The IFT-A complex regulates Shh signaling through cilia structure and membrane protein trafficking. Gli2, Sufu, and Kif7 localized correctly to cilia tips, suggesting that these pathway components were trafficked by IFT-B. In contrast, the membrane proteins Arl13b, ACIII, and Smo failed to localize to primary cilia in the absence of IFT-A. We propose that the increased Shh activity seen in partial loss-of-function IFT-A mutants may be a result of decreased ciliary ACIII and that the loss of Shh activity in the absence of IFT-A is a result of severe disruptions of cilia structure and membrane protein trafficking.

Introduction

The Shh signaling pathway is critical for development of nearly every organ system in vertebrate embryos and has important roles in tumorigenesis (Ingham et al., 2011). Recent studies have shown that Hedgehog (Hh) signaling in vertebrates, unlike in Drosophila melanogaster, depends on the primary cilium, a microtubule-based organelle that projects from the surface of most interphase cells (Goetz and Anderson, 2010). Two evolutionarily conserved intraflagellar transport (IFT) protein complexes, IFT-A and IFT-B, are required to build and maintain cilia structure (Cole, 2003; Pedersen et al., 2006). IFT-B proteins and Kinesin-II are required for anterograde trafficking from the base to the tip of the cillum, whereas the IFT-A complex is believed to work with the cytoplasmic dynein-2 motor to control retrograde ciliary trafficking (Pedersen and Rosenbaum, 2008).

The relationship between Shh signaling and cilia is best understood in the patterning of cell types in the ventral half of the developing neural tube, where a gradient of Shh activity controls a set of five different neuronal cell types. Shh is first made in the notochord, which lies ventral to the developing neural tube, and different levels of Shh activity specify different neural cell types, with the highest level of Shh activity specifying the floor plate and V3 interneuron progenitors, whereas intermediate levels of Shh activity specify motor neurons (Briscoe, 2009). Two Gli transcription factors, Gli2 and Gli3, implement the responses to Shh, where the activator form of Gli2 is essential for specification of the most ventral cell types in the developing neural tube. We showed that mutations that inactivate mouse IFT-B proteins block ciliogenesis and prevent the specification of Shh-dependent ventral neural cell types (Huangfu et al., 2003). Subsequent studies showed that all the core Shh pathway proteins that mediate the response to ligand are enriched in cilia and change their ciliary localization in response...
to pathway activation, including the Shh receptor Patched, the membrane protein Smoothed, the Kinesin-4 family member Kif7, the negative regulator Sufu, and the Gli transcription factors (Goetz and Anderson, 2010).

The roles of IFT-A proteins in ciliogenesis appear to be more complex than those of IFT-B proteins. Biochemical studies have identified six evolutionarily conserved proteins in the IFT-A complex in both Chlamydomonas reinhardtii and mammalian cells, IFT122, IFT144, IFT139 (Ttc21b), IFT140, IFT121 (WDR35), IFT43, and IFT144 (WDR19) (Mukhopadhyay et al., 2010; Behal et al., 2012). A role for IFT-A in retrograde trafficking in cilia and flagella was first defined in the alga Chlamydomonas, where temperature-sensitive mutations in two Chlamydomonas IFT-A genes, fla15 (IFT144) and fla17 (IFT139), cause bulged flagella of normal length, associated with decreased rates of retrograde IFT (Iomini et al., 2001, 2009). Null mutations in mouse ift139a/Ttc21b and ift122 cause similar phenotypes: null mutant cilia are of approximately normal length but have bulges at the tips of the axoneme, consistent with a defect in retrograde trafficking (Tran et al., 2008; Cortellino et al., 2009; Qin et al., 2011), and slower rates of retrograde trafficking were measured after knockdown of Ift139a (Tran et al., 2008). In contrast to the relatively mild ciliary defects of Ift139a and Ift122 mutants, null mutations in mouse Ift121/Wdr35, another IFT-A gene, lead to the formation of very short cilia (Mill et al., 2011). Caenorhabditis elegans null mutations in the IFT-A gene encoding IFT140 (che-11) allow formation of normal-length cilia that fail to function normally (Qin et al., 2001), whereas dfy-2 mutants, which lack WDR19/IFT144, make very short cilia, similar to those seen in IFT-B mutants (Efimenko et al., 2006). Thus, some mutants reveal a role for IFT-A proteins in retrograde ciliary trafficking, and others suggest that IFT-A has a role in building cilia. Despite the differences among the mouse and worm phenotypes, mutations in all six human IFT-A genes—IFT139a/TTC21b, IFT121/WDR35, IFT43, IFT122, IFT144/WDR19, and IFT140—have recently been shown to cause a set of related human genetic syndromes, including short-rib polydactyly, Jeune asphyxiating thoracic dystrophy, Sensenbrenner syndrome/cranioectodermal dysplasia, and Mainzer-Saldino syndrome (Gilissen et al., 2010; Arts et al., 2011; Bredrup et al., 2011; Davis et al., 2011; Mill et al., 2011; Perrault et al., 2012).

Paralleling the different effects on cilia structure, IFT-A proteins appear to have different roles in mouse Shh signaling than the IFT-B proteins. Whereas IFT-B–null mutants fail to respond to Shh, embryos that lack Ift139a/Ttc21b and Ift122 show ectopic, ligand-independent activation of the Shh pathway in the neural tube. The basis of the inappropriate activation of the Shh pathway in the IFT-A mutants is not clear.

