Synthesis and Evaluation of a Conjugate Vaccine Composed of \textit{Staphylococcus aureus} Poly-N-Acetyl-Glucosamine and Clumping Factor A

Tomás Maira-Litrán*, Leticia V. Bentancor*, Cagla Bozkurt-Guzel, Jennifer M. O’Malley, Colette Cywes-Bentley, Gerald B. Pier

Channing Laboratory, Department of Medicine, Brigham and Women’s Hospital, Harvard Medical School, Boston, Massachusetts, United States of America

Abstract

The increasing frequency, severity and antimicrobial resistance of \textit{Staphylococcus aureus} infections has made the development of immunotherapies against this pathogen more urgent than ever. Previous immunization attempts using monovalent antigens resulted in at best partial levels of protection against \textit{S. aureus} infection. We therefore reasoned that synthesizing a bivalent conjugate vaccine composed of two widely expressed antigens of \textit{S. aureus} would result in additive/synergetic activities by antibodies to each vaccine component and/or in increased strain coverage. For this we used reductive amination, to covalently link the \textit{S. aureus} antigens clumping factor A (Cifa) and deacetylated poly-N-β-(1–6)-acetyl-glucosamine (dPNAG). Mice immunized with 1, 5 or 10 μg of the dPNAG-CIFA conjugate responded in a dose-dependent manner with IgG to dPNAG and CIFA, whereas mice immunized with a mixture of CIFA and dPNAG developed significantly lower antibody titers to CIFA and no antibodies to PNAG. The dPNAG-CIFA vaccine was also highly immunogenic in rabbits, rhesus monkeys and a goat. Moreover, affinity-purified, antibodies to CIFA from dPNAG-CIFA immune serum blocked the binding of three \textit{S. aureus} strains to immobilized fibrinogen. In an opsonophagocytic assay (OPKA) goat antibodies to dPNAG-CIFA vaccine, in the presence of complement and polymorphonuclear cells, killed \textit{S. aureus} Newman and, to a lower extent, \textit{S. aureus} Newman ΔclfA. A PNAG-negative isogenic mutant was not killed. Moreover, PNAG antigen fully inhibited the killing of \textit{S. aureus} Newman by antisera to dPNAG-CIFA vaccine. Finally, mice passively vaccinated with goat antiserum to dPNAG-CIFA or dPNAG-diphtheria toxoid conjugate had comparable levels of reductions of bacteria in the blood 2 h after infection with three different \textit{S. aureus} strains as compared to mice given normal goat serum. In conclusion, CIFA is an immunogenic carrier protein that elicited anti-adhesive antibodies that fail to augment the OPK and protective activities of antibodies to the PNAG cell surface polysaccharide.

Introduction

\textit{Staphylococcus aureus} is a leading etiology of hospital-acquired infections worldwide. This versatile organism, including strains with a troublesome pattern of antibiotic resistance as accentuated by methicillin-resistant \textit{S. aureus} (MRSA), cause a wide spectrum of diseases that range from mild skin and soft tissue infections to more severe invasive ones such as endocarditis, blood and lower respiratory tract infections, septic arthritis, osteomyelitis or deep-seated abscesses among others [1,2]. With the emergence of these many difficult-to-treat strains the need to develop new antimicrobials and/or immunotherapeutic approaches to combat infections is more urgent than ever. \textit{S. aureus} elaborates a large collection of virulence factors including pore-forming toxins, superantigens, phagocytosis-evasion molecules and inhibitors of host immune effectors, as well as variably encoded and expressed microbial surface components recognizing adhesive matrix molecules (MSCRAMMs). Among these, a fair number have been tested individually as vaccine targets in preclinical studies using either active or passive immunization, including the capsular polysaccharides types 5 and 8 (CP5 and CP8), alpha-toxin (non-toxic derivative H35L), Panton-Valentine leukocidin (PVL), enterotoxins B, A, C1, nontoxic mutant toxic shock syndrome toxin 1 (TSST), lipoteichoic acid (LTA), and other virulence factors carrying the LPXTG motif needed for anchoring to the cell wall, such as fibronectin.
binding protein (FnBP), collagen binding protein (CnBP), clumping factor A (ClfA), and the iron surface determinant B protein (IsdB) [3]. Some vaccine antigens including CP5 and CP6 conjugate vaccines, the IsdB antigen, human polyclonal antibodies to ClfA and a humanized monoclonal antibody to LTA have reached phase III human trials. Despite promising results obtained in pre-clinical studies, all have failed to meet their defined endpoints in preventing S. aureus infection [3]. As a result of these disappointing outcomes with monovalent vaccine components, a shift towards use of polyvalent vaccines has garnered significant interest.

