Lysosomes are ubiquitous intracellular organelles that have an acidic internal pH, and play crucial roles in cellular clearance. Numerous functions depend on normal lysosomes, including the turnover of cellular constituents, cholesterol homeostasis, downregulation of surface receptors, inactivation of pathogenic organisms, repair of the plasma membrane and bone remodeling. Lysosomal storage disorders (LSDs) are characterized by progressive accumulation of undigested macromolecules within the cell due to lysosomal dysfunction. As a consequence, many tissues and organ systems are affected, including brain, viscera, bone and cartilage. The progressive nature of phenotype development is one of the hallmarks of LSDs. In recent years biochemical and cell biology studies of LSDs have revealed an ample spectrum of abnormalities in a variety of cellular functions. These include defects in signaling pathways, calcium homeostasis, lipid biosynthesis and degradation and intracellular trafficking. Lysosomes also play a fundamental role in the autophagic pathway by fusing with autophagosomes and digesting their content. Considering the highly integrated function of lysosomes and autophagosomes, it was reasonable to expect that lysosomal storage in LSDs would have an impact upon autophagy. The goal of this review is to provide readers with an overview of recent findings that have been obtained through analysis of the autophagic pathway in several types of LSDs, supporting the idea that LSDs could be seen primarily as “autophagy disorders.”

Introduction

Lysosomes are ubiquitous intracellular organelles that have an acidic internal pH, and have crucial roles in cellular clearance. Numerous functions have been shown to depend on normal lysosomes, including turnover of cellular constituents, cholesterol homeostasis, downregulation of surface receptors, inactivation of pathogenic organisms, repair of the plasma membrane and bone remodeling. Lysosomal biogenesis involves maturation of early endosomes to form multivesicular bodies (i.e., late endosomes), remodeling. Lysosomal biogenesis involves maturation of early endosomes to form multivesicular bodies (i.e., late endosomes), remodeling. Lysosomal storage disorders (LSDs) are characterized by progressive accumulation of undigested macromolecules within the cell due to lysosomal dysfunction. As a consequence, many tissues and organ systems are affected, including brain, viscera, bone and cartilage. The progressive nature of phenotype development is one of the hallmarks of LSDs.
in most storage disorders appear to develop and function normally, and only later is this followed by insidious disease onset and progression. In recent years biochemical and cell biology studies of LSDs have revealed an ample spectrum of abnormalities in a variety of cellular functions. These include defects in signaling pathways, calcium homeostasis, lipid biosynthesis and degradation and intracellular trafficking (see ref. 6 for a review). Therefore, an emerging view to explain the disease cascade is one focused on the importance of the multiple endosomal and autophagosomal processes flowing into the lysosomal system for processing. Failure to degrade and recycle sequestered materials in lysosomal disease may also lead to deficiency states in which precursors for metabolic pathways in the cell are diminished, followed by altered synthetic pathways and an increased metabolic demand on affected cells. The lysosomal system has thus emerged from being considered only an end-organelle, to being at the very hub of metabolic regulatory control. Perhaps the best example of the interconnection of the lysosome with other cellular systems is autophagy. Lysosomes play a fundamental role in the autophagic pathway by fusing with autophagosomes and digesting their content. Recent evidence of the cooperative and integrated roles of lysosomes and autophagosomes comes from the discovery of an overarching regulatory gene network (CLEAR) and a master gene, transcription factor EB (TFEB), controlling the biogenesis and function of both lysosomes and autophagosomes. Considering the highly integrated function of lysosomes and autophagosomes it was reasonable to expect that lysosomal storage in LSDs would have an impact upon autophagy. The goal of the present review is to provide readers with an overview of recent findings that have been obtained through analysis of the autophagic pathway in several types of LSDs. The main results of the studies on autophagy in LSDs are reported in Table 1.

