(Dated: April 2, 2012)

Abstract

We study spinless bosons in a decorated square lattice with a near-diagonal tilt. The resonant subspace of the tilted Mott insulator is described by an effective Hamiltonian of frustrated quantum Ising spins on a non-bipartite lattice. This generalizes an earlier proposal for the unfrustrated quantum Ising model in one dimension which was realized in a recent experiment on ultracold \textsuperscript{87}Rb atoms in an optical lattice. Very close to diagonal tilt, we find a quantum liquid state which is continuously connected to the paramagnet. Frustration can be reduced by increasing the tilt angle away from the diagonal, and the system undergoes a transition to an antiferromagnetically ordered state. Using quantum Monte Carlo simulations and exact diagonalization, we find that for realistic system sizes the antiferromagnetic order appears to be quasi-one-dimensional; however, in the thermodynamic limit the order is two-dimensional.
I. INTRODUCTION

Recent experimental progress in the field of ultracold atomic gases has made it possible to study quantum many-body physics in a controllable and clean setting. This makes cold atoms in optical lattices candidates for analog quantum simulators of real materials. Since the observation of a quantum phase transition from a superfluid state to an interaction driven insulating state\(^1\), there has been much effort to simulate other correlated quantum phases, such as magnetic phases. Many proposals suggest using an internal degree of freedom of the atoms to simulate a spin degree of freedom. Virtual hopping processes then lead to an effective magnetic interaction called super-exchange. The energy scale of those processes is still low compared to experimentally reachable temperatures, and so magnetic long range order has not yet been observed.

An important milestone was recently reached taking a surprising new route: an equilibrium quantum phase transition of an antiferromagnetic spin chain was simulated using spinless bosons in a non-equilibrium situation. Following the theoretical proposal of Ref. \(^2\) Simon et al.\(^3\) examined a one-dimensional array of \(^{87}\)Rb atoms in an optical lattice; an additional potential gradient (‘tilt’) drove the transition from the Mott insulating state to a state with density wave order. This happened in a metastable state, which is not the ground state of the full bosonic hamiltonian. However, the dynamics of the tilted lattice was confined to a resonantly connected effective subspace, which has an energy bounded from below, and so a mapping to an antiferromagnetic Ising model in a transverse and longitudinal field is possible.\(^2\) Changing the tilt magnitude corresponds to changing the strength of the longitudinal field, and this takes the systems through an Ising quantum phase transition.

In Ref. \(^4\) we have shown that a variety of correlated phases are possible in tilted two dimensional lattices. A mapping to a spin model is in general not possible in two dimensions. In this paper we focus on a lattice- and tilt configuration where a spin mapping is possible also in two dimension: a diagonally tilted decorated square lattice of bosons leads to a spin model on a non-bipartite lattice, the “octagon-square-cross lattice” (see Figure \([1]\)). We start from the Mott insulator with a filling factor of one atom per lattice site, and assume that effective three-body interaction are important, such that triply occupied sites are not allowed. It has been shown\(^4\) that in this system, three-body interactions have important qualitative effects; in particular, if three body interactions are negligible, then the system maps to a quantum dimer model on a square lattice.\(^4\)

When the potential drop per lattice site is comparable to the on-site repulsion, then the only processes allowed in the resonant subspace are creations of ‘dipoles’ along the links of the lattice. A dipole is created when a boson follows the tilt direction and moves onto a neighboring site, which already contains one boson. This process costs the on-site repulsion energy \(U\) and gains potential energy \(E\). In the parameter regime \(|U - E| \ll U, E\) all other processes are off-resonant.\(^2\)

Due to conservation of energy any lattice site can be part of no more than one dipole.
FIG. 1: Decorated square lattice in a near-diagonal tilt: a) shows the physical lattice for the bosons. The spins reside on the links, which form the lattice shown in b). The effective resonant subspace of the boson model of the decorated square lattice (a) maps to an antiferromagnet on the octagon-square-cross lattice (b) in a strong longitudinal and in a transverse magnetic field. If the tilt is not exactly diagonal, then spins on horizontal lines experience a different longitudinal field than spins on vertical lines. The spin lattice is not bipartite, and in this sense the antiferromagnet is frustrated.

We can map the Hamiltonian of the resonant subspace to a spin model by associating a spin state to each link: spin up if no dipole has been created on that link, and spin down if a dipole has been created on that link. The hard constraint forbidding overlapping dipoles translates to a strong antiferromagnetic interaction in a strong longitudinal field, and so we obtain an Ising antiferromagnet.

As this lattice is not bipartite, antiferromagnetic order is not possible, even for a weak longitudinal field (where the antiferromagnetic interaction dominates over the magnetic field). In this sense the Ising spin model on this lattice is geometrically frustrated.

