OBJECTIVE: Diabetic retinopathy (DR) is associated with hyperglycemia-driven microvascular pathology and neuronal compromise in the retina. However, DR is also linked to dyslipidemia. As omega-3 (ω-3) polyunsaturated fatty acids (PUFAs) are protective in proliferative retinopathy, we investigated the capacity of ω-3PUFAs to preserve retinal function in a mouse model of type 2 diabetes mellitus (T2DM).

DESIGN: Male leptin-receptor-deficient (db/db) mice were maintained for 22 weeks (4 weeks–26 weeks of life) on calorically and compositionally matched diets, except for 2% enrichment in either ω-3 or ω-6PUFAs. Visual function was assessed at 9, 14 and 26 weeks by electroretinography. Retinal capillary and neuronal integrity, as well as glucose challenge responses, were assessed on each diet.

RESULTS: The ω-3PUFA diet significantly preserved retinal function in the mouse model of T2DM to levels similar to those observed in nondiabetic control mice on normal chow. Conversely, retinal function gradually deteriorated in db/db mice on a ω-6PUFA-rich diet. There was also an enhanced ability of ω-3PUFA-fed mice to respond to glucose challenge. The protection of visual function appeared to be independent of cytoprotective or anti-inflammatory effects of ω-3PUFAs.

CONCLUSION: This study identifies beneficial effects of dietary ω-3PUFAs on visual function in T2DM. The data are consistent with dyslipidemia negatively impacting retinal function. As ω-3PUFA lipid dietary interventions are readily available, safe and inexpensive, increasing ω-3PUFA intake in diabetic patients may slow the progression of vision loss in T2DM.

INTRODUCTION

Diabetic retinopathy (DR) is a major complication of diabetes and the most frequent cause of blindness in ages 30–60 years.1 The number of patients with diabetes worldwide is projected to be 366 million by 2030,2 with type 2 diabetes mellitus (T2DM) accounting for the greatest increase in new cases. It is estimated that over 80% of patients afflicted with T2DM will develop a form of DR within 20 years of diagnosis.3 Clinically, DR is first seen as a progressive loss of retinal vasculature (nonproliferative DR) characterized by microaneurysms, pericyte loss and basement membrane thickening.4 Importantly, often preceding vascular changes, retinal neurons, including retinal ganglion cells (RGCs), are damaged.5–7 Nonproliferative DR is also associated with increased inflammation, increased vascular permeability and leukostasis. In response to retinal hypoxia resulting from the vessel loss in nonproliferative DR,8 there is a second phase consisting of pathological vasoproliferation (proliferative DR), which can cause tractional retinal detachment leading to blindness.

Besides hyperglycemia, dysregulation of lipid metabolism is associated with DR. Modulating a patient’s lipid profile9–11 can improve DR. Lipids have important regulatory roles beyond energy storage and membrane structure. Importantly, intake of essential omega-3 (ω-3) long-chain polyunsaturated fatty acids (PUFAs) directly influences lipid signaling and has therapeutic potential in metabolic and inflammatory conditions.12,13 As mammals are not readily capable of synthesizing ω-3 and ω-6PUFAs, the content of these PUFAs in tissue is almost solely defined via dietary intake.

In a mouse model of oxygen-induced retinopathy with characteristics of proliferative DR, we have previously demonstrated that a diet enriched in ω-3PUFAs (similar to human Japanese diets) effectively reduces pathological retinal neovascularization when compared with an ω-6PUFA-rich diet (mimicking human American diets).14–16 These findings are consistent with the human Age-Related Eye Disease Study reports, which found that total dietary intake of ω-3PUFAs is inversely associated with the risk of neovascular age-related macular degeneration.17 Moreover, a lower incidence of T2DM has been reported in individuals whose diets are rich in ω-3PUFAs.18

Although tight glycemic control retards retinopathy, compliance is difficult. A safe nutritional intervention to help prevent DR would answer a clinically unmet need. Here we present the first evidence that dietary ω-3PUFA supplementation reduces hyperglycemia, improves glucose tolerance and directly preserves
In this model, \( R_m \) is the intensity that elicits a half-maximum \( P_2 \); the Lamb and Pugh21 model of the activation of phototransduction: \[ P_2(i) = \frac{C_0}{1 + \left( \frac{i}{C_1} \right)^{1/2}} \] where \( C_0 \) is the fractional sensitivity, \( C_1 \) is the sensitivity at threshold and \( \Phi_{1/2} \) is the stimulus intensity at which sensitivity has fallen by half.