### Autophagy in Glycogen Storage Type II (Pompe Disease) and Danon Disease

**Pompe disease.** Pompe disease was the first recognized lysosomal storage disorder. The disease is caused by deficiency of acid maltase, also known as acid α-glucosidase (GAA). Clinical heterogeneity of the disease is a well-established phenomenon. In the most serious infantile form, the disease leads to profound weakness, heart failure, and if left untreated causes death within one year. Even in milder late-onset form the illness is relentless and debilitating; patients eventually become confined to a wheelchair or a bed and many die prematurely from respiratory failure.

It took more than 30 y to define the cause of Pompe disease after its discovery in 1932, and even longer to develop a therapy. Only recently, enzyme replacement therapy (ERT) using recombinant human acid α-glucosidase designed to supplement the defective enzyme was approved for all forms of the disease. This therapy stemmed from a straightforward hypothesis to explain the disease pathogenesis, namely that progressive enlargement of glycogen-filled lysosomes would lead to lysosomal rupture and to release of glycogen and toxic substances into the cytosol. The assumption was that early treatment, initiated before lysosomal integrity was compromised, would reverse this pathogenic cascade. Now, after years of preclinical and clinical experience with this therapy it has become clear that this assumption is only partially correct: while cardiac muscle responds very well to therapy, skeletal muscle does not. The poor muscle response to therapy led to the need to revisit the pathogenesis of the disease, with increased attention to an involvement of the autophagic pathway in disease pathogenesis.

**Danon Disease.** Danon disease is a multisystem disorder characterized by cardiac, skeletal, and neuromuscular involvement. Danon disease is caused by mutations in the gene for the sarcomeric protein LAMP2 (lysosome-associated membrane protein 2). Lysosomes are impaired in Pompe skeletal muscle. The components of the system, such as BECN1, GABARAP, ATG7 and LC3, are present in excess, but this excess is associated with functional deficiency of autophagy. The phenotypic defect in fast muscle of the GAA-KO mice appears to arise not from an induction of autophagy but rather from a block in autophagosomal turnover (a defect in autophagosome-lysosome fusion) in the diseased muscle. Autophagy substrates, such as p62/SQSTM1 and ubiquitinated proteins accumulate in the core of Pompe muscle fibers. The formation of ubiquitin-positive protein aggregates in the GAA-KO mice precedes the development of clinical symptoms and parallels the progression of the disease.

**Autophagic buildup poses a significant problem for the lysosomal delivery of the therapeutic enzyme.** The enzyme traffics to its destination, lysosomes, via mannose-6-phosphate receptor-mediated endocytosis. Autophagic and endocytic pathways converge at several steps along the way; autophagosomes fuse not only with lysosomes but also with late and even early endosomes. Therefore, it is perhaps not surprising that the recombinant enzyme ends up in the area of autophagosome accumulation by electron microscopy in the diseased muscle. Autophagy substrates, such as p62/SQSTM1 and ubiquitinated proteins accumulate in the core of Pompe muscle fibers. The formation of ubiquitin-positive protein aggregates in the GAA-KO mice precedes the development of clinical symptoms and parallels the progression of the disease. Thus, the removal of autophagic buildup seemed a reasonable approach to improve the therapy.

Indeed, ERT in muscle-specific Atg5- or Atg7-deficient Pompe mice results in near-complete glycogen clearance. This outcome observed in both young and older mice is never seen in Pompe mice in which autophagy is not tampered with. Of note, ERT plus suppression of autophagy converts Pompe mice into muscle-specific autophagy-deficient wild-type mice; the health of these mice is far better than the health of Pompe mice. The accumulation of dysfunctional mitochondria, mild atrophy and age-dependent decrease in

force have been reported in muscle-specific autophagy-deficient wild-type mice, but these abnormalities seem to be a reasonable price to pay for the reversal of pathology in Pompe disease. In humans, autophagic buildup is present in many muscle cells in late-onset patients (both juvenile and adults), thus making the observations in the mouse model relevant to the human study. Furthermore, in many fibers autophagic accumulation is the overwhelming (and in some fibers the only) pathology, because the lysosomes that lie outside the autophagic region appear essentially normal. In contrast, the role of autophagy in the pathogenesis of infantile Pompe disease is much less obvious. Unexpectedly, the autophagic component which is so prominent in late-onset cases is insignificant in infants whose biopsies were analyzed within days after birth. Instead, the major characteristic of these fibers is the presence of hugely expanded lysosomes without clear borders, a finding consistent with the hypothesis of lysosomal rupture as a cause of muscle destruction.