Here, we carry out studies that resolve the apparently disparate phenotypes caused by loss of different mouse IFT-A proteins. We first compare two different ethyl nitrosourea (ENU)-induced mutations that disrupt mouse IFT144, a core component of the mammalian IFT-A complex (Mukhopadhyay et al., 2010). We find that a partial loss-of-function Ift144 allele causes ectopic activation of the Shh pathway in the neural tube, similar to the phenotypes seen in mouse Ift122 and Ift139a mutants. In contrast, mutant embryos homozygous for a strong allele of Ift144 appear to have the opposite phenotype: neural cell types that require a high level Shh activity are not specified. We find that the structure of the weak Ift144 mutant cilia is relatively normal, whereas cilia of the null mutant are short and have highly disrupted axonemes. Analysis of double mutants carrying mutations in two different IFT-A genes confirms that strong loss of IFT-A disrupts ciliogenesis and blocks high-level activity of the Shh pathway. The data indicate that IFT-B is sufficient for trafficking of key proteins required for Shh signaling (Gli2, Sufu, and Kif7) into cilia. In contrast, we find that IFT-A is required for localization of a set of membrane-associated proteins to cilia, and we suggest how the loss of these membrane proteins may account for the Shh pathway phenotypes of both weak and strong IFT-A mutants.

Results

Identification of two alleles of mouse Ift144/Wdr19

We identified a recessive mouse mutant, diamondhead (dmhd), in an ENU mutagenesis screen based on altered expression of a transgenic motor neuron reporter gene (Liem et al., 2009). The HB9-GFP transgene is expressed throughout the spinal cord in motor neurons, a cell type that is specified by intermediate levels of Shh pathway activity (Fig. 1 A). In the dmhd mutant, HB9-GFP was not expressed at rostral levels of spinal cord but was strongly expressed in caudal regions. Homozygous dmhd mutant embryos also had a set of defects in external morphology including exencephaly, with an open diamond-shaped forebrain, and left–right randomization of heart looping. The dmhd mutant embryos arrested at midgestation, at approximately embryonic day 10.5 (E10.5).

We used meiotic recombination mapping to localize the dmhd mutation on chromosome 5 (see Materials and methods). Because disruption of primary cilia can cause defects in both left–right asymmetry and Shh signaling, we examined candidate genes in the interval that might affect the formation of primary cilia. We identified a splice site mutation that was predicted to lead to a truncated protein in the gene encoding Wdr19/IFT144 (Fig. 2 A), the homolog of the Chlamydomonas IFT144 and C. elegans Dyf-2, which are required for normal formation of flagella and cilia (Efimenko et al., 2006; Iomini et al., 2009). We were unable to detect wild-type Ift144 transcript by PCR from mutant embryo cDNA and could not detect IFT144 protein with a polyclonal antibody to the N-terminal domain of the protein by immunofluorescence (Fig. 2 B), suggesting that dmhd is a strong loss-of-function or null allele. Consistent with disruption of an IFT protein, cilia structure was strongly disrupted in the dmhd mutant, and only very short cilia were formed (Fig. 2 B).

A second allele of Ift144, twinkletoes (twt), was identified in an independent screen for ENU-induced mutations (Ashe et al., 2012). twt homozygotes survived to the end of gestation, when they showed polydactyly and craniofacial abnormalities. The twt mutation was associated with a missense change in the first tetratricopeptide repeat of IFT144, but the mutation did not affect the amount of protein made (Fig. S1 B; Ashe et al., 2012). The twt mutants showed increased HB9-GFP expression
throughout the spinal neural tube (Fig. 1 B). In contrast to the very abnormal dmhd cilia, twt mutant cilia appeared nearly normal in structure, although IFT-140, another IFT-A protein, was not detectable in the twt mutant cilia (Fig. 2 B). dmhd/twt compound heterozygotes died at E12–13 with exencephaly and polydactyly, confirming that the two mutations disrupted the same gene. Because twt homozygotes survived longer than dmhd/twt embryos and because of the stronger disruption in cilia structure in dmhd than in twt, we concluded that twt is a hypomorphic allele of the gene. Therefore, we refer to the dmhd mutation as Ift144^dmhd and twt as Ift144^twt.

Weak and strong alleles of Ift144 have opposing effects on specification of Shh-dependent ventral neural cell types

To define how IFT144 affects Shh signaling, we examined neural tube patterning in the mutants. Neural patterning in Ift144^dmhd embryos was unlike that of other previously characterized IFT mutants. Null mutations in two other IFT-A genes, Ift122 and Ift139a, cause a ventralization of the neural tube, in which the most ventral cell types that require the highest level of Shh (the floor plate and V3 interneuron progenitors) are expanded as a result of elevated ectopic activity of the Shh pathway (Tran et al., 2008; Qin et al., 2011). In contrast, Ift144^dmhd mutants lacked the cell types that require high levels of Shh activity, the FoxA2+ floor plate and Nkx2.2+ V3 progenitors, throughout the spinal cord (Figs. 1 C and S1 A). In anterior (cervical) regions, Ift144^dmhd embryo mutants lacked all Shh-dependent cell types, but motor neurons, which require intermediate levels of Shh activity, were present in the posterior (lumbar) neural tube, where they expanded to more dorsal positions than seen in wild type (Figs. 1 C and S1 A).

Whereas the ventral neural cell types that require high levels of Shh activity were absent in Ift144^dmhd at all rostrocaudal positions, Ift144^twt showed an opposing phenotype: the floor plate, V3 progenitor, and motor neuron domains were dorsally expanded (Fig. 1 C). This ectopic specification of Shh-dependent ventral neural cell types in the Ift144^twt neural tube was similar to that caused by null mutations in two IFT-A genes, Ift139a^dm and Ift122^twt (Tran et al., 2008; Cortellino et al., 2009; Qin et al., 2011).