To assess if additive or synergistic protection could be engendered in a multivalent vaccine, we evaluated a conjugate vaccine composed of two highly conserved S. aureus surface antigens, poly-N-β-(1–6)-acetyl-glucosamine (PNAG) and ClfA by using the protection-inducing deacetylated glycoform of PNAG (dPNAG) [4] conjugated to ClfA as a vaccine candidate against S. aureus infections. Previous work carried out in our laboratory has already demonstrated the ability of a vaccine composed of dPNAG conjugated to the carrier protein diphtheria toxoid (dPNAG-DT) to induce high titers of opsonic and protective antibodies [4]. In addition to the potential additive/synergistic activity between antibodies to dPNAG and ClfA the synthesis of a bivalent dPNAG-ClfA vaccine is also aimed to potentially expand the coverage of a single-component vaccine to include S. aureus strains expressing only one of the vaccine components.

Specifically this study investigated the value of ClfA as a carrier protein for dPNAG, the functional activity and specificity of antibodies to the dPNAG-ClfA vaccine using anti-adhesive and opsonic killing assays, and protective efficacy in a mouse model of S. aureus bloodstream infection.

**Materials and Methods**

**Ethics Statement**

This study was carried out in strict accordance with the recommendations in the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health. All animal protocols were reviewed and approved by the Harvard Medical Area Standing Committee on Animals IACUC which has Animal Welfare Assurance of Compliance number A3431-01 on file with the Office of Laboratory Animal Welfare of the U.S. Public Health Service. During all animal experimentation procedures all efforts were made to minimize suffering.

Studies involving human subjects were approved by the Partners Health Care System Institutional Review Board (IRB). All subjects donating blood provided written informed consent to participate in the studies.

**Bacterial strains and growth conditions**

The strains used in this work (Table 1) were routinely grown to stationary phase in tryptic soy broth (TSB) supplemented with 1% glucose. When necessary, TSB as well as tryptic soy agar (TSA) were supplemented with ampicillin (100 μg/ml), tetracycline (10 μg/ml) or erythromycin (10 μg/ml).

**PCR detection of icaABCD and clfA genes in S. aureus strains**

Primers pairs icAI (5′-CCAGAAATTGATATTGATT-GAACAGAAGAC-3′)/icAI-R (5′-GATGGCCGACCTATCA- TAATCTAAAATGAA-3′) and clfA-F (5′-CGGAAAAATATC-GATTGGGCTGGCCIT-3′)/clfA-R (5′-GTATGAACGTAT-TGATGCTAAATACCCCA-3′) were used to amplify the entire icaABCD locus or the clfA gene, respectively, from genomic DNA extracted from the strains S. aureus Newman, 476 and MN8. The genomic DNA was isolated by using the Wizard genomic DNA purification kit (Promega) according to the manufacturer’s instructions.

**Purification of clumping factor A**

Recombinant clumping factor A (ClfA) protein, residues (221–559), containing an N-terminal extension of six histidine residues was expressed from the plasmid pCFH1 carried by E. coli XL-1 Blue and kindly provided by Dr Timothy Foster. E. coli was grown in LB supplemented with ampicillin in a 6-liter fermentor at 37°C until the optical density at 650 nm (OD650 nm) reached 1. The temperature was maintained at 37°C; isopropyl β-D-thiogalacto-

**Coupling of dPNAG to ClfA**

dPNAG was first dissolved in 5M HCl, neutralized with an equal volume of 5 M NaOH and dialyzed against 20 mM HEPES buffer plus 50 mM NaCl pH 8 and stored frozen at −20°C.

**Chemical analysis of dPNAG-ClfA conjugate vaccine**

The dPNAG-ClfA conjugate vaccine was analyzed for its content of polysaccharide using hexosamine assay described by Smith and Gillkerson [5] with N-acetylglucosamine as the standard
and for protein by the Bradford method [6] with bovine serum albumin (BSA) as the standard.