The difference between the relative contribution of the lysosomal and autophagic pathologies in untreated infants and adults presents a conundrum in Pompe disease. One thing appears to be clear: infants lacking the enzyme are born with already severely damaged muscle fibers filled with giant lysosomes with ruptured membranes and massive glycogen deposits. The lack of autophagic buildup in such infants suggests that the role of autophagy in muscle development is minimal, perhaps because of a constant supply of nutrients through the umbilical cord. This hypothesis is consistent with the data in mice showing a low level of autophagy throughout the embryonic period. Analysis of biopsies from infants receiving ERT shows that lysosomes shrink in some patients, but remarkably, autophagic buildup resembling that found in skeletal muscle from adults emerges. A long-term study and a larger number of samples are needed to evaluate the fate of autophagic buildup in ERT-treated infants.

Glycogen passage from the cytosol to lysosomes must involve some type of autophagic pathway since by definition autophagy is a process of transport and lysosomal degradation of any intracellular material. Early morphological data showing the presence of glycogen particles inside autophagic vacuoles in skeletal muscle, liver and heart of the newborn rats implied the involvement of macroautophagy. In contrast, the role of autophagy in the pathogenesis of infantile Pompe disease is much less obvious. Unexpectedly, the autophagic component which is so prominent in late-onset cases is insignificant in infants whose biopsies were analyzed within days after birth. Instead, the major characteristic of these fibers is the presence of hugely expanded lysosomes without clear borders, a finding consistent with the hypothesis of lysosomal rupture as a cause of muscle destruction.

macroautophagic pathway. However, it remains unclear how the remaining glycogen is transported to the lysosome. Yet another recent hypothesis suggests that the intracellular glycogen trafficking to lysosomes may proceed via a nonclassical LC3-independent autophagy mediated by glycogen-binding protein STBD1 (starch binding domain-containing protein 1), which anchors glycogen molecules to vesicular membranes.\(^5\)\(^1\)

Danon disease. Danon disease (also called “glycogen storage disease due to LAMP2 deficiency” or “lysosomal glycogen storage disease with normal acid maltase activity”) is a lysosomal glycogen storage disease due to LAMP2 (lysosomal-associated membrane protein 2) deficiency.\(^3\)\(^5\) The disease is inherited as an X-linked trait and is extremely rare. The disease phenotype is characterized by severe cardiomyopathy and variable skeletal muscle weakness often associated with mental retardation.

Danon disease was the first LSD in which an involvement of autophagy was reported.\(^3\)\(^2\) Accumulation of autophagic vacuoles is detected in several tissues, particularly the muscle, from a mouse model of the disease.\(^3\)\(^3\)

Autophagy in Mucopolysaccharidoses

Multiple sulfatase deficiency (MSD) and mucopolysaccharidosis type IIIA (MPS IIIA). The mucopolysaccharidoses (MPSs) are a group of lysosomal storage disorders caused by deficiency of enzymes catalyzing the degradation of glycosaminoglycans (GAGs), which are long, repeating chains of complex sugar molecules. When one of several enzymes is absent, a progressive buildup of GAGs occurs. Depending on the enzyme deficiency, catabolism of dermatan sulfate, heparan sulfate, keratan sulfate, chondroitin sulfate, or hyaluronan may be blocked, singly or in combination.\(^5\)\(^3\) Lysosomal accumulation of GAGs results in cell, tissue and organ dysfunction. There are 11 known enzyme deficiencies that give rise to 7 distinct MPSs. MPS III, also referred to as Sanfilippo syndrome, is caused by a deficiency of enzymes that are needed to break down heparan sulfate. MPS III is classified into four types (A, B, C and D), with each type caused by a deficiency of a different enzyme. MPSIIIA is due to deficiency of the heparan N-sulfatase enzyme, and is characterized by profound mental deterioration, hyperactivity, and relatively mild somatic manifestations.

