$$(4) \quad L(E, s) = \prod_{p \mid \Delta} \frac{1}{1 - (1 + p - N_p)p^{-s} + p^{1-2s}} \cdot \prod_{p \nmid \Delta} \frac{1}{1 - (1 + p - N_p)p^{-s}} = \sum_{n=1}^{\infty} \frac{a_n}{n^s}.$$ 

The integers $a_n$ are defined by expanding the Euler product; e.g., $a_p = p + 1 - N_p$ and $a_{p^2} = a_p^2 - p$ when $p \nmid \Delta$, etc. As an example, if $E$ is $y^2 = x^3 - x$ then

$$L(E, s) = 1 - \frac{2}{2^s} - \frac{3}{3^s} + \frac{2}{4^s} - \frac{2}{5^s} + \frac{6}{6^s} - \frac{1}{7^s} + \frac{6}{9^s} + \frac{4}{10^s} - \frac{5}{11^s} + \cdots.$$ 

For any elliptic curve $E$, the celebrated papers of Wiles [Wil95] and others [BCDT01] imply that $L(E,s)$ extends to an entire analytic function on the complex plane. Moreover these results imply that the completed $L$-function $\Lambda(E,s) = N^{s/2} \cdot (2\pi)^{-s} \cdot \Gamma(s) \cdot L(E,s)$ satisfies the functional equation

$$\Lambda(E, s) = u_E \cdot \Lambda(E, 2 - s),$$

where $u_E$ is either $-1$ or $1$, and is called the sign in the functional equation for $E$. Note that $u_E = 1$ if and only if $L(E,s)$ vanishes to even order at $s = 1$.

The classical Birch and Swinnerton-Dyer Conjecture [BSD] asserts that the order of vanishing of this entire function at the point $s = 1$ in the complex plane is equal to the rank of the Mordell-Weil group $E(\mathbb{Q})$. In the data regarding rank that we will be reporting below, at times the Mordell-Weil rank $r$ has been computed directly by finding $r$ rational points of $E$ that are linearly independent and span a subgroup of finite index in $E(\mathbb{Q})$ and we will refer to this $r$ as the arithmetic rank of $E$. At times, however, what is computed is the apparent order of vanishing of $L(E,s)$ at $s = 1$; we refer to this order of vanishing as the analytic rank of $E$. The BSD conjecture asserts that the ranks are in fact equal. We say a curve has even parity if the analytic rank is even, and odd parity if it is odd.

We now state the refined BSD conjecture for curves of rank 0. When $E$ is given by (3), the real period $\Omega_{re}$ is, up to easily determined factors of 2 and 3, equal to the integral $\int_{E(\mathbb{R})} dx/y$. For a prime $p$, the Tamagawa number $\Omega_p$ is the index in $E(\mathbb{Q}_p)$ of the subgroup of $p$-adic points that reduce to a nonsingular point in $E(\mathbb{F}_p)$.

**Conjecture 2.1.** [Birch and Swinnerton-Dyer]. If $L(E,1) \neq 0$, then

$$(5) \quad L(E, 1) = \frac{\Omega(E) \cdot \# \Sha(E)}{\# E(\mathbb{Q})^{2 \text{tor}}},$$

where $\Sha(E)$, the Shafarevich-Tate group of $E$, is a certain (mysterious) group associated to $E$ (it measures the failure of a local-global principle), and

$$\Omega(E) = \Omega_{re} \cdot \prod_p \Omega_p.$$ 

Since $L(E,1) \neq 0$, the group $\Sha(E)$ is known to be finite [Kol88] of order a perfect square [Cas62].
For any \( r = 0, 1, 2, \ldots \) the question we now may ask is: what percentage of elliptic curves (nested according to size of conductor) have rank \( r \)? More correctly, we should ask: do these percentages exist, and if so what are they?

3. Conjectures

One fairly firm anchor in the study of elliptic curves is a principle that goes under the heading of parity. This principle is still only conjectural, but is amply confirmed numerically in our accumulated data, and we also have theoretical reasons to believe it. The parity principle is that 50% of the members of any of the sets of elliptic curves we will be considering have even parity, and 50% have odd parity (under reasonable orderings).