The oscillatory potentials (OPs) characterize activity in retinal cells distinct from those that generate \( P_1 \) and \( P_2 \). The OPs were analyzed in the frequency domain following discrete Fourier transform of the first 128 ms of \( P_x \). The saturating energy in the OPs, \( Em(\omega, t) \), was derived similarly to \( Rm_{P2} \) from the response versus intensity relationship of OP energy. \( Em \) is related to the square of OP amplitude,24 and thus its root (\( Em^{1/2} \)) was used in all analyses.

To evaluate a cone-mediated response, the trough-to-peak amplitude of the light-adapted, 8 Hz flicker response (R8) was measured.

**MATERIALS AND METHODS**

**Animals**

All studies adhered to the Association for Research in Vision and Ophthalmology Statement for the Use of Animals in Ophthalmic and Vision Research, and were approved by Children’s Hospital Boston Animal Care and Use Committee. Institutional Animal Care and Use Committee (IAACUC) protocol number 10-08-1770R. Male db/db mice and nondiabetic heterozygous littermate controls (BKS.Cg-Dock7 <sup>-/−</sup> Lepr<sup>ob</sup>/J, stock number 000642) we from The Jackson Laboratories (Bar Harbor, ME, USA).

**Omega-3, ω-6PUFAs diet and control chow**

Mice were fed for 4 weeks to 26 weeks with defined rodent diets. These calorically matched rodent diets contained either 2% ω-3PUFAs (DHA and EPA) for the treatment group or 2% ω-6PUFAs (arachidonic acid) for the control group. Dietary PUFAs were produced by DSM Nutritional Products ( Parsippany, NJ, USA) under the trade name ROPUFA. The arachidonic acid and DHA supplements, under the trade names ARASCO and DHASCO, respectively, were obtained from Martek Biosciences Corp. (Columbia, MD, USA). Standard rodent chow (‘normal feed’) from Purina (Framingham, MA, USA) was used as a control diet in db/+ control mice for all retinal electrophysiology experiments.

**Blood glucose measurements and glucose tolerance test**

Body weight and fasting baseline blood glucose levels (Accu-Chek, Roche, Indianapolis, IN, USA) of the mice were recorded. Glucose tolerance tests (age 7 weeks) consisted of blood glucose measurement, then injection of 1 ml 10%D-glucose intraperitoneally, followed by blood glucose measurements at 30, 60 and 240 min.

**Electroretinography**

Retinal function was assessed at 9, 14 and 26 weeks by full-field electroretinography (ERG) in db/db mice fed ω-3- or ω-6PUFA chows, and in heterozygous mice on normal chow. The stimuli were 'green' light-flickering 8 Hz in the presence of an amber background that suppressed the saturating rod photoresponse by 

\[ P_3(i) = \frac{1}{2} \left[ 1 - \exp \left( -\frac{1}{2} \right) \right] \] 

for \( t_2 < t < 15 \) ms.

In this model, \( i \) is the intensity of the flash (cd s m<sup>−2</sup>), \( t \) is elapsed time (s), \( Rm_{P3} \) (\( \mu \)V) is proportional to the magnitude of the dark current, \( S(\cd s m^{-2} m^{-2}) \) summarizes the kinetics of phototransduction and \( t_{b} \) is a brief delay (s).

The postreceptor response, \( P_2 \), mostly from bipolar cells,22,23 was obtained by digitally subtracting \( P_1 \) (equation (1)) from the intact ERG. The response versus intensity relationship of \( P_2 \) was fit to the Naka-Rushton equation,

\[ P_2(i) = \frac{P_{R2}}{1 + \left( \frac{i}{k_{R2}} \right)^{1/2}} \] 