Multiple sulfatase deficiency (MSD) is a rare but very severe disorder in which affected individuals present a complex multisystemic phenotype due to the impaired activity of all sulfatases. It is caused by mutations in the Sulfatase Modifying Factor 1 (SUMF1) gene, which is responsible for an essential
post-translational modification of all sulfatases.54,55 Lack of sulfatase activities in MSD patients leads to accumulation of sulfated lipids and mucopolysaccharides resulting in a clinical phenotype that combines the features of at least seven diseases, five of which are mucopolysaccharidoses.56 The sumf1 KO mouse model of MSD recapitulates most of the features of the human disease.57

As for other types of LSDs, the pathogenic mechanisms that lead from enzyme deficiency to cell death in MSD and MPS IIIA are not completely understood. An impairment of autophagy is postulated to play a major role in disease pathogenesis.14 LC3 immunofluorescence reveals a higher number of autophagosomes in several brain regions of mouse models of MSD and MPS IIIA compared with wild-type mice. A decreased colocalization of LAMP1 with the autophagosomal marker LC3 in MSD and MPS IIIA cells compared with wild-type cells in vitro suggests the possibility of impaired lysosome-autophagosome fusion. A defective autophagic flux was also demonstrated by the accumulation of autophagy substrates, such as polyubiquitinated proteins and dysfunctional mitochondria (Fig. 1B and C), both of which are significantly increased in tissues from MSD and MPS IIIA mice.58 In addition, MSD cells show a decreased ability to degrade exogenously expressed aggregate-prone proteins, such as expanded huntingtin and mutated α-synuclein, which are responsible for Huntington and Parkinson disease, respectively.14 Similarly, during skeletal development, chondrocytes from MSD mice suffer from a severe lysosomal storage defect and display a defective autophagosome digestion leading to a defect in energy metabolism and to cell death.14

Studies aimed at the identification of the mechanisms underlying the impairment of the fusion between lysosomes and autophagosomes in MSD and MPS IIIA point to abnormalities of membrane lipid composition and SNARE (Soluble NSF Attachment protein REceptor) protein distribution.15 In particular, a significant accumulation of cholesterol is found in the lysosomal membranes of both MSD and MPS IIIA cells. This is associated with a disorganization of the endolysosomal membrane and with disruption of “lipid rafts.” Interestingly, wild-type cells “loaded” with cholesterol in vitro mirror the fusion defects observed in LSD cells. Conversely, lowering cholesterol by the use of methyl β-cyclodextrin in MSD and MPS IIIA cells rescues normal lysosomal function. The SNARE proteins, which are key components of the cellular membrane fusion machinery, are found aberrantly sequestered within cholesterol-rich regions of LSD lysosomal membranes. This abnormal distribution appears to lock these proteins in complexes and to impair their function and recycling, thereby directly affecting lysosomal membrane fusion capacities.15

These studies provided evidence that a global lysosomal dysfunction leads to the impaired autophagy observed in the pathogenesis of MSD and MPS IIIA and possibly in other types of LSDs. A possible model for disease pathogenesis is depicted in Figure 2. According to this model, lysosomal accumulation of undegraded substrates results in impaired lysosome-autophagosome fusion and a block of the autophagic flux. This figure depicts a generalized mechanism that may apply to several LSDs, even though a reduced efficiency of autophagic degradation may not necessarily be due to impaired lysosomal fusion. The secondary accumulation of autophagic substrates, such as polyubiquitinated proteins and dysfunctional mitochondria, are a consequence of this block. This model places the emphasis on the secondary accumulation of autophagy substrates as a key determinant of cell death, rather than on the primary accumulation of lysosomal substrates.