In general terms, the minimalist principle proclaims that from the rough viewpoint of percentages, there are as few rational points on elliptic curves as is possible, given the constraint of the parity principle. That is, 50% of the members of any of the families of elliptic curves we will be considering have rank \( r = 0 \), and 50% have rank \( r = 1 \), and the remaining ranks \( r \geq 2 \) account for 0% of the family.

As one thing or another things comes to light in the subject, the minimalist position is sometimes favored, and sometimes not. For certain special families of elliptic curves this minimalist conjecture has long been in print, and has had a wild ride in terms of its being believed, and doubted.

3.1. The form of the conjectures. There are two types of asymptotic conjectures that we encounter in discussions regarding rank statistics. The first we might call a rough conjecture where it is asserted, or conjectured, for a certain collection \( \mathcal{F}(x) \) of items indexed by a variable \( x \) that there is an exponent \( a \) and a function \( x(\varepsilon) \) such that the cardinality of \( \mathcal{F}(x) \) is bounded above by \( x^{a+\varepsilon} \) and below by \( x^{a-\varepsilon} \) for any positive \( \varepsilon \) and any \( x \geq x(\varepsilon) \).

We also will be discussing fine conjectures where such collections \( \mathcal{F}(x) \) will be conjectured to have asymptotic estimates of the form

\[
\# \mathcal{F}(x) \sim x^a \cdot (\log x)^b \cdot c,
\]

for constants \( a, b, c \); the delicacy, of course, of these constants is inversely related to their alphabetical order.

What seems to be a pattern is that the exponent \( a \), appearing in both rough and fine versions, in specific contexts under discussion, can usually be guessed by more old-fashioned heuristics. But—at present, at least—the on-going work regarding random matrix eigenvalues is the only source of heuristics that lead us to formulate specific “fine conjectures” regarding ranks, and specifically for guesses regarding the exponent \( b \) of the \( \log x \) term. The fact that the graphs of some of the specific concoctions of the form \( x^a \cdot (\log x)^b \cdot c \) predicted by random matrix statistics can look deceivingly like \( x^a \) even though \( a < 1 \) (and for a significant range of the variable \( x \)) is one of the curiosities of our story.

3.2. Random matrix statistics. Originally developed in mathematical physics, random matrix theory [Meh04] has now found many applications in number theory, the first being the oft-told story of Dyson’s remark to Montgomery regarding the pair-correlation of zeros of the Riemann \( \zeta \)-function. Based on substantial numerical evidence, random matrix theory appears to give reasonable models for the distribution of \( L \)-values in families, though the issue of what constitutes a proper “family”
can be delicate. The work of Katz and Sarnak [KaSa99] regarding families of curves over function fields implies that for quadratic twists of even parity, we should expect orthogonal symmetry with even parity. Though we have no function field analogue of the distribution of the values at 1 of the characteristic polynomials of our random matrices. In the large, this distribution is determined entirely by the symmetry type, while finer considerations are distinguished via arithmetic considerations.

Via the moment conjectures [KeSn00] of random matrix theory and then using Mellin inversion, we expect that this means is that we want to model properties of the eigenvalues of our matrices, and so, as in [KeSn00], we should take 2

\[ \frac{1}{2} \]

in a single object, as the coefficients (weighted by the real period and Tamagawa numbers) of an integral modular form \( g_E \) are squarefree.

There are many conditional and unconditional results regarding Goldfeld’s conjecture. For a survey, see the papers of Rubin and Silverberg [RS02, Sil01].

The values \( L(E_d, 1) \) of quadratic twists \( E_d \) of a given curve \( E \) essentially appear in a single object, as the coefficients (weighted by the real period and Tamagawa numbers) of an integral modular form \( g_E \) of weight 3/2 (this follows from work of Waldspurger, see [Wal81]). In particular, for many \( d \), we have that \( L(E_d, 1) = 0 \) precisely when the \( d \)th (or \(-d\)th, depending on the case) coefficient of \( g_E \) is zero. This object \( g_E \) does not give us values of \( L(E_d, 1) \) for all \( d \), but does provide a large proportion of them. The Ramanujan conjecture for modular forms implies that the coefficients of \( g_E \) should be bounded by about \( |d|^{1/4} \), and so if we assume a coefficient distribution that is somewhat uniform, we approximate the count \( F(D) \) of quadratic twists up to \( D \) with even parity that have \( L(E_d, 1) = 0 \) by \( \sum_{|d| < D} / |d|^{1/4} \).