**Antiserum production**

Antisera to purified dPNAG-ClfA were raised in various animal hosts including two rabbits, two rhesus monkeys and a goat. Antibodies to dPNAG-ClfA were raised in New Zealand White rabbits by subcutaneous (SC) immunization with two 10 μg doses of conjugated polysaccharide emulsified for the first dose in complete Freund’s adjuvant and for the second dose in incomplete Freund’s adjuvant, followed 1 week later by three intravenous (IV) injections of antigen in saline spaced 3 days apart. Rabbits were bled every 2 weeks and sera tested by the enzyme-linked immunosorbent assay (ELISA). Immune sera to dPNAG-ClfA was also raised in two rhesus monkeys by SC vaccination with a single dose of 100 μg of dPNAG-ClfA vaccine in aluminum hydroxide gel adjuvant (Alhydrogel 1.3%, Brenntag Biosector). Finally, a goat was immunized with the dPNAG-ClfA conjugate vaccine following the protocol described earlier for rabbits but with doses of 50 μg per injection in Freund’s incomplete adjuvant. Serum samples used to compare the immunogenicity of the dPNAG-ClfA vaccine in rabbits, monkeys, and a goat were collected four weeks after the last immunization.

**Immunogenicity of dPNAG-ClfA vaccine in mice**

Groups of 10 mice (Swiss-Webster; female, 5–7 weeks of age) were immunized SC 3 times, 1 week apart, with 1, 5 or 10 μg of conjugated polysaccharide suspended in PBS. Blood was withdrawn weekly for a month and antibody titers to both dPNAG and ClfA determined by ELISA. Control groups received a mixture of unconjugated polysaccharide and protein in PBS in the same ratio as in the conjugate vaccine.

**ELISA**

dPNAG and ClfA-specific antibodies were measured in sera obtained from mice, rabbits, monkeys and a goat by ELISA as described previously [7]. Purified dPNAG and ClfA were used to sensitize the ELISA plates at a concentration of 0.3 or 10 μg/ml respectively in phosphate buffer, pH 7.4.

**Phagocyte-dependent killing assays**

Polymorphonuclear cells (PMNs) were prepared from fresh human blood collected from healthy adult volunteers as described earlier [4] under a protocol approved by the Institutional Review Board of Partner’s Healthcare System and the concentration adjusted to 2.5×10^7/ml in modified minimal essential medium (MEM)+1% BSA.

The complement source (1 ml of rabbit serum, Sigma) was adsorbed three times with *S. aureus* Newman at 4°C for 30 min in order to remove all non-specific antibodies present. After adsorption, the complement solution was centrifuged and filter sterilized.

The test sera for the OPK, goat antibodies to dPNAG-ClfA conjugate vaccine and normal goat sera (NGS), were first heated at 56°C for 30 min to inactivate endogenous complement activity and then absorbed three times at 4°C for 30 min with the PNAG-negative strain Newman Δica or the ΔclfA mutant DU5852 to remove antibodies not directed to the PNAG or ClfA antigens, respectively. The bacteria were then removed by centrifugation and the test sera filter sterilized.

Overnight cultures of the bacterial strains to be evaluated in OPKA were diluted 1:100 in fresh TSB+1% glucose, grown to an OD_650 nm of 0.4 (~3×10^8 colony forming units (CFU)/ml), and the final concentration adjusted to 4×10^6 CFU/ml in MEM-1% BSA for use in the killing assay.

The actual phagocytic killing assay was performed by mixing 100 μl (each) of the PMNs suspension, target bacteria, dilutions of test sera, and the complement source. The reaction mixture was incubated on a rotor rack at 37°C for 90 min; samples were taken at time zero and after 90 min. A 10-fold dilution was made in TSB with 0.05% Tween to prevent bacterial aggregation, and samples were plated onto TSA plates. Tubes lacking any serum and tubes with NGS were used as controls, as were tubes containing serum and complement but lacking PMNs to control for potential aggregation of bacteria by the antibody, which would reduce the apparent CFU counts at the end of the assay. At the concentrations of antisera used in the opsonic killing assay, there was no reduction in CFU of >10% in samples lacking phagocytes but containing antibody and complement, indicating little agglutinating activity of the antibodies raised to dPNAG-ClfA vaccine. The percentage of killing was calculated by determining the ratio of the number of CFU surviving in the tubes with bacteria, leukocytes, complement, and goat anti-dPNAG-ClfA sera to the number of CFU surviving in tubes with the same components but containing NGA.