Mucopolysaccharidosis type VI (MPS VI). Mucopolysaccharidosis VI (MPS VI), also known as Maroteaux-Lamy syndrome, is caused by deficiency of the lysosomal enzyme N-acetylgalactosamine-4-sulfatase (aryl sulfatase B, ARSB).59 ARSB hydrolyzes sulfate esters from GAGs, mainly dermatan sulfate (DS), and a deficiency of the enzyme prevents the sequential degradation of DS leading to its accumulation in various cells and tissues.59 Clinically, MPS VI is characterized by coarse faces, short stature, dysostosis multiplex, stiffness and functional impairment of joints, hepatosplenomegaly, cardiac valve anomalies and corneal clouding.59 No evidence of CNS involvement is evident in clinically severe MPS VI,60 although scattered neuronal storage is evident in animal models lacking ARSB activity.59 Studies using fibroblasts from MPS VI patients demonstrated that lysosomal storage in these cells results in impaired autophagy, accumulation of polyubiquitinated proteins and mitochondrial

---

**Figure 2. Model depicting disease pathogenesis in LSDs.**
Niemann-Pick type C disease (NPC). Niemann-Pick type C disease (NPC) is caused by mutations in the NPC1 gene, whose protein products are thought to act cooperatively in the efflux of cholesterol from late endosomes and lysosomes. NPC1 encodes a multipass transmembrane protein that contains a sterol-sensing domain, similar to that found in the regulators of cholesterol biosynthesis, HMG-CoA reductase, SCAP, and TMCO7. NPC2 is a soluble protein primarily localized to the late endosome/lysosome lumen, where it binds cholesterol and participates in the efflux of cholesterol from lipid bilayers, and then transferring it to another bilayer or to the NPC1 N-terminal domain. As a result of NPC1 or NPC2 deficiency, unesterified cholesterol derived from receptor-mediated endocytosis of low-density lipoprotein (LDL)-cholesterol accumulates widely in cells throughout the body. A broad array of glycosphingolipids accumulates as well, although it is uncertain whether this latter phenomenon is attributable to a direct role for NPC1-NPC2 in glycosphingolipid trafficking or is secondary to cholesterol accumulation.

A marked accumulation of autophagosomes occurs in the brains of NPC mice and in skin fibroblasts from NPC patients. This is attributable, in part, to the induction of autophagy through BECN1, as an autophagy activator protein saposin C. Fibroblasts from some patients deficient in saposin C, used to model neuronopathic Gaucher disease, exhibit punctate p62/SQSTM1 accumulations in neurons and astrocytes, and sequester undigested material in vesicles that were shown to involve the resident autophagic pathway. Mice homozygous for mutant V394L glucocerebrosidase and saposin C, used to model neuronopathic Gaucher disease, exhibit punctate p62/SQSTM1 accumulations in neurons and astrocytes, and sequester undigested material in vesicles that were shown to involve the resident autophagic pathway. These observations suggest that NPC1 deficiency leads to both an induction of autophagy and an impairment of autophagic flux, similar to the effects triggered by loading cells with glycosphingolipids. The impairment in degradation of autophagic substrates may contribute to several aspects of NPC neuropathology, including the accumulation of ubiquitinated proteins and the generation of reactive oxygen species.

Gaucher disease. As in NPC, models of Gaucher disease show both an induction of autophagy and an accumulation of autophagosomes and autophagic substrates. Gaucher disease is caused by mutations in either glucocerebrosidase, the lysosomal enzyme that degrades glucosylceramide and glucosylsphingosine, or its activator protein saposin C. Fibroblasts from some patients deficient in saposin C show increased autophagy induction. Mice homozygous for mutant V394L glucocerebrosidase and deficient in saposin C, used to model neuronopathic Gaucher disease, exhibit punctate p62/SQSTM1 accumulations in neurons and astrocytes, and sequester undigested material in vesicles within axons, consistent with an accumulation of autophagic substrates. These observations suggest that degradation of autolysosome cargo is deficient in Gaucher disease cells. Interestingly, an impairment of lysosomal protein degradation due to glucocerebrosidase haploinsufficiency was recently suggested to occur in carriers of the Gaucher disease mutation, leading to increased risk for Parkinson disease due to diminished α-synuclein degradation.