Let us first briefly review the case of a diagonal tilt. The parent Mott insulator remains stable to a weak tilt. In the other limit, the strongly tilted case, the system wants to maximize the number of dipoles. Due to the nearest-neighbor exclusion constraint, and due to the lattice geometry, there can be no more than one dipole per unit cell. The lattice has four links per unit cell, and so there is a lot of room for the dipoles to fluctuate. Quantum fluctuations then create a unique and gapped ground state: an equal amplitude superposition of all classically allowed dipole coverings. This disordered quantum liquid state is continuously connected to the parent Mott insulator; it is part of the same phase, as shown in the phase diagram in Fig. 2.
FIG. 2: Phase diagram of the near-diagonally tilted decorated square lattice, determined by quantum Monte-Carlo calculations. The tuning parameters are $\lambda_x$ and $\lambda_y$ which parametrize the cost for having a dipole in $x$ and $y$ direction, respectively. a) for realistic system sizes there appears to be only one-dimensional order. This is a finite-size artifact, arising from the fact that for these system sizes the finite-size gap dominates over the (antiferromagnetic) inter-chain coupling. b) in the thermodynamic limit we predict 2d quantum Ising transitions to a phase where neighboring chains are aligned antiferromagnetically.

The physics becomes more interesting when the tilt $\vec{E} = (E_x, E_y)$ deviates slightly from the diagonal, $E_x \neq E_y$. Dipoles in $x$ direction and dipoles in $y$ direction now do not cost the same energy, and we define $\Delta_x = U - E_x$ ($\Delta_y = U - E_y$) the energy associated with a dipole in $x$ ($y$) direction.

In the limit $\Delta_y \to \infty$; $\Delta_x/\Delta_y \to 0$ the system can reduce its potential energy by maximizing the number of dipoles in $y$ direction; no dipoles in $x$ direction are created in the ground state. Thus the system decouples into a collection of horizontally aligned chains. In the absence of vertical dipoles these chains cannot interact with each other, and so each of them undergoes an independent 1d Ising transition (see Fig. 2).

In this paper we study the full phase diagram of the near-diagonally tilted decorated square lattice. An important question is whether there is a region in the phase diagram where 2d order develops, i.e. whether a coupling develops between the above mentioned chains. We find that for realistic system sizes the crossover looks like the one of a collection of independent 1d chains. This is due to the fact that the inter-chain coupling is small compared to the finite-size gap of each chain between the symmetric and anti-symmetric superposition of its two ground states. There is thus no 2d order. A schematic phase diagram for this situation is shown in Figure 2a. The situation is different in the thermodynamic limit. As the finite-size gap vanishes the inter-chain coupling dominates, causing the chains to align antiferromagnetically. The schematic phase diagram in the thermodynamic limit is
shown in Figure 2a.

The remainder of this paper is organized as follows. In Section II we introduce the model and describe the effective resonant subspace. In Section III we study the system by quantum Monte-Carlo (QMC) simulations and find no sign of a coupling between the chains. In Section IV we will show by exact diagonalization of a model system consisting of only two chains that there is indeed a very small coupling between these chains, which arises from processes in very high order in perturbation theory. We present conclusions in Section V.

II. MODEL

In this section we describe the effective resonant subspace of a near-diagonally tilted decorated square lattice. We begin by recalling the Hamiltonian of a tilted Mott insulator. It is described by the generalized bosonic Hubbard model with an additional potential gradient along a certain direction,

\[ H = H_{\text{kin}} + H_U + H_{\text{tilt}} \]

\[ H_{\text{kin}} = -t \sum_{<ij>} \left( \hat{b}_i^\dagger \hat{b}_j + \hat{b}_j^\dagger \hat{b}_i \right) \]  

\[ H_U = \frac{U}{2} \sum_i \hat{n}_i (\hat{n}_i - 1) + \frac{U_3}{6} \sum_i n_i(n_i - 1)(n_i - 2) + \ldots \]  

\[ H_{\text{tilt}} = -E \sum_i \mathbf{e} \cdot \mathbf{r}_i \hat{n}_i. \]

Here \( \hat{b}_i \) are canonical boson operators on lattice sites \( i \) at spatial co-ordinate \( \mathbf{r}_i \), and \( \hat{n}_i \equiv \hat{b}_i^\dagger \hat{b}_i \). The first term in \( H_U \) describes two body interactions. The second term is an effective three body interaction, generated by virtual processes involving higher bands. Such a term is present in ultracold atomic systems, and dramatically changes the physics of a tilted lattice, as we have shown in Ref. 4: if \( U_3 \) is not negligible compared to other energy scales in the problem, then this term causes processes which create triply occupied sites to be off-resonant. The potential gradient is \( E \), and the fixed vector \( \mathbf{e} \) is normalized so that the smallest change in potential energy between neighboring lattice sites has magnitude \( E \). We assume that the potential drop per lattice site \( E \) is comparable to the on-site repulsion \( U \). The tilt has now two components \( \vec{E} = (E_x, E_y) \), we define \( \Delta_x = U - E_x \) and \( \Delta_y = U - E_y \), and we work in the parameter regime where

\[ |\Delta_x|, |\Delta_y|, t \ll |U|, |E|, |U_3|. \]  