wherein \( P_{R2} \) is the amplitude (\( \mu \)V) of the response to a stimulus of 1 intensity, \( Rm_{P2} \) (\( \mu \)V) is the saturating bipolar response and \( k_2 \) is the intensity that elicits a half-maximum \( P_2 \). \( P_2 \) and \( S \) are suprathreshold measures of sensitivity. However, \( P_2 \) increases in linear proportion to stimulus intensity over a narrow range of dim flash intensities,25 and thus the sensitivity of \( P_2 \) at threshold was defined in this range26 by scaling the amplitude of each \( P_2 \) by the intensity used to elicit it and fitting

\[ S(i) = \frac{i^{-1}}{i^{-1} + \Phi_{1/2}} \]
compositionally matched diets, except for 2% enrichment in either ω-3 or ω-6PUFAs. These rigorously defined diets are identical, except for fatty acids: 1% docosahexanoic acid and 1% eicosapentaenoic acid for ω-3PUFAs or 2% arachidonic acid for ω-6PUFAs. Undefined and variable ‘standard rodent chow’ varies in its composition from batch to batch, depending on which oils happen to be available to the manufacturer at the time of feed production. For this reason, standard chow was only given to wild-type control mice as a reference.

Nondiabetic heterozygote controls were maintained on normal chow to assess baseline retinal function in healthy individuals. We performed ERGs on db/db and control mice throughout the progression of disease at 9, 14 and 26 weeks, and found that, in contrast to ω-6PUFAs, ω-3PUFAs significantly preserved retinal function to levels akin to wild-type control mice receiving standard chow (Figure 1a–d). With ω-6PUFAs, we observed a protracted loss in retinal function by 26 weeks of life compared to levels akin to wild-type control mice receiving standard chow (Figure 1a–d). With ω-3PUFAs significantly preserved retinal function to levels akin to wild-type control mice receiving standard chow (Figure 1a–d).

In contrast to ω-6PUFA-enriched diets, ω-3PUFAs-rich diets showed no degeneration; db/db mice fed ω-6PUFA-rich diets showed a severe decline (~1 log unit) in cone-pathway function at age 26 weeks. Retinal sensitivity at threshold (Sm) derived from P2 was plotted (again as in b). Sm was somewhat low in all db/db mice, but was preserved by ω-3PUFAs. In contrast, ω-6-fed db/db mice suffered a profound loss of sensitivity (~1.2 log units).

Figure 1. Omega-3 PUFAs preserve retinal function in db/db mice. ERG assessment of db/db mice at 9, 14 and 26 weeks of age indicated that ω-3PUFAs preserve retinal function. (a) Selected from a dark-adapted ERG intensity series spanning a 2^10 range of stimuli, averaged responses (lines) and one s.d. (fills) of 26-week-old mice maintained on ω-6- and ω-3PUFA-rich diets are shown; both increments are 2^8 after correcting for the retina’s 50% lower sensitivity to the ‘white’ stimulus. The dim flash (bottom) evoked a marked b-wave in the ω3PUFA-fed mice, but no detectable response in the ω6PUFA-fed mice. The moderate flash (middle) evoked a pronounced a-wave in both the ω-3- and ω-6PUFA-fed mice, but did not elicit a detectable post-receptor response (b-wave or OPs) in the ERG of the ω-6PUFA-fed mice. The bright flash (top) evoked a saturating a-wave in both the ω-3- and the ω-6PUFA-fed mice. In the former, the a-wave was large, the OPs were pronounced and the b-wave rose well above baseline; in the latter, the a-wave was smaller, and both the b-wave and the OPs were strikingly enervated. (b) Mean values of ERG parameters describing the saturating amplitude of responses originating in photoreceptors (RmR9), bipolar cells (RmR7 middle) and other postreceptor neurons (Em1/2) are plotted for the ω-3 and ω-6 db/db mice after normalizing by the values in age-matched heterozygotes on normal chow (grayed data). These parameters were significantly attenuated in ω6PUFA-fed, 26-week-old db/db mice. (c) The amplitude of the response to 8 Hz flicker isolated to the cone pathway by a rod-suppressing adapting background (R8) is plotted as in b. R8 was somewhat reduced in db/db mice fed ω-3PUFAs-rich diets, but did not degenerate; db/db mice fed ω-6PUFA-rich diets showed a severe decline (~1 log unit) in cone-pathway function at age 26 weeks. (d) Retinal sensitivity at threshold (Sm), derived from P2, is plotted (again as in b). Sm was somewhat low in all db/db mice, but was preserved by ω-3PUFAs. In contrast, ω-6-fed db/db mice suffered a profound loss of sensitivity (~1.2 log units).
Epidemiological studies show a lower incidence of T2DM in omega-3-rich diets enhance glucose homeostasis in heterozygotes did differ from one another. Suprathreshold sensitivity parameters (S, k2) did not differ between the omega-3 and omega-6PUFA db/db mice (data not shown). However, retinal sensitivity at threshold (S0, Figure 1d), which depends on the function of both the photoreceptors and bipolar cells, was low in the db/db mice (P < 0.0001), especially in those maintained on the omega-6PUFA diet. Again, post-hoc testing, and effects of age (P = 0.001) and age x group (P = 0.01) revealed that the loss in sensitivity in the omega-3PUFA-fed mice was significantly less than in the omega-6PUFA-fed mice.