Fabry disease and GM1 gangliosidosis. Increased basal expression of the autophagosome marker LC3-II is observed in models of other sphingolipid disorders as well, including GM1-gangliosidosis and Fabry disease. GM1-gangliosidosis is an autosomal recessive lysosomal lipid storage disorder caused by mutations of the lysosomal β-galactosidase (β-gal) and results in the accumulation of galactosylceramide. Fabry disease is an X-linked disorder caused by mutations of the α-galactosidase (α-gal) gene, leading to impaired degradation of globotriaosylceramide, a lipid that accumulates in patients with Fabry disease.
of GM1 ganglioside. The disease phenotype is characterized by severe CNS dysfunction, visceral megaly and skeletal dysplasia. An increased number of autophagosomes, as detected by the LC3 marker, elevated BECN1 levels, and dysfunctional mitochondria are observed in brains from GM1 gangliosidosis mice.26 In Fabry disease, deficiency of the lysosomal enzyme α-galactosidase A leads to an accumulation of its substrate glycosphingolipids (Gb) throughout the body. Measurement of LC3 in cultured cells from Fabry patients reveals increased basal levels compared with wild type cells and a larger increase in response to starvation. Treatment of staved Fabry disease fibroblasts and lymphocytes with lysosomal protease inhibitors reveals a block in autophagic flux, demonstrating a more severe disruption of degradation through macroautophagy than that observed in other sphingolipidoses. Furthermore, increased staining of p62/SQSTM1 and ubiquitin in renal tissues and in cultured fibroblasts from Fabry patients further supports impairment of autophagic flux.26 For Fabry disease and other sphingolipid storage diseases, defining where and how the impairment of autophagic flux occurs, and establishing the extent to which alterations in macroautophagy contribute to the disease phenotype remain important research objectives.

**Autophagy in Mucolipidosis**

Mucolipidosis type IV. Mucolipidosis type IV (MLIV) is an autosomal recessive disorder characterized by acute psychomotor delays, achlorhydria and visual abnormalities including retinal degeneration, corneal clouding, optic atrophy and strabismus.81-83 Mucolipidosis type IV-galactosidase A (GB3) throughout the body. Measurement of LC3 in cultured cells from Fabry patients reveals increased basal levels compared with wild type cells and a larger increase in response to starvation. Treatment of staved Fabry disease fibroblasts and lymphocytes with lysosomal protease inhibitors reveals a block in autophagic flux, demonstrating a more severe disruption of degradation through macroautophagy than that observed in other sphingolipidoses. Furthermore, increased staining of p62/SQSTM1 and ubiquitin in renal tissues and in cultured fibroblasts from Fabry patients further supports impairment of autophagic flux.26 For Fabry disease and other sphingolipid storage diseases, defining where and how the impairment of autophagic flux occurs, and establishing the extent to which alterations in macroautophagy contribute to the disease phenotype remain important research objectives.

**Autophagy in Mucolipidosis**

Mucolipidosis type IV. Mucolipidosis type IV (MLIV) is an autosomal recessive disorder characterized by acute psychomotor delays, achlorhydria and visual abnormalities including retinal degeneration, corneal clouding, optic atrophy and strabismus.81-83 Lyosomal inclusions are found in most tissues in MLIV patients. The composition of the storage material is heterogeneous and includes lipids and mucopolysaccharides forming characteristic multilamellar lamellae, as well as soluble, granulated proteins.84-86 MLIV is caused by mutations in MCOLN1 (mcoln1, also known as TRPML1), an endolysosomal cation channel belonging to the transient receptor potential (TRP) superfamily of ion channels.87-91 Whole cell patch clamp, as well as recording of native endolysosomal membranes, have led to the conclusion that MCOLN1 functions as an inwardly (from lumen to cytoplasm) rectifying channel permeable to Ca2+, Na+, K+ and Fe3+ with Na+ and Fe3+ whose activity is potentiated by low pH.88-90