To test whether the changes in neural patterning were a result of changes in activity of the Shh pathway, we examined expression of Ptch1, a direct transcriptional target of the Shh pathway, using a Ptch1-lacZ reporter (Goodrich et al., 1997). As predicted by the loss of ventral neural cell types, Ptch1-lacZ was reduced in the Ift144^dmhd neural tube anterior to the forelimbs (Fig. S1, C and D). In the caudal neural tube, Ptch1-lacZ was expressed ectopically in dorsal regions, although the strong Ptch1-lacZ expression at the ventral midline was absent (Figs. 1 D and S1 D). Ptch1-lacZ was ectopically

Figure 2. Two mutations in mouse Ift144 affect cilia structure. (A) Schematic drawing of how the mutations affect protein structure. Two isoforms of the 1,341-amino acid WDR19/IFT144 protein have been described; conserved protein–protein interaction motifs are shown in colored boxes. Depending on the isoform, the dmhd splice site mutation would truncate the protein at amino acid 592 (ENSMUSP00000038098) or amino acid 543 (ENSMUSP000000109414). The twt mutation causes a leucine-to-proline substitution in the first tetratrico peptide repeat (TPR; Ashe et al., 2012). Asterisks indicate the position of the sequence changes in the mutant proteins. CHCR, clathrin heavy chain repeat; wt, wild type. (B) Altered cilia protein expression and structure in the mutants. Cilia in twt MEFs are of approximately normal length and width but accumulate higher than normal levels of IFT88 (an IFT-B protein) at cilia tips and lack detectable IFT140 (an IFT-A protein; 0/9 twt cilia were positive for IFT140 compared with 13/14 wild-type cilia). Cilia in dmhd MEFs are short and wide; they accumulate IFT88 but lack any detectable IFT144 protein, consistent with the hypothesis that dmhd is a null allele (0/18 were positive for IFT144). ac, acetylated. Bar, 2 µm.
IFT144 could, in principle, exert its effect on Shh signaling through either a ciliary or nonciliary role of the protein. To test whether cilia were required for the specification of motor neurons in Ift144null embryos, we generated double mutants that lacked both IFT144 and the IFT-B complex protein IFT172. Embryos homozygous for the Ift172null mutation lack cilia and fail to specify Shh-dependent cell types in the neural tube, including motor neurons (Huangfu et al., 2003). The Ift144null IFT172null double mutants showed the same loss of ventral neural cell types seen in Ift172null single mutants (Fig. S3, A–D). Thus, the changes in the activity of the Shh pathway in Ift144null embryos must be a result of changes in cilia structure or ciliary trafficking caused by loss of this IFT-A protein.

**Weak and strong alleles of Ift144 have distinct effects on cilia structure**

Each of the neural progenitor cells that respond to Shh has a single primary cilium that projects from its apical surface into the central lumen of the neural tube. When cells of the neural tube were examined en face by scanning electron microscopy, wild-type cilia on E10.5 neural progenitors were \~1 μm in length, with shorter cilia emanating from ciliary pockets (Fig. 3 A), consistent with the appearance of primary cilia in other cell types (Sorokin, 1962; Molla-Herman et al., 2010; Rohatgi and Snell, 2010). In contrast, the primary cilia on Ift144null neural epithelial cells were short and bulbous (Fig. 3 B and Table S1). The neural cilia in Ift144null were approximately normal in length (Fig. 3 C and Table S1), whereas Ift144globnull compound heterozygote neural cilia were shorter and wider than wild type (Fig. 3 D and Table S1). The vast majority of Ift144null and Ift144globnull cilia lacked the bulges near the tips that have been described in other IFT-A mutants.

To characterize the aspects of ciliogenesis that require IFT144, we analyzed cilia and basal bodies in neuroepithelial cells by transmission EM (TEM). Cross-sections showed that wild-type basal bodies had the typical triplet microtubule structure, and cilia had the characteristic 9 + 0 doublet microtubule arrangement (Fig. 4 A). Basal bodies of Ift144null, Ift144null, and Ift144globnull cilia appeared to be of normal size and structure and were present close to the apical surface (Fig. 4, B–D). Ift144null and Ift144globnull cilia were similar in structure to wild type in both longitudinal sections and cross-sections, although there was a slightly greater distance between the plasma membrane and the microtubule axoneme, which could account for the greater cilia width seen by scanning electron microscopy (Fig. 4 [B and C] and Table S1). Despite the normal structure of the basal body, the majority of Ift144globnull cilia analyzed lacked any visible microtubules in longitudinal or transverse sections (Figs. 4 D and S4). Instead, the cilia compartment contained disorganized electron-dense material. This phenotype suggests that IFT144 is required for building the cilium rather than functioning exclusively in retrograde trafficking.

**The phenotype of IFT-A double mutants confirms that the IFT-A complex is required for ciliogenesis and for high-level responses to Shh**

The Ift144null mutation caused a much more severe disruption of cilia architecture than null mutations in the mouse IFT-A genes.
IFT122 or Ift139 (Tran et al., 2008; Qin et al., 2011). To test whether this represented a unique property of the Ift144<sup>dmdh</sup> allele or was a result of a more crucial role of IFT144 in the IFT-A complex, we analyzed double mutants that were homozygous for both the weak allele Ift144<sup>sopb</sup> and the null allele Ift122<sup>mmi</sup>. Whereas neural cilia in both Ift144<sup>sopb</sup> and Ift122<sup>mmi</sup> embryos were of nearly normal length (Fig. 3, C and E), the Ift144<sup>sopb</sup>-Ift122<sup>mmi</sup> double-mutant cilia were less than half the length of wild type and more bulbous than either single mutant (Fig. 3 F and Table S1). The Ift144<sup>sopb</sup>-Ift122<sup>mmi</sup> double-mutant cilia were similar in size and shape to those present in Ift144<sup>dmdh</sup> embryos. Whereas Ift144<sup>sopb</sup> and Ift122<sup>mmi</sup> single mutants showed expansion of Shh-dependent ventral neural cell types, neural patterning in Ift144<sup>sopb</sup>-Ift122<sup>mmi</sup> double mutants was similar to that seen in Ift144<sup>dmdh</sup> embryos. Like Ift144<sup>dmdh</sup>, the Ift144<sup>sopb</sup>-Ift122<sup>mmi</sup> double-mutant cilia lacked all ventral cell types in spinal cord regions anterior to the forelimbs and lacked floor plate and most Nnx2.2+ V3 progenitors cells at more posterior positions (Figs. 5 [A and B] and S1 A). Also like Ift144<sup>dmdh</sup>, motor neurons in the double mutant spanned the midline and were expanded dorsally in the caudal neural tube (Fig. 5 B). We conclude that the Ift144<sup>sopb</sup>-Ift122<sup>mmi</sup> double-mutant and Ift144<sup>dmdh</sup>-null single-mutant phenotypes in cilia formation and neural patterning are the result of stronger disruption of the IFT-A complex than seen in Ift122-null single mutants.