Sarnak’s rough heuristic asserts that this count lies between \( D^{3/4-\varepsilon} \) and \( D^{3/4+\varepsilon} \). Using random matrix theory [CKRS04] gets the refined heuristic that

\[ F(D) \sim D^{3/4} \cdot (\log D)^{b} \cdot c, \]

where there are four possibilities for \( b \) and \( c \) is still mysterious.

In [CKRS04], Rubinstein used weight 3/2 forms to give data about \( L(E_d, 1) \) for over 2000 elliptic curves \( E \). For each of these he computed \( L(E_d, 1) \) for a substantial subset of the quadratic twists by fundamental discriminants \( d \) with \( |d| < 10^{b} \). (For

\[ 3 \]

Here we wish the mean density of zeros of the \( L \)-functions to match the mean density of eigenvalues of our matrices, and so, as in [KeSn00], we should take \( 2M \approx 2 \log N \).
example, for the curve $E$ given by $y^2 + y = x^3 - x^2$ of conductor 11, the only twist $E_{-d}$ of even parity for $3 < d < 91$ is $d = 47.$) The data of Rubinstein agree fairly well with predictions such as (1).

We can also consider other twist families. For example, Kramarz and Zagier [ZK87] considered cubic twists $x^3 + y^3 = m$ of the Fermat cubic $x^3 + y^3 = 1$ and found in their data that 23.3% of the curves with even parity have rank at least 2, and 2.2% of those with odd parity have rank at least 3. One of the authors of the present article [Wat04] and independently Fermigier (unpublished) have followed up on these computations. Also, Patricia Quattrini (Universidad de Buenos Aires) as part of her thesis work did some extensive calculations of the analytic rank for the curves $y^2 = x^3 - nx$. As in the Kramarz-Zagier case, the percentage of curves with analytic rank $\geq 2$ was in the 20% range but did seem to be going down. Similar computations [DFK04] have also been undertaken for twists by other (complex) Dirichlet characters, which are related to ranks over number fields.

3.4. Conjectures when counting all elliptic curves. Before we can count curves with even parity and infinitely many points, we might first take a step back, and just try to count curves. Though before we ordered curves by conductor, when deriving heuristics it is often easier to sort by discriminant. Indeed, Brumer and McGuinness [BM90, §5] state a heuristic estimate for the number of discriminants of elliptic curves up to a given bound:

**Conjecture 3.2.** [Brumer-McGuinness]. We have the following estimates for the number of positive or negative minimal discriminants of elliptic curves of absolute value at most $X$ (respectively):

$$A_{\pm}(X) \sim \frac{\alpha_{\pm}}{\zeta(10)} X^{5/6}$$

where $\alpha_+ = 0.4206\ldots$ and $\alpha_- = \sqrt{3}\alpha_+ = 0.7285\ldots$ are given by

$$\alpha_{\pm} = \frac{\sqrt{3}}{10} \int_{1}^{\infty} \frac{du}{\sqrt{u^3 + 1}}.$$

Brumer and McGuinness say little about their derivation of this heuristic, but remark that it suggests a heuristic for prime discriminants that matches very well with their data. We can derive their heuristic by counting lattice points in the $(c_4, c_6)$-plane, restricting to congruence classes modulo powers of 2 and 3 to ensure that $\Delta$ is integral. Because $\Delta = (c_4^3 - c_6^2)/1728$, we heuristically have that $A_{+}(X)$ is proportional to the area of the region $0 < c_4^3 - c_6^2 < 1728X$, and similarly with $A_{-}(X)$. This gives $\alpha_{\pm}X^{5/6}$; the extra factor of $\zeta(10)$ comes about since we need (for $p \geq 5$, and similarly for $p = 2, 3$) to eliminate $(c_4, c_6)$ pairs with $p^4|c_4$ and $p^6|c_6$. For a more complete derivation of the value of $\alpha_{\pm}$ see [Wat06].

We expect that half of these curves have even parity. Now we wish to estimate how many of the curves with even parity have $L(E, 1) = 0$.