These data indicate that omega-3PUFAs effectively preserve retinal function in T2DM. The average weight of omega-3- and omega-6PUFA-fed mice did not vary significantly in db/db mice or in control heterozygotes (Supplementary Figure 1), although the db/db and heterozygotes did differ from one another.

Omega-3 rich diets enhance glucose homeostasis in db/db mice. Epidemiological studies show a lower incidence of T2DM in individuals who consume higher levels of omega-3PUFAs, and omega-3PUFAs may enhance tolerance to systemic spikes in glucose. To evaluate the influence of omega-3PUFA-rich diets on glucose homeostasis, we first measured fasting baseline glycemia in db/db and heterozygous db/+ controls. Omega-3PUFA-fed mice persistently demonstrated lower blood glucose levels at 10 (P = 0.0087), 13 (P = 0.0203) and 16 (P = 0.0205) weeks; (Figure 2a).

Glucose tolerance tests on mice of 7 weeks of age showed improved glucose excretion from serum in omega-3-fed db/db mice (at 30 min) when compared with omega-6PUFA-fed mice (P = 0.0379) (Figure 2b). A similar benefit was noted in heterozygous control mice, with omega-3PUFA-rich diets significantly improving glucose tolerance compared with normal chow (P = 0.0025; Figure 2c). Thus, omega-3PUFA-fed T2DM mice responded more normally to spikes in glucose, suggesting that diets rich in omega-3PUFAs confer a protective systemic effect against the early manifestation of T2DM.

The protective effects of omega-3PUFA-rich diets on retinal function are independent of gross retinal cytoprotection. A primary manifestation of intermediate stage DR is the degeneration of microvascular capillaries. Similar densities of acellular capillaries were found in db/db mice on either diet (P = 0.1973; Figures 3a–c), suggesting that the observed preservation in ERGs is independent of any omega-3PUFA-mediated preservation of retinal vasculature integrity.

During progression of DR, there is specific loss of RGCs in humans and animal models. It is speculated that loss of RGCs may precede the vascular manifestation of the disease. We assessed if the heightened retinal function observed in omega-3-fed db/db mice was secondary to RGC neuroprotection. Equal numbers of RGCs are present in omega-3- and omega-6PUFA-fed mice (Figures 3d and e) in both central (P = 0.5538) and peripheral (P = 0.8599) zones of the retina (Figure 3f). In line, the expression of retinal beta-tubulin mRNA remains constant, confirming that RGC numbers are equivalent in mice receiving either diet (P = 0.6698; Figure 3g). Similarly, we did not detect any appreciable morphological differences in photoreceptors, or in the thickness of the outer nuclear layer (Figures 3h–j). Consistent with these observations, the mRNA levels of cone opsin (Figure 3k) or rhodopsin (Figure 3l) did not significantly vary between the feed groups, suggesting similar photoreceptor numbers between the feed groups. Taken together, these data suggest that the benefit in retinal function observed in omega-3PUFA-fed db/db mice precedes detectable anatomic changes in retinal vasculature and RGC integrity, and may be independent of the vasoprotective effects of omega-3PUFAs.