IFT122 is required for recruitment of specific cilia components, but not IFT88, to cilia

The TEM analysis showed that Ift144<sup>dmdh</sup> cells have short, abnormal cilia. However, standard molecular markers for cilia were not detectable in the mutant cilia. Arl13b, a palmitoylated membrane-associated protein of the ARL family of small GTPases (Caspary et al., 2007; Cevik et al., 2010; Larkins et al., 2011), is localized to all cilia in the wild-type embryos and mouse embryo fibroblasts (MEFs). Arl13b was present in primary cilia of Ift144<sup>sopb</sup> and Ift122<sup>mmi</sup> embryos and
In contrast, Arl13b was not detectable in mesenchymal cells of the weak IFT-A mutants, and little or no ACIII was detected in strong IFT-A mutants (Fig. S5 and Table S2).

However, it was possible to visualize Ift144dmhd cilia by immunofluorescent staining, as the mutant cilia showed strong expression of the IFT-B protein IFT88. IFT88 was localized to neural cilia that point into the lumen of the neural tube in all genotypes analyzed: wild type, Ift144dmhd, Ift144wt, Ift122sopb, and Ift144wt Ift122sopb (Fig. 6 A). Thus, we infer that IFT-A is not required for targeting or entry of IFT88 into cilia. In wild-type MEFs, IFT88 was enriched at the transition zone at the base of the cilium and in a punctate pattern along the ciliary axoneme (Figs. 2 B and 6 [B–D]). In Ift144dmhd and Ift144wt Ift122sopb MEF cilia, IFT88 extended distal to the basal bodies (marked by γ-tubulin) and often appeared to be continuous from the transition zone into the short mutant axoneme, in contrast to its more punctate localization in wild type, suggesting that this IFT-B protein accumulates in cilia in the absence of IFT-A.

**IFT-A is required for recruitment of Smo, but not Gli2, Sufu, and Kif7, to cilia**

To determine how the changes in cilia structure and composition in the mutants affected the activity of the Shh pathway, we analyzed the localization of Shh pathway proteins in cilia of MEFs derived from mutant embryos. Smo was not detected in the cilia of any of the genotypes analyzed in the absence of Shh pathway activation. In wild-type, Ift144wt, and Ift122sopb MEF cilia, Smo moved into cilia when the Shh pathway was activated with the small molecule Smoothened agonist (SAG; Fig. 7 A). In contrast, no Smo was detected in the cilia of Ift144dmhd mutant or Ift144wt Ift122sopb double-mutant MEFs when the pathway was activated with SAG (Fig. 7 A).

In wild-type cells, Gli2 localizes to cilia tips in the absence of ligand, and its concentration at cilia tips increases in response to pathway activation (Fig. 7 B; Chen et al., 2009; Endoh-Yamagami et al., 2009). In the absence of pathway activation, the amount of Gli2 at cilia tips appeared to be elevated in all of the IFT-A mutants examined (Fig. 7 B).

To confirm that the localization of Shh pathway proteins in MEFs reflected their behavior in the embryo, we examined the distribution of the proteins in mesenchymal cells surrounding the neural tube in wild-type and mutant embryos. In cells near the notochord, a source of Shh, Smo was present along the ciliary axoneme of wild-type cells (Fig. S5). In mesenchymal cells in Ift144dmhd embryos, no Smo was detected in the axoneme, as in MEFs. As in MEFs, Gli2 was present at the tips of wild-type and Ift144dmhd mesenchymal cilia (Fig. S5). In mesenchymal cells in Ift144dmhd embryos, no Smo was detected in the axoneme, as in MEFs. As in MEFs, Gli2 was present at the tips of wild-type and Ift144dmhd mesenchymal cilia (Fig. S5). In mesenchymal cells in Ift144dmhd embryos, no Smo was detected in the axoneme, as in MEFs. As in MEFs, Gli2 was present at the tips of wild-type and Ift144dmhd mesenchymal cilia (Fig. S5).
IFT-A and Shh signaling

Liem et al.

**Figure 6.** A subset of cilia markers is not detected in IFT-A mutant cilia. (A) Neural tube cilia. Arl13b is expressed in the cilia that project into the lumen of the E10.5 neural tube in wild-type (wt), \( \text{IFT-A}^{\text{dmhd}} \), and \( \text{IFT-A}^{\text{sopb}} \) embryos. Arl13b cannot be detected in \( \text{IFT-A}^{\text{dmhd}} \) or \( \text{IFT-A}^{\text{sopb}} \) double-mutant cilia. IFT88 localizes to cilia in all genotypes analyzed. ACIII is present in neural cilia in wild type but is present in fewer neural cilia in the IFT-A mutants. Bars: (top row) 200 µm; (bottom rows) 10 µm. (B–D) MEF cilia. The basal body is marked by γ-tubulin and the axoneme by IFT88. (B) Arl13b marks the ciliary axoneme in wild-type \( (35/35) \), \( \text{IFT-A}^{\text{dmhd}} \) \( (0/9) \) and greatly reduced or \( \text{IFT-A}^{\text{sopb}} \) cilia. IFT88 accumulates in the cilia of \( \text{IFT-A}^{\text{dmhd}} \) or \( \text{IFT-A}^{\text{sopb}} \) mutants. (C) Like Arl13b, acetylated γ-tubulin (ac γ-tub) is detected in the primary cilia of wild-type \( (12/12) \), \( \text{IFT-A}^{\text{dmhd}} \) \( (1/13) \), and \( \text{IFT-A}^{\text{sopb}} \) mutant MEFs but is detected only in a small fraction of \( \text{IFT-A}^{\text{dmhd}} \) \( (1/13) \) or \( \text{IFT-A}^{\text{sopb}} \) cilia. (D) ACIII is strongly expressed in wild-type MEF cilia \( (12/13) \) but is not detectable in either \( \text{IFT-A}^{\text{dmhd}} \) \( (0/8) \) or \( \text{IFT-A}^{\text{sopb}} \) cilia \( (0/12) \). ACIII+ MEF cilia showed ACIII staining \( (13/13) \), but the intensity of staining was reduced to 62 ± 14% of wild type. Only 30% of \( \text{IFT-A}^{\text{sopb}} \) showed ACIII staining, and, in the ACIII+ cilia, the intensity was 22 ± 10% of wild type. Bars, 2 µm.