3.5. Rank conjectures for all curves. To make use of the heuristic (6), we introduce a discretization process. We want to connect $L(E, 1)$ with the winding

---

Note that this is rationally isomorphic to the elliptic curve in the form (3) given by the equation $Y^2 = X^3 - 54 \cdot 5832$ via the map $(X, Y) = (108/(x + y), 972(y - x)/(y + x))$. 
number $W = W(E) = |L(E,1)/\Omega_{re}|$ (see [MSD74, §2.2]), $^5$ and measure the likelihood that $W$ is $0$. Ignoring torsion (so that $W$ is an integer) we are trying to estimate the probability that $L(E,1) < \Omega(E)$. If we consider only elliptic curves for which $\Omega(E)$ lies in a fixed interval $c_1 < \Omega(E) < c_2$ then we get a neat estimate of this probability. So this line of reasoning leads one to try to deal with the statistics of the invariant $\Omega(E)$ for varying $E$.

Next, we simplify matters by restricting to curves with prime positive discriminant (and even parity). Three nice things about these curves are that (except for a sparse subset): all have trivial torsion; all have $\Omega_p = 1$ for all (finite) primes $p$; and all have that $N = \Delta$. The idea of our discretization is that $W$ can only take on integral values (note that when $W \neq 0$, Conjecture 2.1 implies that $W = \#III(E)$, which is a perfect square, but we will not use this). Thus, in terms of our probability distribution of $L$-values, we get that $L(E,1) < \Omega_{re}$ if and only if $L(E,1) = 0$; this is because

$$0 \leq W = \left| \frac{L(E,1)}{\Omega_{re}} \right| < 1$$

and $W$ is an integer.

Putting $t = \Omega_{re}$ and $N = \Delta$ in (6) we get:

**Heuristic 3.3.** A curve with positive prime discriminant and even parity has infinitely many points with probability $c\Omega_{re}^{1/2}(\log \Delta)^{3/8}$.

Using the above, the number $B(X)$ of such curves up to $X$ with even parity and infinitely many points is estimated by integrating $\int \int c\Omega_{re}^{1/2}(\log \Delta)^{3/8-1}du_4du_6$ over the region $|u_4^2 - u_6^2| < 1728X$, where the “$-1$” in the exponent of $\log \Delta$ comes about from the prime number theorem. Also, the integral makes sense because $\Omega_{re}$ and $\Delta$ are smooth functions of $c_4$ and $c_6$, that is, we can define $\Omega_{re}$ and $\Delta$ for $c_4$ and $c_6$ that are not necessarily integral (or even rational). So, similar to the above discussion of the Brumer-McGuinness heuristic, we have replaced a lattice-point problem with the “area” of a region in a plane, but here the “area” is weighted by a factor depending on the real period and the discriminant (and congruence restrictions as before).

We expect that the real period $\Omega_{re}$ is typically$^6$ roughly of size $1/|\Delta|^{1/12}$, and so, from the above heuristic,$^7$ we thus get a crude estimate that $B(X)$ is of size $X^{19/24}$.

The preprint [Wat06] handles more of the details. Indeed, if $F(\Delta)$ is the number of elliptic curves with discriminant $\leq \Delta$ (not just those with prime discriminant), the heuristic predicts

$$F(\Delta) \approx cX^{19/24}(\log X)^{5/8},$$

---

$^5$ We could relate $W$ to the Birch and Swinnerton-Dyer conjecture, but the (topological) winding number interpretation is rigorous and sufficient for our needs.

$^6$This is also an upper bound; the ABC conjecture says $\Omega_{re}$ is never much smaller than $1/|\Delta|^{1/2}$.

$^7$Note that random matrix theory is largely used to determine the power of logarithm in this heuristic. The cruder estimate of $X^{19/24}$ can alternatively be obtained by assuming that the winding number is a random square integer of size up to $1/\Omega_{re}$ (this is similar to Sarnak’s heuristic); indeed this was probably known to Brumer and McGuinness, as they conclude their paper with

While our data may seem massive, $N = 10^8$ is not sufficient to distinguish growth laws of $\log \log N$, $N^{1/12}$ or $N^{1/24}$ from constants. So we have to be cautious in formulating conjectures based on the numerical evidence.
with a computable\textsuperscript{8} positive constant $c$.

In any case, since we expect $cX^{5/6}/\log X$ such curves, this heuristic says that 100\% of the even parity curves have rank 0.