For inhibition studies, goat antiserum raised to dPNAG-ClfA was diluted 1:10 and incubated for 90 min at 4°C with an equal volume of a solution containing 25 to 200 μg/ml of either purified dPNAG or ClfA. Subsequently, the antiserum was centrifuged,

Bivalent Vaccine for *S. aureus* Infections
and the supernatant was used in the opsonophagocytic assay as described above.

Murine bacteremia model

Groups of eight mice (FVB; female; 3–5 weeks of age) were immunized intraperitoneally (IP) with 0.4 ml of heat-inactivated (36°C for 30 min) immune goat sera raised to dPNAG-CIa, dPNAG-DT (dPNAG conjugated to diphtheria toxoid protein) vaccines, or NGS 40 and 24 h before infection. Mice were challenged IV with the S. aureus strains Newman (4.3 x 10^7 CFUs), MN8 (8.6 x 10^7 CFUs), 476 (6.7 x 10^7 CFUs), Newman ΔΔa (7.5 x 10^7 CFUs) or DU5852 (3.5 x 10^7 CFUs), as the doses indicated, in 0.2 ml of PBS. Two hours later mice were sacrificed and samples of 0.5 ml blood obtained from the heart, mixed with 20 µl of heparin (Sigma), and plated onto TSA plates. Bacteremia was quantified by colony counts after overnight growth and values expressed as CFU/ml of blood.

Preparation of affinity purified antibodies to CIa

Three grams of CNBr-activated Sepharose 4B gel (Pharmacia Biotech, Uppsala, Sweden) was suspended in 250 ml of 1 mM HCl for 30 min at 4°C, and then the gel was washed with alternating amounts of 750 ml of 1 mM HCl, 100 ml of distilled water, and 300 ml of reaction buffer containing 0.1 M NaHCO_3 and 0.5 M NaCl (pH 8.3). The gel was suspended in 10 ml of the reaction buffer (pH 8.3), incubated with 5 mg of CIa overnight at 4°C, and then the coupled gel was packed into a low-pressure column and washed with 250 ml of 1 M glycine in reaction buffer (pH 8.3) to block unused activation sites. Subsequently, the coupled gel was washed three times with alternating 200 ml amounts of borate buffer containing 0.1 M boric acid and 1 M NaCl (pH 8.5), 100 ml of distilled water, 200 ml of acetic acid buffer containing 0.1 M sodium acetate and 1 M NaCl (pH 4.0), and 100 ml of distilled water, and then was suspended in PBS.

Ten ml of rabbit antisera raised to dPNAG-CIa was passed through a CNBr-activated Sepharose 4B-packed affinity column that was immobilized with CIa. After intensive washing with PBS, the specific anti-CIa immunoglobulins, which bound to the beads were eluted with 0.1 M glycine-HCl, pH 2.7 buffer and collected into fractions that were immediately neutralized with 1 M Tris base buffer ammonium bicarbonate, pH 9 and monitored for their absorbance at OD_295 nm. Fractions containing affinity-purified rabbit antibodies specific to CIa were then pooled and quantified for protein content with the Bradford assay [6] using rabbit IgG as standard.

Adherence of S. aureus to immobilized fibrinogen

Adherence of S. aureus to fibrinogen (Fn) (Sigma) was assessed in 96-well polystyrene plates coated for with 400 ng/well of Fn for 1 h at 37°C. The S. aureus strains Newman, MN8, and the Newman ΔCl strain DU5852 were grown overnight on TSA plates, harvested by centrifugation, washed with PBS and resuspended in PBS to an OD_650 nm of 1.0. S. aureus cultures were then further concentrated 5 fold and pre-incubated with either rabbit antibody-purified antibodies to CIa or control non-immune polyclonal rabbit IgG at concentrations ranging from 0.3–300 µg/ml in PBS for 1 h at room temperature. After Fn-coated plates were incubated with the S. aureus strains for 1 h at room temperature, wells were washed three times with PBS and bound cells fixed with 200 µl of glutaraldehyde (2% v/v in PBS) for 1 h and stained with crystal violet (Sigma) 0.5% v/v for 5 minutes. Plates were rinsed with water, air-dried and the absorbance at 595 nm (OD_595 nm) determined using an ELISA plate reader (BioTek Instruments, Winoski, III).