**Figure 7.** Localization of Shh pathway proteins in IFT-A mutant MEF cilia. (A and B) γ-Tubulin marks the basal body; IFT88 marks the ciliary axoneme. (A) Smo is present in the cilia of wild-type \( (9/9) \), \( \text{IFT-A}^{\text{dmhd}} \) \( (0/9) \), and \( \text{IFT-A}^{\text{sopb}} \) MEFs in cells where the Shh pathway is activated by SAG \( (>90\% \text{ of cilia are Smo+}; n > 10) \). Smo movement into the cilium in response to activation of the Shh pathway by SAG is abolished in \( \text{IFT-A}^{\text{dmhd}} \) \( (0/9) \) and greatly reduced in \( \text{IFT-A}^{\text{sopb}} \) cilia. (B) Gli2 is two- to threefold enriched at wild-type MEF cilia tips in response to SAG \( (n > 14 \text{ for each condition}) \). The level of Gli2 is slightly elevated at the tips of the \( \text{IFT-A}^{\text{dmhd}} \) and \( \text{IFT-A}^{\text{sopb}} \) mutant cilia in the absence of SAG and is further enriched in the presence SAG \( (n > 16 \text{ for each condition}) \). The level of Gli2 is elevated at the tips of the \( \text{IFT-A}^{\text{dmhd}} \) or \( \text{IFT-A}^{\text{sopb}} \) mutant cilia in the absence of SAG and does not increase further in the presence SAG \( (n > 9 \text{ for each condition}) \). Bar, 2 µm.
**Discussion**

**IFT144 is required for anterograde, as well as retrograde, ciliary trafficking**

Our results define an allelic series in the mouse Ift144 gene, which shows that partial loss of IFT-A and complete loss of IFT-A have very different effects on cilia structure and on cilia-dependent Shh signaling. Previous experiments have shown that the IFT-A complex in both Chlamydomonas and mouse is important for the normal rate of retrograde ciliary trafficking (Iomini et al., 2001, 2009; Tran et al., 2008). Embryos homozygous for the partial loss-of-function mutation Ift144<sup>dnhd</sup> have a strong defect in ciliogenesis. The loss of microtubules and the absence of Arl13b, ACIII, and Smo in Ift144<sup>dnhd</sup> mutant cilia suggest that the mutation decreases anterograde trafficking in the cilium.

Additional evidence for a role of IFT144 in anterograde trafficking comes from the analysis of double mutants that lack the dynein motor. Although both IFT-A and cytoplasmic dynein-2 are important for retrograde trafficking in the cilium, our data highlight the different requirements for the two classes of proteins in cilia structure. In Ift144<sup>dnhd</sup> cilia, a membrane compartment filled with electron-dense material extends distal to the basal body, but the normal microtubule structure of the axoneme is absent, and only a few microtubules are present in the cilium. This contrasts with the structure of Dyn2h1<sup>mmi</sup> cilia, which are filled with a regular array of particles spaced at ~40-nm intervals. These structures are likely to be trains of IFT particles, based on comparison with the arrays of IFT trains with 40-nm periodicity observed by electron tomography in Chlamydomonas LC8 mutants, which lack a dynein light chain (Pigino et al., 2009). Ift144<sup>wt</sup>Dyn2h1<sup>mmi</sup> double-mutant cilia do not accumulate the ordered IFT trains seen in Dyn2h1<sup>mmi</sup>. This is consistent with our previous results showing that reduction of either IFT-B or IFT-A partially rescued the cilial phenotype of Dyn2h1<sup>mmi</sup> mutants because of roles of both IFT-B and IFT-A in anterograde ciliary trafficking (Ocbina et al., 2011). Thus, we conclude that IFT144 is required for normal anterograde trafficking.

The cilia phenotypes of the mouse Ift144 allelic series parallel findings with Chlamydomonas IFT-A mutants. At the permissive temperature, temperature-sensitive mutations in two Chlamydomonas IFT-A genes, fla15 (IFT144) and fla17 (IFT139), cause bulged flagella, associated with slowed rates of retrograde IFT (Iomini et al., 2001, 2009). However, at restrictive temperature, fla15 and fla17 mutant cells appear to be flagellate, similar to the phenotype of null mutants in Chlamydomonas Ift140 (another IFT-A gene; Cole, 2003). Thus, in both Chlamydomonas and the mouse, partial loss of IFT-A proteins leads to a defect in retrograde trafficking, and complete loss of IFT-A function leads to the formation of very short cilia. Studies on Dyf-2, the C. elegans homolog of IFT144, are also consistent with roles of this protein in both retrograde and anterograde trafficking (Efimenko et al., 2006).

**Overlap functions of mouse IFT-A genes**

Our genetic analysis of mouse mutants provides a different perspective on the function of individual IFT-A proteins than seen in biochemical experiments. Those studies suggested that mammalian IFT144/Wdr19 and IFT122 were core components of the mammalian IFT-A complex, whereas IFT139/Ttc21b and IFT121/Wdr35 were peripheral proteins that were not required for the formation of the core complex (Mukhopadhyay et al., 2010). In contrast, the genetic data indicate that loss of IFT144 or IFT121/Wdr35 (Mill et al., 2011) has a stronger effect on IFT-A function than does loss of IFT139a or IFT122.