The protective effects of omega-3PUFA-rich diets on retinal function are independent of inflammatory modulation. Given the anti-inflammatory effects of omega-3PUFAs and the role of inflammation in DR, we determined the inflammatory status of the

Figure 2. Dietary omega-3PUFAs improve glucose tolerance in db/db mice. (a) Fasting baseline blood glucose levels measured in omega-3 and omega-6PUFA-fed db/db mice showed significantly lower blood glucose levels at 10, 13 and 16 weeks in omega-3PUFA-fed db/db mice (P < 0.05; **P < 0.01; n = 14 per group). Baseline glycemia did not vary between the two feed groups in control non-diabetic heterozygotes db/+ mice. (b) Glucose tolerance tests reveal omega-3PUFA-fed db/db mice to be significantly protected against glycemic spikes 30 min after glucose injection (P < 0.05; n = 5 per group). (c) A similar protective pattern by omega-3PUFA feed was noted in non-diabetic heterozygote control mice. (P < 0.05, **P < 0.01; n = 5 per group).
Figure 3. Lack of change in acellular capillary, retinal ganglion cell and photoreceptor densities in db/db mice on ω-3 or ω-6PUFA feeds. Representative images of retinal capillaries from ω-3- (a) or ω-6PUFA-fed (b) db/db mice at 26 weeks of age reveal no statistically significant change in the number of acellular capillaries (white arrows) as quantified in (c). Representative images of β-III tubulin-stained RGCs from the peripheral (d) and central regions (e) of retinas from ω-3- and ω-6PUFA-fed db/db mice at 26 weeks reveal no statistically significant change in total numbers between feed groups (f). (g) Real-time qPCR quantification of β-III tubulin from whole retinas of 26-week-old db/db mice (normalized to millions of copies of Cyclophilin A (cyclo) mRNA) confirm comparable numbers of RGCs in both feeds; n = 7 retinas for ω-3PUFA and n = 5 for ω-6PUFA group. Photoreceptor densities were unaffected by feeds. 4',6-diamidino-2-phenylindole (DAPI)-stained retinas from ω-3- (h) and ω-6-fed (i) db/db mice at 26 weeks of age revealed that photoreceptor densities were unaffected. Real-time qPCR quantification of cone opsin (j) and rhodopsin (k) mRNA.
retina in ω-3- and ω-6PUFA-fed db/db mice. At 26 weeks, corresponding to the time point of maximal measured discrepancy in ERG signal between ω-3- and ω-6PUFA-fed db/db mice, (Figure 1) all tested inflammatory cytokines, including IL-1β (P = 0.7484; Figure 4a), IL-6 (P = 0.6163; Figure 4c), tumor necrosis factor-α (P = 0.3456; Figure 4b), intercellular adhesion molecule-1 (P = 0.2976; Figure 4d) and the anti-inflammatory cytokine IL-10 (P = 0.4296; Figure 4e), showed similar retinal mRNA expression levels in animals receiving either ω-3- or ω-6PUFA-rich diets.

We next assessed the expression of key constituents of vascular barrier function. As with the profiles of inflammatory mediators, retinal mRNA levels of the tight-junction protein claudin-5 (P = 0.3501; Figure 4f) and plasmalemma vesicle-associated protein, an indicator of vessel permeability (P = 0.7220; Figure 4g), did not vary with feeds and neither did vascular endothelial growth factor (P = 0.8449; Figure 4h). Similarly, protein levels of the key inflammatory mediators did not vary with feed in the serum of ω-3- and ω-6-fed mice: IL-1β (P = 0.9046; Figure 5a), tumor necrosis factor-α (P = 0.7609; Figure 5b), IL-6 (P = 0.9362; Figure 5c) and IL-10 (P = 0.8857; Figure 5d). Moreover, systemic levels of VEGF remained unaffected by feed (P = 0.9576; Figure 5e), as did the levels of insulin (P = 0.2020; Figure 5f).

Taken together, our data suggest that the protective effects of ω-3PUFAs on retinal function in T2DM occur independently of inflammation, cell survival or barrier function, suggesting that ω-3-rich diets robustly protect neuronal function via a mechanism independent of or preceding macrocellular changes.