Confocal laser scanning microscopy

Confocal laser scanning microscopy (CLSM) was used to evaluate the production of PNAG and CIa in three S. aureus strains, Newman, MN8 and 476. S. aureus strains were grown overnight at 37°C in TSB supplemented with 1% glucose, washed twice with PBS and blocked overnight with PBS 1% BSA and 10% normal rabbit sera (NRS). Cells were washed twice with PBS and a 10 µl aliquot of the cell suspension was air-dried onto a glass slide. Bacteria were fixed to the slide with methanol for 1 min at room temperature. At this point S. aureus samples were incubated for 2 h at room temperature with antibodies to PNAG (human monoclonal antibody (mAb) F598 conjugated to Alexa Fluor 488) and CIa (goat anti-human CIa-β-globulin coupled to Alexa Fluor 488) for 1 h at room temperature. At this point, the slides were washed twice with PBS and mounted with Mowiol mounting media and a glass coverslip and observed with a Zeiss LSM 5 Pascal confocal inverted microscope equipped with an Argon 488 nm laser and a HeNe 543 nm laser, and a HeNe 633 nm laser. Samples were viewed using a Plan Apochromat 63x/1.4 oil objective and data analyzed with Zeiss LSM Imaging software.

Statistical analysis

All statistical analyses were performed with Prism 4.0 (GraphPad Software, http://www.graphpad.com/). An unpaired t test was used to compare the IgG antibody titers generated against CIa between mice immunized with the conjugate dPNAG-CIa vaccine and the mixture of unconjugated dPNAG+CIa. One-way analysis of variance (ANOVA) was applied for comparisons of the opsonophagocytic killing among the isogenic S. aureus Newman strains and the protective efficacy of dPNAG-DT and dPNAG-CIa antibodies versus NGS in bacteremia studies followed by Tukey's post-hoc test. A P-value of <0.05 was considered significant.

Results

Synthesis of dPNAG-CIa conjugate vaccine

CIa and dPNAG were covalently linked via reductive amination in the presence of NaBH_4CN. Results presented in Figure 1 show that both CIa (OD_595 nm) and dPNAG (OD_550 nm) co-eluted in the void volume of the column (void volume: approximately 40 ml) and significantly earlier than the unconjugated dPNAG and CIa that eluted at approximately 100 and 110 ml, respectively, denoting the formation of a large MW dPNAG-CIa conjugate. To identify fractions containing dPNAG-CIa conjugate free of unconjugated CIa and/or dPNAG all fractions were analyzed by sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE) followed by silver staining. Fractions in the elution volume of 42–70 ml contained high MW dPNAG-CIa conjugate which did not enter the SDS-PAGE gel (no signal detected by silver staining) whereas the remaining fractions contained various levels of free dPNAG and/or CIa and were not included in the final conjugate vaccine pool (data not shown).
Pooled fractions containing the purified dPNAG-ClfA conjugate were dialyzed overnight against HEPES buffer pH 8 and analyzed for polysaccharide and protein content using the Gilkerson-Smith and Bradford assays, respectively. The dPNAG-ClfA conjugate vaccine contained 31% dPNAG and 69% ClfA.

**Immunogenicity of dPNAG-ClfA conjugate vaccine in various animal species**

Mice (n = 10) were immunized three times with 1, 5 or 10 μg of either the dPNAG-ClfA conjugate or a mix of comparable amounts of unconjugated dPNAG plus ClfA (dPNAG+ClfA) as a control. As seen in Fig. 2A mice vaccinated with the dPNAG-ClfA conjugate responded with IgG antibodies to dPNAG in a dose-dependent manner. No antibodies to dPNAG were detected in the mice receiving the unconjugated dPNAG and ClfA mixture (Titer below level of detection of 25) (Fig. 2A). Similarly, mice vaccinated with the dPNAG-ClfA conjugate developed dose-dependent antibody titers to ClfA while the animals given the dPNAG+ClfA mix responded with significantly lower antibodies to ClfA (Antibody titers to ClfA in dPNAG-ClfA conjugate versus dPNAG+ClfA mixture ***P<0.0001 unpaired t test in all three doses and time points post-immunization except for mice