Double mutants that are homozygous for both a null allele of Ift122 and the weak allele of Ift144 (IFT144<sup>gen</sup>Ift122<sup>opg</sup>) have stronger defects in ciliogenesis than either single mutant and are indistinguishable from Ift144<sup>dnhd</sup> mutants in both cilia structure and protein localization. Therefore, we conclude that IFT144 and IFT122 partially overlap in function, and, in the absence of IFT122, decreased activity of IFT144 is sufficient to block the activity of the IFT-A complex. This conclusion is consistent with data from Chlamydomonas that some IFT proteins can substitute for each other (Iomini et al., 2009) and reveals functional differences among the IFT-A proteins.

**Loss of Shh pathway activity in strong IFT-A mutants is associated with the disruption in cilia structure**

Strong disruption of IFT-A, as in Ift144<sup>dnhd</sup> mutants, blocks the formation of a normal ciliary axoneme and the specification of ventral neural cell types that require high levels of Shh activity (Fig. 8 C). Because of the important roles of cilia in promoting Shh activity, a simple model is that the decreased activity of the Shh pathway in Ift144<sup>dnhd</sup> is a result of the collapse of cilia structure in the absence of the IFT-A complex and that normal cilia structure is required for cilia-associated Shh pathway proteins to respond correctly to ligand.

Despite the loss of high-level responses to Shh, the Ift144<sup>dnhd</sup> and Ift144<sup>gen</sup>Ift122<sup>opg</sup> embryos show ectopic activation of the pathway in the caudal neural tube, albeit at a lower level than in Ift144<sup>gen</sup>. As the ectopic motor neurons seen in Ift144<sup>dnhd</sup> embryos are also present in Ift144<sup>dnhd</sup>Dyn2h1<sup>mmi</sup> double-mutant embryos (Fig. S3 F), where retrograde trafficking should be completely disrupted, the data argue that the activation of the Shh pathway seen in IFT-A mutants is not the result of defects in retrograde trafficking. Instead, the results suggest that the ligand-independent activation of the Shh pathway is the result of a defect in IFT-A-dependent anterograde trafficking.

**Cilia localization of soluble Shh pathway proteins does not depend on IFT-A**

Given the absence of most microtubules in the ciliary axoneme in the null allele Ift144<sup>dnhd</sup>, it is remarkable that the mutants can specify the ventral neural cell types that require intermediate levels of Shh activity and that this intermediate level of pathway activity depends on the presence of the Ift144<sup>dnhd</sup> cilium. We observed that Gli2, Kif7, and Sufu, which are critical for activity of the Shh pathway, are all present at the tips of the small Ift144<sup>dnhd</sup> and Ift144<sup>gen</sup>Ift122<sup>opg</sup> double-mutant cilia,
which suggests that the IFT-B complex is sufficient for trafficking of Gli, Kiif7, and Sufu to cilia tips and therefore for the activation of midlevel Shh activity. A critical role for IFT-B in cilia localization of Gli proteins is consistent with the reduction of Gli2 at cilia tips caused by a modest reduction in the level of the IFT-B protein IFT172 (Friedland-Little et al., 2011).

**IFT-A-dependent trafficking of membrane proteins into cilia may account for the neural patterning phenotypes of IFT-A mutants.**

Our analysis indicates that a variety of proteins and protein complexes, including IFT88, Gli2, Sufu, and Kiif7, can translocate into cilia that lack a functional IFT-A complex. In contrast, several membrane proteins, including Arl13b, ACIII, and Smo, are not detectable in cilia of either of the strong IFT-A mutants (Ift144dmhd single mutants or Ift144wt Ift122soph double mutants). A role for the IFT-A–associated protein Tulp3 in trafficking of specific G protein–coupled receptors into cilia was previously defined (Mukhopadhyay et al., 2010), and our findings suggest that IFT-A has a general role in the trafficking of membrane proteins into cilia. Recent work has shown that a membrane-associated protein complex at the transition zone that includes the protein Tectonic1 is important for entry of some membrane proteins (ACIII and Arl13b) but had less effect on others (Smo) into cilia (Garcia-Gonzalo et al., 2011). This raises the possibility that the Tectonic1 and IFT-A complexes act in concert to promote the transport of membrane proteins into cilia.

The membrane proteins affected by loss of IFT-A (Arl13b, Smo, and ACIII) all have documented or plausible roles in Shh signaling and are likely to contribute to the Shh phenotypes of the IFT-A mutants. Mouse mutants that lack Arl13b show strong defects in Shh signaling and neural patterning (Caspar et al., 2007), so the absence of detectable ciliary Arl13b in the strong IFT-A mutants (Ift144dmhd and Ift144wt Ift122soph) could be responsible for some aspects of the neural patterning phenotypes of these embryos. Indeed, cell types that require high levels of Shh activity (the floor plate and V3 interneurons) fail to be specified, and the motor neuron domain is expanded in the mutant embryos because the IFT-A–dependent trafficking of mammalian Shh pathway proteins in the primary ciliary. When Shh ligand is present (illustrated here), Smo moves into cilia, and a complex of proteins required for activation of the pathway, including Kiif7, Gli2, and Sufu, is present at cilia tips. Primary cilia are required for the production of the Gli2 transcription activator and therefore to respond to a gradient of Shh activity, which specifies ventral cell types in the developing neural tube, including floor plate, V3 progenitors, and motor neurons. Arl13b and ACIII are present in both cilia in the presence or absence of Shh and can modulate the activity of the pathway.