Although the cellular role of MCOLN1 is still under investigation, the current model suggests that this protein mediates Ca2+ influx from late endosomes/lysosomes and lysozymes are delayed compared with control cells.29 This leads to a dramatic accumulation of autophagosomes in the lysosomal MLIV cells as demonstrated by indirect immunofluorescence (Fig. 1D). LC3-II/LC3-I immunoblot and electron microscopy.91 Impairment of the autophagic pathway has detrimental consequences for the cell leading to inefficient degradation of protein aggregates and damaged organelles. In particular, accumulation of p62/SQSTM1 inclusions and abnormal mitochondrial morphology has been described in MLIV fibroblasts. Findings suggest that MCOLN1 has a key role in the regulation of autophagy. MCOLN1 interacts with HSPA8 (HSC70) and DNAJB1 (HSP40), two components of the chaperone-mediated autophagy (CMA) molecular machinery.92 MLIV fibroblasts show defective CMA and decreased levels of LAMP2A resulting in increased levels of oxidized proteins.93 Finally, MCOLN1 has the ability to form hetero-oligomers with the two other members of the mucolipin family, MCOLN2 and MCOLN3.94-96 Depletion of endogenous MCOLN3 or expression of a channel-dead dominant negative MCOLN3 mutant inhibits starvation-induced autophagy.94-96 Therefore, MCOLN1 might also play an indirect role in the initiation of autophagy.

Autophagy has also been shown to be defective in primary neurons cultured from a murine model of MLIV. The mcoln1-/- mouse provide an excellent phenotypic model of the human disease, and all of the hallmarks of MLIV are present in the mice with the exception of corneal clouding.97 At birth, the knockout animals display no obvious behavioral or morphological phenotypes when compared with wild-type littermates, but as they age they show progressive limb weakening, eventual limb paralysis, and death at approximately eight months. Analysis of the brain at 8 mo shows lyssosomal inclusions in multiple cell types, including neurons, astrocytes, oligodendrocytes, microglia and endothelial cells, with larger inclusions present in neurons. The MLIV inclusions are unusual in their combination of dense lamella and granular matrices, and they do not resemble those typically seen in the glycosphingolipidoses, the mucopolysaccharidoses, or most other types of lysosomal disease.98-100 Electron microscopy of primary cerebellar neurons from Mcoln1-deficient mouse embryos demonstrates significant membranous intracytoplasmic storage bodies, despite the lack of gross phenotype at birth.97 Evaluation of macroautophagy in neurons by LC3-II/LC3-I immunoblot shows increased levels of LC3-II, similar to what is seen in human MLIV fibroblasts. LC3-II clearance is also defective, as treatment of the mcoln1-/- neuronal cultures with protease inhibitors to stimulate autophagy does not result in increased LC3-II levels.97 Demonstration of defective autophagy in Mcoln1-deficient neurons suggests a possible mechanism underlying neurodegeneration, whereby increased protein aggregation and organelle damage lead to autophagic stress and eventual neuronal death.97 The MLIV mouse model provides an important tool for evaluating the complicated interplay between chaperone-mediated autophagy and macroautophagy and their role in neurodegeneration. Mucolipidosis type II and Mucolipidosis type III. Mucolipidosis type II (MLII) and Mucolipidosis type III (MLIII) are autosomal recessive diseases caused by deficiency of the
Autophagy in Neuronal Ceroid-Lipofuscinoses

The neuronal ceroid lipofuscinoses (NCLs) are the most common cause of neurodegeneration among children. These disorders typically manifest with blindness, seizures, progressive cognitive defects and motor failure. NCLs are both genetically and phenotypically heterogeneous. The juvenile onset NCL (JNCL), also known as Batten disease, is the most common form of NCL, and is due to mutations in the CLN3 gene. The congenital form of NCL is due to mutations in the cathepsin D gene (CTSD/CLN1). A significant increase in the number of autophagosomes is observed in patients affected by these two types of NCLs and in the murine models of these diseases.

In addition, accumulation of dysfunctional mitochondria and downregulation of the MTOR pathway, a sign of activation of autophagosome formation, are detected in JNCL due to mutations of the Clc3 gene.