3.6. \textbf{Ordering by conductor.} The predictions become much more crude when we order by conductor instead of discriminant, as this introduces arithmetic considerations related to the ABC-conjecture (see [GT02]) in the accounting. Even giving a heuristic for the number $C(X)$ of curves of conductor less than $X$ is quite difficult. The preprint [Wat06] asserts heuristic upper bounds of $X^{5/6}\exp(c_1\sqrt{\log X})$ for $C(X)$ and similarly $X^{19/24}\exp(c_2\sqrt{\log X})$ for the number of rank 2 curves with conductor less than $X$. So in all cases we get that 100\% of the even parity curves have rank 0. Despite our lack of numerical confirmation, we label these guesses as “conjectures”:

\begin{conjecture}
The number of even parity elliptic curves with infinitely many rational points and absolute discriminant less than $X$ is asymptotically given by $cX^{19/24}(\log X)^{3/8}$ for some positive computable constant $c$ as $X \to \infty$. If we replace absolute value of the discriminant by conductor, we get an upper bound of $X^{19/24}\exp(c_2\sqrt{\log X})$. In particular, asymptotically almost all elliptic curves with even parity have finitely many rational points. See [Wat06] for more details.
\end{conjecture}

4. \textbf{Data}

The opinion had been expressed that, in general, an elliptic curve might tend to have the smallest possible rank, namely 0 or 1, compatible with the rank parity predictions of Birch and Swinnerton-Dyer. We present evidence that this may not be the case. [...] This proportion of rank 2 curves seemed too large to conform to the conventional wisdom. – Brumer and McGuinness [BM90]

In [BM90], Brumer and McGuinness considered 310716 curves of prime conductor $\leq 10^8$. In this section we discuss extensions of their data, and answer in the affirmative that there is a similar large proportion of rank 2 curves for composite conductor $\leq 10^8$, and for prime conductor $\leq 10^{10}$. More precisely, we consider 136832795 curves of all conductors $\leq 10^8$, and 11378911 curves of prime conductor $\leq 10^{10}$. The results of the rank computation we describe are similar to those of Brumer and McGuinness, which appear to suggest that if one orders all elliptic curves over $\mathbb{Q}$ by conductor, then the average rank is bigger than 0.5. However, as discussed above, we conjecture that the average rank is 0.5.

4.1. \textbf{Brumer-McGuinness.} In [BM90], Brumer and McGuinness found, by thousands of hours of computer search, 311219 curves of prime conductor $\leq 10^8$. For 310716 of these curves they computed the probable rank by a combination of point searches and computation of apparent order of vanishing of $L$-functions. Table 1 (expanded from [BM90]) summarizes the rank distribution that they found\textsuperscript{9}

In Table 1, note that curves with $\Delta > 0$ are more likely to have large rank. Let $r_e(X)$ be the average rank of elliptic curves in [BM90] with conductor at most $X$.

\textsuperscript{8}Our imprecise discretization might make the computed value of $c$ not too relevant.

\textsuperscript{9}Some of their counts were computed incorrectly (for instance, they only used 4000 terms of the $L$-series, and thus mis-identified 11 curves of rank 0 as having rank 2), but this has little influence on the overall statistics.

and discriminant sign \(\varepsilon\). They observe that in their data, \(r_+\) climbs to 1.04 and \(r_-\) climbs to 0.94, and they remark that “An interesting phenomenon was the systematic influence of the discriminant sign on all aspects of the arithmetic of the curve.” The more extensive computations do not always find this to be the case; see, in particular, Figure 3 below, where the graphs split by discriminant cross.

4.2. The Stein-Watkins Database. Brumer and McGuinness fixed the \(a_1, a_2, a_3\) invariants (12 total possibilities, as (2) can be modified first to be integral, and then to ensure that \(|a_1, a_3| \in \{0, 1\}\) and \(|a_2| \leq 1\) and then searched for \(a_4\) and \(a_6\) that made \(|\Delta|\) small. Stein and Watkins [SW02] broke the \(c_4\) and \(c_6\) invariants into congruence classes, and then found small solutions to \(c_4^3 - c_6^2 = 1728\Delta\), with \(c_4, c_6\) minimal in the sense of (3). There is little theoretical advantage in this approach; more computing power and disk space were the main advances in [SW02]. Stein and Watkins searched for curves with prime conductor up to \(10^{10}\), and for composite conductor chose \(|\Delta| < 10^{12}\) and \(N \leq 10^8\) as search bounds, and then included isogenous curves and twists (with \(N \leq 10^8\)) of the curves they found.