(A) In wild type (wt), IFT is required to maintain the axonemal structure and to mediate trafficking of mammalian Shh pathway proteins into cilia. In the primary ciliary. When Shh ligand is present (illustrated here), Smo moves into cilia, and a complex of proteins required for activation of the pathway, including Kiif7, Gli2, and Sufu, is present at cilia tips. Primary cilia are required for the production of the Gli2 transcription activator and therefore to respond to a gradient of Shh activity, which specifies ventral cell types in the developing neural tube, including floor plate, V3 progenitors, and motor neurons. Arl13b and ACIII are present in both cilia in the presence or absence of Shh and can modulate the activity of the pathway. (B) In Ift144wt mutants, cilia appear to have nearly normal morphology but are slightly wider than wild type. IFT-A complex proteins are reduced in cilia, whereas IFT-B particles tend to accumulate in the cilia tips. Smo trafficking into cilia in response to ligand is not affected, but Gli2 is enriched in the cilia regardless of pathway activation, as seen in other IFT-A complex mutants such as Ift122soph. The level of ACIII in the ciliary membrane is reduced, which may lead to decreased cAMP and decreased activity of PKA, a negative regulator of the pathway. Shh-dependent ventral cell types are dorsally expanded in the neural tube. (C) Ift144dmhd mutant cilia have only rare microtubules and accumulate IFT-B particles, but no IFT-A particles are present. Smo, Arl13b, and ACIII fail to localize to the ciliary membrane, but Kiif7, Sufu, and Gli2 accumulate at the tip of the short cilia. In the ciliary neural tube, floor plate and V3 progenitors are absent, but motor neurons are formed, demonstrating the presence of an intermedial ciliary membrane. In the primary ciliary, floor plate and V3 progenitors are absent, but motor neurons are formed, demonstrating the presence of an intermediate level of Shh pathway activity. Ift144wt Ift122soph double mutants are indistinguishable from Ift144dmhd mutants in both cilia structure and neural patterning. D, dorsal; V, ventral.

The one core component of the Shh pathway that does not traffic into cilia of the strong IFT-A mutants (Ift144dmhd and Ift144wt Ift122soph) is Smo, a positive regulator of the pathway. However, the absence of Smo in the ciliary cannot account for the neural patterning phenotypes in Ift144dmhd embryos, as our double-mutant analysis shows that the Ift144dmhd phenotype is independent of the presence or absence of Smo. Nevertheless, our data provide the first evidence that IFT proteins play a role for Smo movement into cilia and contrast with models that suggest
Smo moves into cilia by lateral transport from the plasma membrane (Milenkovic et al., 2009). IFT-A could directly promote Smo movement from the transition zone into the cilium. Alternatively, the strong IFT-A mutations might disrupt axonemal structure in a way that other proteins cannot transport Smo past the transition zone.

The increased Shh pathway activity seen in the weak IFT-A mutants is a long-standing puzzle. The neural patterning phenotype of the hypomorphic mutant *If* / is similar to those of null alleles of *If* and *If* (Fig. 8, A and B; Tran et al., 2008; Qin et al., 2011). All three mutations cause an expansion of Shh-dependent cell types in the neural tube, and the three mutants also cause polydactyly and craniofacial phenotypes (Tran et al., 2008; Qin et al., 2011; Ashe et al., 2012). Mutations in *Tulp3*, an IFT-A–associated protein, also cause ectopic activation of the Shh pathway in the neural tube, but the structure of *Tulp3* cilia appears to be normal (Cameron et al., 2009; Norman et al., 2009; Patterson et al., 2009), and it has been suggested that the *Tulp3* neural patterning phenotype reflects its role in the anterograde trafficking of a membrane-associated negative regulator of the pathway (Mukhopadhyay et al., 2010).

Our findings suggest a possible explanation for gain of Shh activity in the weak IFT-A mutants. Although ACIII is generally considered a cilia marker, ACIII and other adenylyl cyclases (Bishop et al., 2007; Choi et al., 2011) that are localized to cilia are likely to be important for Shh signaling. cAMP-dependent protein kinase is a strong negative regulator of Shh signaling (Tuson et al., 2011). It is reasonable to propose that the adenylyl cyclases in the cilium are the source of the cAMP that activates PKA (Barzi et al., 2010). In the absence of ciliary cAMP, we predict that PKA activity would be decreased, which would lead to ligand-independent activation of the Shh pathway. Therefore, we hypothesize that the gain of Shh activity seen in the weak IFT-A mutants may be the result of decreased levels of adenylyl cyclase in the cilia. The activation of intermediate, but not high, levels of Shh pathway activity in the strong IFT-A mutants (Fig. 8 C) could be a result of the combined loss of ACIII and Arl13b in the mutant cilia or a result of the absence of those proteins in combination with the disrupted cilia structure.

**IFT-A and human genetic disease**

Mutations in all six IFT-A genes—*IFT139a*, *IIFT21b*, *IFT121*, *WDR35*, *IFT43*, *IFT122*, *IFT44*, and *IFT40*—cause human ciliopathies (Gillissen et al., 2010; Arts et al., 2011; Bredrup et al., 2011; Davis et al., 2011; Mill et al., 2011; Perrault et al., 2012), whereas disease-causing mutations have been identified in only a single IFT-B gene (Beales et al., 2007). The higher frequency of disease-causing IFT-A mutations is likely to reflect the overlap in function we have observed among IFT genes, so that even null mutations cause relatively mild phenotypes that are compatible with postnatal life. As the *IIFT44* mutant recapitulates many of the skeletal and craniofacial anomalies seen in these diseases (Ashe et al., 2012), our findings suggest that the complex phenotypes seen in IFT-A syndromes are likely to be a result of the loss of specific membrane proteins in the mutant cilia.