Size exclusion chromatography profile of dPNAG conjugated to ClfA through a Superose 6 gel column.** Fractions were assayed for polysaccharide by the hexosamine assay (OD_{650} nm) and for protein with the Bradford assay (OD_{595} nm). Double-headed arrows indicate the fractions containing conjugated dPNAG and ClfA, as well as where the unconjugated polysaccharide (dPNAG) and protein (ClfA) eluted. doi:10.1371/journal.pone.0043813.g001

**Figure 2. Immunogenicity of dPNAG-ClfA vaccine in mice.** Mean titers of IgG antibodies to PNAG and ClfA in sera from mice (n = 10) immunized three times at weekly intervals with 1, 5 or 10 μg of dPNAG–ClfA conjugate vaccine or dPNAG mixed with ClfA (dPNAG+ClfA). Sera were collected weekly for 4 weeks starting 1 week after the last immunization and were tested by ELISA for antibodies to dPNAG and ClfA. A) IgG antibody levels to dPNAG in sera of mice vaccinated with dPNAG–ClfA conjugate vaccine or a mixture of unconjugated dPNAG+ClfA. Horizontal line depicts the limit of detection (titer = 25). For clarity, titers from mice receiving the mixture dPNAG+ClfA, which were below the limit of detection, were assigned a value of the limit of detection. B) IgG antibody titers to ClfA in sera of mice given the dPNAG–ClfA conjugate vaccine or control dPNAG+ClfA. Bars represent means and error bars indicate standard deviations. P as determined by unpaired t test. * P<0.05, ** P<0.005 and *** P<0.0001. All pre-immune titers were <25. doi:10.1371/journal.pone.0043813.g002
immunized with 1 μg at week 2 and 3 post immunization that were \( P<0.05 \) and \( P<0.005 \), respectively (Fig. 2B).

The immunogenicity of dPNAG-ClfA was also evaluated in two rabbits, two rhesus monkeys and a goat. As shown in Table 2 the dPNAG-ClfA vaccine was highly immunogenic in all three of these animal species, eliciting high antibody titers to both dPNAG and ClfA antigens. Interestingly there were differences in the levels and the relative response to each vaccine component among the three animal hosts. These differences might be explained in terms of doses, immunization regimes and/or host-specific differences among the various animal hosts.

Table 2. IgG titers to dPNAG and ClfA in various animal host species including two rabbits, two rhesus monkeys and a goat vaccinated with dPNAG–ClfA.

Inhibition of \( S. aureus \) binding to fibrinogen by antibodies to ClfA

Affinity purified antibodies specific to ClfA or control rabbit IgG were incubated at concentrations ranging from 0.8 to 500 μg/ml with \( S. aureus \) bacteria which were then added to Fn-coated microtiter plates. Bacterial binding was detected by crystal violet staining and quantification at OD595 nm. As shown in Figure 4 affinity-purified antibodies to ClfA were highly effective at blocking the binding of the three \( S. aureus \) strains Newman, MN8 and 476 to immobilized Fn in a dose-dependent manner. In addition, there was no detectable binding of the ClfA-negative strain \( S. aureus \) DU5852 to immobilized Fn (data not shown).

Phagocyte-dependent killing by goat antibodies to the dPNAG-ClfA conjugate vaccine

As shown in Figure 5A, antisera to dPNAG-ClfA at a 1:10 dilution promoted the killing of wild type \( S. aureus \) Newman (54% killing) but there was no killing of the PNAG-negative strain Newman Δica (5.4% killing) (Killing of \( S. aureus \) Newman versus Δica; \( P<0.001 \), one-way ANOVA). This antiserum also killed the ClfA-negative mutant DU5852 but to a lower extent (35% killing) (Killing of \( S. aureus \) Newman versus DU5852; \( P<0.01 \), one-way ANOVA). This reduction in susceptibility of the ClfA-negative
strain DU5852 in comparison to wild type *S. aureus* Newman is most likely attributable to the variation in PNAG retention on the bacterial cell surface when other factors are changed, as retention is often due to post-synthetic effects such as that of the extracellular IcaB deacetylase [8,9]. Based on our previous experience in testing mAbs and polyclonal sera to dPNAG in the OPKA we found that opsonic killing levels >30% identify antisera with *in vivo* protective activity [4,10].