4.3. Completeness of the Database. Note that neither the method of Brumer-McGuinness nor Stein-Watkins is guaranteed to find all curves of prime (absolute) discriminant up to a given bound (indeed, it is more likely that they miss a few curves), but we think that their datasets are reasonable surrogates, and should exhibit validity when compared to the the predictions of the theoretical model.

For curves of composite conductor, the Stein-Watkins database is much more likely to miss curves. Here the comparison is to the dataset of Cremona [Cre], who used the algorithms of [Cre97] and the modularity theorem of [BCDT01] to find every elliptic curve of conductor up to 120000. Cremona found 782493 curves up to conductor 120000. In the Stein-Watkins computation, they found 614442 curves of conductor up to 120000, so they found over 78.5% of the curves. The first case in which Cremona has a curve and Stein-Watkins do not is the curve

\[
y^2 + xy + y = x^3 - 7705x + 1226492\]

of conductor 174, which has discriminant \(-621261297432576 = -2^{11} \cdot 3^{21} \cdot 29\), whose absolute value is substantially larger than \(10^{12}\). The conductors up to 500 where they miss curves are

\[174, 222, 273, 291, 330, 354, 357, 390, 420, 442, 462, 493.\]

Figure 2 shows the proportion of the number of curves in the Stein-Watkins database to the number of curves in Cremona’s database, as a function of the conductor.

The rank distribution of Cremona’s curves is given in Table 2. The average rank for Cremona’s curves is about 0.688. This is smaller than the average rank in other
datasets we consider (and is probably explainable via the real period considerations of the last section), but we prefer to highlight the results from other datasets.

As noted above, when ordering by conductor, there is presently no consensus guesstimate for the number of curves up to $X$. Cremona has commented that there is approximately linear growth (in contrast to the comments preceding Conjecture 3.4) in the number of curves of conductor less than 120000, and extrapolating this gives a prediction close to 650 million for the number of curves with $N \leq 10^8$.

D. J. Bernstein suggested that we try to quantify the completeness of the Stein-Watkins database by considering what percentage of Cremona’s curves would be obtained by using their search methods with a smaller discriminant bound. That is, for a parameter $B$, if we find all curves with $N \leq B^2$, $|\Delta| \leq B^3$, and $c_4 \leq 100 \cdot (12B)^2$, and then take all isogenous curves and twists of these with conductor less than $B^2$, what percentage of Cremona’s curves do we obtain? With $B = 300$, we get 246532 curves, while Cremona has 592519 curves of conductor $\leq 90000 = 300^2$, so we get about 42%. Applying this percentage to the Stein-Watkins database with $B = 10^4$, this would suggest that there are about 325 million elliptic curves with conductor less than $10^8$. So the two guesses differ by a factor of two, exemplifying our ignorance on so basic an issue.
5. Average Ranks: Graphs of Data

This section contains graphs that at a glance suggest that the minimalist principle is contradicted by the data for curves of conductor $\leq 10^8$; indeed, particularly in Figure 3, we see that the average rank is increasing! However, for prime conductor $\leq 10^{10}$ the average rank drops, though only slightly from 0.978 to 0.964. With some imagination, the distribution of rank for prime conductor might appear to support the minimalist conjecture that the average rank is 0.5. Table 3 gives the average rank for various collections of curves that are described in more detail elsewhere in this paper and section.

In this section when we write elliptic curves with property $P$, we mean elliptic curves in the Stein-Watkins database with property $P$.

![Figure 3. Average Rank of Stein-Watkins Curves of Conductor $\leq 10^8$](image)

5.1. Curves Ordered By Conductor. The average rank of all Stein-Watkins curves with conductor $\leq 10^8$ is about 0.87. Figure 3 gives the average rank as a function of log of the conductor, and also the average rank for curves of positive and negative discriminant. We created this graph by computing the average rank of curves of conductor up to $n \cdot 10^5$ for $1 \leq n \leq 1000$. Figure 4 graphs the proportion...
of curves with each rank 0, 1, 2, and 3, as a function of log of the conductor, all on a single graph. The overall rank proportions are in Table 4.