DISCUSSION

The clinical diagnosis of DR presently relies entirely on the detection of vascular lesions such as capillary degeneration, retinal edema and hemorrhages (in early stages), or neovascular
proliferation (in later stages). This has led to the general presumption that the disease is exclusively microvascular in nature and that effective treatments would have to either directly counter stressors to the endothelium or alleviate the burden of pro-angiogenic factors present in the vitreous. On the other hand, T2DM is also characterized by a general metabolic dysregulation and systemic dyslipidemia. By directly modulating dietary lipid consumption to favor \( \omega-3 \)PUFA intake, we efficiently stalled the deterioration of retinal visual function associated with DR before any vasoprotective effects, and independent of the anti-inflammatory properties of these lipids. This suggests that \( \omega-3 \)PUFAs have the capacity to protect cellular function in DR and thus delay the early events of diabetes-induced neuronal dysfunction in the retina. With a 2% change in fatty acid content (\( \omega-3 \) vs \( \omega-6 \)), there is a two-fold increase in retinal \( \omega-3 \) levels, and this is also reflected in erythrocyte composition. It is however important to note that the diabetic-like phenotype observed in \( db/db \) mice results secondarily to dyslipidemia and obesity, and therefore specific changes in lipid metabolism may differ from that observed in human type 2 diabetes. Hence, it is conceivable that lipid supplementation protocols could have beneficial effects in \( db/db \) mice that differ from human diabetic patients.

Although the mechanisms assuring the functional protection of the neural retina by \( \omega-3 \)PUFAs presently remain elusive, it is important to note that the observed benefits were accompanied by enhanced glucose tolerance in \( \omega-3 \)PUFA-fed mice. Neurons require a steady supply of glucose and thus cannot rely on glycolytic bursts nor depend on episodic insulin-driven glucose uptake. Consequently, neuronal glucose uptake is highly dependent on the insulin-unresponsive GLUT-1, and thus the extracellular concentrations of glucose. Persistent hyperglycemia in diabetes can result in sustained levels of neuronal glucose up to fourfold in healthy individuals and lead to glucose neurotoxicity. It is therefore tempting to speculate that the lower systemic glycemia and significantly improved ability to respond to glucose challenge in \( \omega-3 \)PUFA-fed animals may contribute, in part, to the protective effects of \( \omega-3 \)PUFAs on neuronal function. It is noteworthy that there is a loss of weight in \( \omega-6 \)PUFA-fed mice that commences after 12 weeks of life (Supplementary Figure 1), suggesting that animals on these diets thrive less than those on \( \omega-3 \)PUFA-rich diets.

Although we observed a beneficial effect of \( \omega-3 \)PUFA-rich diets on the preservation of retinal function in T2DM, our study has limitations. For example, retinal samples were collected and analyzed subsequent to the final ERG recordings at 26 weeks.

---

Figure 5. Systemic markers of inflammation in serum of \( db/db \) mice do not vary with \( \omega-3 \) or \( \omega-6 \)PUFA feeds. ELISA measurements performed on serum at 26 weeks; (a) IL-1\( \beta \), (b) tumor necrosis factor (TNF)-\( \alpha \), (c) IL-6 and (d) the anti-inflammatory cytokine IL-10 reveal no change in inflammatory profiles between feeds at this stage of the disease. Similarly, vascular endothelial growth factor (VEGF) levels (e) and insulin (f) do not vary with feed; \( n = 5 \) mice per group.
of age. It is therefore conceivable that a change in inflammatory profiles occurred at an earlier time point, but normalized by 26 weeks of age. Conversely, it is also possible that gross changes in retinal structure, such as capillary dropout and RGC loss, would be detected at later time points than those sampled. However, we carried out these analyses at a time corresponding to the greatest discrepancy in retinal function between our treatment groups. Although the functional protection afforded by the ω-3-rich diets did not show detectable cellular preservation, our study was not designed to account for discrepancies in cell–cell interaction nor for differences in retinal signaling.

Given that the current treatment modalities to counter DR are costly, invasive, and unproven for the long term, nutritional interventions have the potential to result in a significant improvement over existing approaches in that the proposed interventions have the potential to result in a significant reduction in retinal function, such as capillary dropout and RGC loss, by 26 weeks of age. Conversely, it is also possible that gross changes in retinal structure, such as capillary dropout and RGC loss, would be detected at later time points than those sampled. However, we carried out these analyses at a time corresponding to the greatest discrepancy in retinal function between our treatment groups. Although the functional protection afforded by the ω-3-rich diets did not show detectable cellular preservation, our study was not designed to account for discrepancies in cell–cell interaction nor for differences in retinal signaling.