Concluding Remarks

Autophagy has been analyzed in a variety of LSDs with different severities of the phenotype, different tissues involved, and different types of storage molecules. Table 1 shows the main findings obtained and Figure 1 displays some examples of the results obtained by these studies. In spite of all the above-mentioned differences among the diseases and samples analyzed, a common theme can be recognized (see also ref. 115 for a further review). In most cases there is an impairment of autophagic flux, causing a secondary accumulation of autophagy substrates such as polyubiquitinated proteins, p62/SQSTM1 and dysfunctional mitochondria, on one end, and an increase in factors involved in autophagosome formation, such as BECN1, as an attempt to compensate for the impaired autophagic flux, on the other. Accordingly, LSDs can be seen primarily as "autophagy disorders." Interestingly, a defect in autophagic lysosome formation, due to abnormal MTOR activation, is reported in several LSDs.

Impairment of autophagy and accumulation of autophagy substrates in LSDs suggest that at least some mechanisms underlying the LSD phenotype may be similar to other diseases in which defective autophagy has been observed. In particular, the potential importance of macroautophagy as a critical player in the formation of these aggregates was largely unappreciated prior to studies in which key autophagy regulatory proteins were conditionally knocked out in mouse models. Genetic ablation in the CNS of Agt6 and Agt7, each critical for the formation of autophagosomes in cells, was found to cause progressive neurological disease in mice accompanied the accumulation of protein aggregates and inclusion bodies, and by neuron death.

A further link between LSDs and neurodegenerative disorders comes from studies showing accumulation of phosphorylated-tau aggregates and neurofibrillary tangles, which are typically detected in patients with Alzheimer disease, in LSDs such as Niemann-Pick type C and several age-dependent protein aggregation neurodegenerative disorders are striking, and include the accumulation of phosphorylated tau and α-synuclein, and in some cases amyloid β. The recent identification of a defect of lysosomal acidification in a murine model of Alzheimer disease and of pathogenic lysosomal depletions in a mouse model of Parkinson disease further support a connection between lysosomal dysfunction and neurodegenerative diseases.

The acknowledged importance of autophagy in maintaining normal bulk protein recycling in these diseases has led to interest in whether pharmacological stimulation of autophagy could provide therapeutic benefit by delaying or preventing protein aggregate accumulations in disorders such as Huntington disease. Rapamycin was demonstrated to protect against neurodegeneration in a fly model of Huntington and to improve neuropathology in a mouse model of Huntington disease by enhancing autophagy-mediated clearance of huntingtin accumulation. Rapamycin was also shown to have a clearing effect on a variety of aggregate-prone proteins with polyglutamine or polyalanine expansions, leading to an improvement in cellular phenotype. These data suggest that enhancement of autophagy can be an effective approach to reduce toxic protein accumulation and cell death also in LSDs. Trehalose, a disaccharide present in many nonmammalian species, is an mTOR-independent autophagy activator, that has an anti-apoptotic effect.
in cultured neurons and accelerates the clearance of mutant huntingtin and α-synuclein. However, one should also take into consideration that the defect observed in most LSDs is not a dysfunction in the formation of autophagosomes, but a block in autophagic flux. Therefore, activation of autophagy in this scenario is not a sufficient condition for the alleviation of pathological conditions. It is possible that drugs aiming at reduced cholesterol in membranes, such as bezafibrate, could rescue the functional and morphological defects observed in LSDs. It is possible that drugs aiming at reduced cholesterol in membranes, such as bezafibrate, could rescue the functional and morphological defects observed in LSDs, as recently described for MPS IIH and GM1 gangliosidoses.13 This compound is toxic in vivo, but FDA approved cyclodextrins (e.g., hydroxypropyl-β-cyclodextrin in mice with NPC disease results in cholesterol and ganglioside storage reduction, normalization in the autophagy marker LC3-II and significantly increased survival, although similar studies in MPS IIH and GM1 gangliosidoses mice do not show similar benefits.23 Finally, a potentially attractive possibility would be to induce a global enhancement of both the lysosomal and autophagic pathways by acting on the master gene TFEB.12 Further studies are needed to explore the effects of modulators of autophagy, which operate at different steps of the autophagic flux, on the LSD phenotype in cell culture and in animal models. Hopefully, these studies will lead to the development of effective treatments for several LSDs.