**Materials and methods**

**Mouse strains and phenotypic analysis**

A screen for recessive *E*-null mutations (Garcia-Garcia et al., 2005) was performed by mutagenizing C57BL/6J (The Jackson Laboratory) male mice and out-crossing to FVB/NJ (The Jackson Laboratory) females homozygous for the Bsh-GFP transgene, which expresses EGFP in spinal motor neurons (Liem et al., 2009). The *dnhd* mutation was identified based on decreased GFP expression in whole E10.5 N3 embryos that were potentially homozygous for newly induced mutations. For analysis of neural patterning, embryos were processed as previously described (Casparty et al., 2007); embryos were fixed in 4% PFA in PBS for 40 min on ice, cryoprotected with 30% sucrose, embedded in Tissue-Tek (Sakura), and cryosectioned at 12 µm. The sections were then stained for expression of region-specific neural antigens. All sections were counterstained with DAPI (blue in all figures) to stain nuclei. The following mouse strains were used for analysis: *Pch* (a gift from M. Scott, Stanford University; Stanford, CA; Goodrich et al., 1997), *Gli2* (a gift from A. Joyner, Sloan-Kettering Institute, New York, NY; Matise et al., 1998), *Gli3* (a gift from A. Joyner; Hui and Joyner, 1993), *Dync2h1* (an EN-induced allele; Liem et al., 2009), *If* (an EN-induced allele; Ashe et al., 2012), and *If* (an EN-induced allele provided by J.T. Eggenschwiler, Princeton University, Princeton, NJ; Qin et al., 2011).

**Cell culture and antibodies**

MEFs were derived from E10.5 embryos using standard protocols, as previously described (Ocbina and Anderson, 2008). Confluent MEF cultures were serum starved for 48 h to induce ciliogenesis and treated with 100 nM SAG (EMD) for 24 h to activate the Shh pathway. Cultures were fixed for 10 min in 2% PFA followed by 5 min in 100% methanol. The Gli2 antibody (raised in guinea pig) was a gift from J.T. Eggenschwiler. The *If* and *If* antibodies (both raised in rabbits) were gifts from B. Yoder (University of Alabama, Birmingham, AL) and G. Pazzou (University of Massachusetts Medical School, Worcester, MA). The Shh antibody (rabbit) was previously described (Ocbina et al., 2011). The rabbit Kit* P5* peptide (Apono Rabbit Farm and Laboratory, Inc.) was raised to a Kit* peptide (amino acids 362–600) fused to a His tag expressed in bacteria. The following additional antibodies were used: rabbit anti-Arl13b (Casparty et al., 2007), mouse anti-Nl2.2 (Developmental Studies Hybridoma Bank), rabbit anti- FoxA (Abcam), mouse anti-WDR144 antibody (immunofluorescence; GeneTex Inc.), mouse anti-IFT88 antibody (rabbit) was previously described (Ocbina et al., 2011). The antibody (rabbit) was previously described (Ocbina et al., 2011). The rabbit anti-IFT88 antibody (rabbit) was previously described (Ocbina et al., 2011). The antibody (rabbit) was previously described (Ocbina et al., 2011). The antibody (rabbit) was previously described (Ocbina et al., 2011). The antibody (rabbit) was previously described (Ocbina et al., 2011).

**Image acquisition**

Immunofluorescent imaging of cilia was performed using an image restoration system (DeltaVision; Applied Precision) with a wide-field microscope (IX70; Olympus). Imaging was performed using a 100× 1.4 NA objective at room temperature mounted in VECTASHIELD (Vector Laboratories) and captured with a cooled charge-coupled device camera (CoolSNAP GE; Photometrics). Images were acquired using SoftWorks, and data sets were processed using the Velocity software package to produce an extended-view snapshot (PerkElmer). To improve clarity, some images were adjusted using the curves tool in Photoshop (Adobe); in each case, the entire image was adjusted identically, and all panels in a figure were adjusted with identical settings. Quantification of proteins within cilia was performed using MetaMorph software (Molecular Devices) and measuring the sum of intensities in DeltaVision 2 stacks. Neural tube sections were analyzed with a microscope (AxioiLoro; Carl Zeiss) using a 10× 0.5 NA lens at room temperature in VECTASHIELD. Images were acquired with a wide-field monochrome camera (AxioCam MR) using AxioVision software (v.4.6; Carl Zeiss).

**Identification of the dnhd mutation**

The *dnhd* mutation was mapped to a segment of chromosome 5 based on the identification of regions homozygous for C57BL/6J polymorphisms in IFT139a from mutant embryos on an inbred C57BL/6J genome.

EM

EM 9.5 or 10.5 embryos were fixed with 2% PFA and 2.5% glutaraldehyde in 0.1 M sodium cacodylate buffer. For scanning electron microscopy, embryos were dissected to expose the lumen of the neural tube in 0.1 M cacodylate buffer and dehydrated in ethanol (Huangfu et al., 2003). Scanning electron microscopy was performed using a field emission microscope (1200 EX; JEOL Ltd.) at 80 kV.

Online supplemental material

Fig. S1 shows the molecular and phenotypic characterization of the Ift144dm and Ift144a-mutant mice. Fig. S2 shows double-mutant analysis that places Ift144 in the genetic pathway downstream of Patch1 and Smo and upstream of Gli2 and Gli3. Fig. S3 shows that the Ift144dmh phenotype depends on cilia but is independent of Dyn2h1. Fig. S4 shows the range of structural defects of Ift144dmh neural cilia seen by TEM. Fig. S5 shows the localization of Shh pathway and ciliary components in IFT-A mutant embryonic mesenchymal cells. Table S1 shows cilia dimensions in wild type and mutants. Table S2 shows cilia localization of Shh pathway proteins in embryonic mesenchymal cells. Online supplemental material is available at http://www.jcb.org/cgi/content/full/jcb.201110049/DC1.

We thank Leslie Gunther Cummins (Alpert Einstein College of Medicine, Bronx, NY) for assistance with TEM, Carlo Iomini (Mount Sinai Hospital, New York, NY) for helpful discussions, Jonathan Eggenschwiler for antibodies and the Ift122mice, and Brad Yoder and Greg Pazour for antibodies. We thank Sarah Goetz for helpful comments on the manuscript. We thank Nina Lampen for help with scanning electron microscopy and the Memorial Sloan-Kettering Cancer Center core facilities and Tao Tong of the Rockefeller University Bio-Imaging Resource Center for help with imaging.