To ascertain the specificity of the OPKA, purified dPNAG or ClfA were added to diluted antisera then tested for killing activity. Purified dPNAG inhibited the OPKA of goat antisera to dPNAG-ClfA conjugate, with inhibition titering out in a dose-dependent manner (Fig. 5B). ClfA failed to inhibit the opsonic killing of *S. aureus* Newman by antibodies elicited by the dPNAG-ClfA conjugate at all concentrations tested, indicating that the OPKA measured here was all due to antibody to PNAG.

**Protective efficacy of goat antiserum to the dPNAG-ClfA conjugate vaccine in a murine bacteremia model**

We evaluated the ability of goat antisera to the dPNAG-ClfA conjugate vaccine along with goat antisera raised to a conjugate of dPNAG and diphteria toxoid (dPNAG-DT) that had comparable antibody titers to PNAG, to reduce bacterial levels in the blood of mice 2 h after IV injection. As shown in Figure 6, mice injected with antibodies to the dPNAG-ClfA conjugate vaccine had a significant reduction in blood CFU levels of *S. aureus* Newman 2 h post infection in comparison to animals given control NGS. A comparable reduction in the blood levels of *S. aureus* Newman was achieved with the antiserum to the dPNAG-DT conjugate vaccine, suggesting there was an immeasurable contribution of the antibodies to ClfA to the protective efficacy of the antibodies to the dPNAG-ClfA vaccine. Comparable results were also seen with the *S. aureus* strains MN8 and 476 (Fig. 6).

When similar protection studies were carried out with *S. aureus* DU5852 which does not elaborate ClfA, mice immunized with dPNAG-DT or dPNAG-ClfA had significantly and comparable lower bacterial blood levels than animals given non-immune NGS (dPNAG-DT and dPNAG-ClfA vs NGS, P<0.01). On the other hand mice that had been passively immunized with antisera raised to the dPNAG-DT vaccine then infected with the PNAG-deficient strain Newman Δica had no significant changes in blood CFU levels in comparison to the control NGS (dPNAG-DT vs NGS; ns). However, mice infected with the Δica strain after passive immunization with antibodies raised to the dPNAG-ClfA vaccine exhibited significant bacterial blood clearance in comparison to the NGS-immunized group (dPNAG-ClfA vs NGS, P<0.01). These findings indicate that in the presence of the PNAG antigen, antibodies to ClfA are not effective at mediating protection from bacteremia. However in the absence of PNAG, the ClfA antigen could be either significantly more expressed or exposed on the surface of bacteria, allowing the antibody to ClfA to be protective in the bacteremia model of infection. Presumably this is by a non-OPK mechanism as antibody to ClfA does not appear to have significant opsonic activity against wild type or Δica *S. aureus* strains.

**Discussion**

In this work we report the synthesis of a conjugate vaccine covalently linking two *S. aureus* surface components, ClfA and the
The deacetylated derivative of PNAG, and showed that immunization of mice with this conjugate vaccine dramatically enhanced the immunogenicity of both components of the vaccine.

The increased immunogenicity of ClfA in dPNAG–ClfA-vaccinated mice in comparison to animals receiving dPNAG plus ClfA may be explained in part by the likely enhanced immunogenicity of the high molecular weight, highly cross-linked, three-dimensional structure of the dPNAG–ClfA conjugate in comparison to the mixture of unconjugated ClfA and dPNAG.

On the other hand, the lack of immunogenicity of unconjugated dPNAG in mice immunized with 1, 5 or 10 µg doses of a mixture of dPNAG–ClfA was not entirely surprising. Previous studies carried out in our laboratory have demonstrated that mice immunized with 100 µg doses of the fully acetylated PNAG, which was used to prepare the dPNAG for the present study, failed to elicit a detectable IgG response [7].

The dPNAG–ClfA vaccine was also highly immunogenic in multiple animal species including rabbits, rhesus monkeys and a goat wherein vaccination elicited high antibody titers to both dPNAG and ClfA. Although the total number of animals immunized was limited to two rabbits, two monkeys and a goat we found relative differences in antibody responses to dPNAG and ClfA among the different animal hosts. These could relate to differences in vaccine dosage (10, 50 and 100 µg doses for rabbits, goat and monkeys respectively), immunization protocol (2 SC injections followed by 3 IV doses in rabbits and goat versus one single SC dose for the monkeys), type of adjuvant (Freund’s incomplete for rabbits and the goat or alum for monkeys), used and/or to host-specific responses.