5.2. **Prime Conductor Curves.** The average rank for the curves of prime conductor $\leq 10^{10}$ is about 0.964; see Table 5 for the rank distribution. Figure 5 plots the average rank of curves of prime conductor $\leq 10^{10}$ as a function of log of the conductor. Note that here the average ranks are decreasing, unlike in Figure 3.

5.2.1. **An experiment.** The data of [BM90] and [SW02] for curves of prime conductor up to $10^8$ and $10^{10}$ show very little drop in the observed average rank. To investigate the possibility that the average rank might not decrease much below 0.964 we chose a selection of curves with prime conductor of size $10^{14}$. It is
non-trivial to get a good data set, since we must take congruence conditions on the elliptic curve coefficients and the variation of the size of the real period into account; see [Wat06] for more details on how to account for this.

Our data sets contained 89913 curves of positive prime discriminant, and 89749 similar curves with negative discriminant, with $|\Delta|$ near $10^{14}$ for all the curves. It then took a few months to compute the analytic rank for these curves. We
found that for positive discriminant the average analytic rank is approximately 0.937 and for negative discriminant it is approximately 0.869 (see Table 6 for more details). Note that this is significantly less than the average rank found in [BM90] and [SW02]. It could be said that this is the strongest numerical evidence yet for the Minimalist Conjecture, though, it is still very weak. Incidentally, the largest rank found in any of these data sets is 6.

</tbody>
</table>

Let \( f(\Delta) \) be the “probability” that \( L(E, 1) = 0 \) for an even parity curve of discriminant near \( \Delta \) for \( \Delta \) positive. For example, Tables 5 and 6 suggests that

\[
\begin{align*}
L(10^{10}) & \sim \frac{0.204 + 0.004}{0.291 + 0.204 + 0.004} = 0.417 \\
L(10^{14}) & \sim \frac{0.176 + 0.004}{0.319 + 0.176 + 0.004} = 0.361
\end{align*}
\]

(Note that we approximated \( f(10^{10}) \) using data for all \( |\Delta| < 10^{10} \).) Motivated by the discussion in Section 3, we might heuristically approximate this probability function by \( \hat{f}(\Delta) = c \cdot (\log \Delta)^{3/8}/\Delta^{1/24} \), where \( \Delta^{1/24} \) comes about as the square root of the “typical” real period. The value of \( \hat{f}(10^{10})/\hat{f}(10^{14}) \) is about 1.29, which is not ridiculously far from the observed ratio of

\[
\frac{f(10^{10})}{f(10^{14})} \sim \frac{0.417}{0.361} \sim 1.16.
\]

5.3. Variants. We also carried out computations similar to the ones described above when counting isogeny classes instead of curves (this is a coarser equivalence relation than isomorphism, grouping together curves between which there is a finite degree morphism). In our data the average size of isogeny classes for all curves of conductor up to \( X \) converges reasonably quickly to 1 (Duke has shown [Duk97] that this is indeed the case under a different ordering). Thus the data and graphs look almost identical to those presented above. Table 7 gives rank data for other subsets of the Stein-Watkins database of curves of conductor \( \leq 10^8 \). In the table, “has CM” refers to curves that have complex multiplication, i.e., whose endomorphism ring (over \( \mathbb{C} \)) is bigger than \( \mathbb{Z} \).

6. How can we systematically account for the Mordell-Weil rank we have already computed?

Forget all questions of asymptotics. Consider only the curves of prime conductor up to \( 10^{10} \) in our data. Is there an argument other than just computing ranks for each of the elliptic curves in the databases—is there a pure thought heuristic—that explains why we are witnessing so much Mordell-Weil rank? In a sense, these rational points are both analogous, and not analogous, to the physicist’s dark matter.\(^{10}\)

\(^{10}\) The original idea is due to Zwicky [Zwi33]; recent SDSS and WMAP data [Teg04] seem to confirm its existence, though there are still some doubters (such as [Bek04]).

This large mass of rational points for elliptic curves of prime conductor $\leq 10^{10}$ is palpably there. We aren’t in the dark about that. We are merely in the dark about how to give a satisfactory account of it being there, other than computing instances, one after another.

We are, in a word, just at the very beginning of this story.