The goat antiserum was found to mediate opsonic killing of S. aureus that was specific to the dPNAG antigen. In addition, we found that affinity-purified antibodies to ClfA inhibited the adherence of three S. aureus strains to immobilized Fn in vitro. However, antibody to ClfA had negligible opsonic activity against S. aureus Newman and did not augment the protective efficacy of

**Figure 6. Protective efficacy of dPNAG–ClfA vaccine in a murine bloodstream infection model.** Comparative protective efficacy elicited by goat immune sera raised to dPNAG–ClfA and dPNAG-DT conjugate versus NGS against S. aureus strains Newman, MN8, 476, Newman Δica, or DU5852 in a murine bacteremia model. Groups of eight FVB mice were immunized IP with 0.4 ml of heat-inactivated antisera raised to dPNAG-DT, dPNAG–ClfA vaccines or with control NGS, 48 and 24 h before IV challenge with the S. aureus strains Newman (4.3×10⁵ CFUs), MN8 (8.6×10⁵ CFUs), 476 (6.7×10⁶ CFUs), Newman Δica (7.5×10⁵ CFUs), or DU5852 (3.5×10⁷ CFUs), sacrificed 2 h post infection and the number of CFU/ml of blood estimated by serial dilutions and plating. Bars indicate the mean CFU per ml of blood, error bars the SEM. P values as determined by one-way ANOVA with Tukey’s post-hoc analysis. (ns: not significant).

dPNAG-specific sera in a murine model of bacteremia against three PNAG- and ClfA-positive strains of *S. aureus*.

Previous reports have demonstrated that the use of single vaccine antigens such as CP or ClfA resulted in protection of animals against *S. aureus* infections [11–14] but single component vaccines have failed in all human trials to date [3]. We therefore reasoned that the combination of PNAG and ClfA in the form of a bivalent dPNAG-ClfA conjugate vaccine might be required to confer full protection against *S. aureus* infection and/or to broaden the vaccine coverage to include *S. aureus* strains which do not fabricate either PNAG or ClfA. Moreover since *S. aureus* capsular polysaccharide have been shown to mask clumping factor A-mediated adherence of *S. aureus* to fibrinogen and platelets [15] then the addition of PNAG to ClfA-based vaccines might be advantageous.

The evidence presented in this work is in full agreement with previous reports showing that either polyclonal or monoclonal antibodies against ClfA inhibit the binding of *S. aureus* to immobilized fibrinogen in vitro [11,16,17], thought to be one correlate of protective efficacy. However, the sera raised to the dPNAG-ClfA conjugate was no better than antibodies raised to dPNAG conjugated to DT at reducing blood levels of *S. aureus* following IV challenge with three strains. These findings are consistent with a previous report showing that passive immunization of mice with affinity-purified ClfA specific antibodies could not prolong the survival in a sepsis model after receiving an intravenous lethal challenge of *S. aureus* N315 or *S. aureus* MW2 [18].

In conclusion the conjugation of dPNAG to ClfA, enhanced the immunogenicity of each component of the vaccine and elicited functional anti-adhesive and opsonic/protective antibodies specific to ClfA and dPNAG, respectively. However the lack of opsonic activity of antibodies to ClfA against wild type *S. aureus* Newman combined with their negligible protective efficacy against wild type *S. aureus* strains expressing PNAG suggests no major role for immunity to ClfA in *S. aureus* bacteremia. While levels of the PNAG-defective mutant of *S. aureus* Newman were reduced in the blood of mice passively administered the antibody to dPNAG-ClfA, this situation is not representative of human infections which occur almost exclusively with PNAG-producing *S. aureus*. Antibody to ClfA might be useful in other settings of *S. aureus* infections but incorporation of this bacterial component into a vaccine is made difficult by the poor availability of the antigen to antibodies when surface capsules, including both CP5 or CP6 and PNAG are made [15]. Coupled with the failure of the clinical trial using ClfA-enriched human immune globulins for prevention of *S. aureus* infections in neonates it appears that validating use of either passive antibody to this antigen or inclusion of ClfA in a vaccine will require better definition of where, when and how immunity to ClfA could augment human resistance to *S. aureus* infection.