We assume that the parent Mott insulator has filling factor one atom per lattice site. The effective resonant subspace of the near-diagonally tilted decorated square lattice is then
FIG. 3: Effective five-state model: each unit cell of the decorated square lattice can be in one out of five possible states: having no dipole, or having a dipole on one of the four links. There is also a constraint that dipoles may not overlap: two neighboring unit cells may not have dipoles directed towards each other. Thus the effective model is a constraint five state model on a simple square lattice.

described by the Hamiltonian

\[ \hat{H} = \Delta_x \sum_{i \in \text{x-links}} \hat{d}_i^\dagger \hat{d}_i + \Delta_y \sum_{j \in \text{y-links}} \hat{d}_j^\dagger \hat{d}_j - \sqrt{2t} \sum_a \left( \hat{d}_a^\dagger \hat{d}_a + \hat{d}_a \hat{d}_a^\dagger \right), \] (2.3)

here \( \hat{d}_a^\dagger \) (\( \hat{d}_a \)) creates (annihilates) a dipole on a link \( a \); where the first sum runs only over links aligned in \( x \) direction, the second sum only over links aligned in \( y \) direction. These two terms describe the energy cost/gain for having a dipole. The last sum comes from the hopping term and describes creation and annihilation of dipoles; it runs over all links. The dipoles obey a hard-core constraint: there can be no more than one dipole on each link. Additionally there is a constraint which does not allow dipoles to overlap on a site: each lattice site can be part of no more than one dipole.

For following discussion, we define the two independent tuning parameters

\[ \lambda_x = \frac{\Delta_x}{\sqrt{2t}}, \quad \lambda_y = \frac{\Delta_y}{\sqrt{2t}} \] (2.4)

These two parameters can take all real values.

A. Description by a constrained five-state model

We can describe the resonantly connected subspace for all values of our tuning parameters \( \lambda_x \) and \( \lambda_y \) by a constrained five-state model on a simple square lattice. We let our unit cell be centered about the sites with four neighbors. Each of the unit cells may be in one out of five states, see Fig. 3. It may contain no dipole (state \( |0\rangle \)), or it may contain one dipole, and there are four links to choose from (states \( |1\rangle, |2\rangle, |3\rangle, |4\rangle \)). The Hamiltonian of a single
site is then given by

\[ H_{\text{site}} = H_{\text{pot}} + H_{\text{kin}} \]

\[ H_{\text{pot}} = \lambda_x (|2\rangle \langle 2| + |4\rangle \langle 4|) + \lambda_y (|1\rangle \langle 1| + |3\rangle \langle 3|) \]

\[ H_{\text{kin}} = -|0\rangle \langle 0| + |2\rangle \langle 2| + |3\rangle \langle 3| + |4\rangle \langle 4| + \text{h.c..} \]  

(2.5)

Summing over all sites we obtain the free Hamiltonian of the five state system

\[ H_{\text{free}} = \sum_{x,y=1}^{L_x,L_y} H_{\text{site}}(x,y). \]

Additionally there is a constraint that the dipoles may not overlap: two neighboring unit cells may not point toward each other. We take this into account by projecting out all the states which would create such a collision

\[ H^c = P_c H_{\text{free}} P_c \]

where \( P_c \) is a projection operator which projects out all the states that are forbidden by the constraint.

B. Mapping to a frustrated Ising spin model

In Refs. 2 and 3, the physics of a tilted one-dimensional Mott Insulator was described by an antiferromagnetic Ising spin chain in a transverse and longitudinal field. In the same spirit, we map the diagonally tilted decorated square lattice to an antiferromagnetic spin model, also in longitudinal and transverse field, on a frustrated lattice. Note that the spin degrees of freedom reside on the links of the decorated square lattice, so that the lattice of the spin model is an ‘octagon-square-cross’ lattice as depicted in Fig. 1. This lattice has four sites per unit cell, and each spin has \( z_{\text{coord}} = 4 \) neighbors. As the lattice is not bipartite, an antiferromagnetic spin model on this lattice is frustrated, and two-dimensional Ising order is not possible. The Hamiltonian of the resonant subspace can be described by the following spin model

\[ H = J \left( \sum_{(i,j)} S^i_x S^j_x - h^{LR}_z \sum_{i \in \text{LR}} S^i_z - h^{UD}_z \sum_{i \in \text{UD}} S^i_z - h_x \sum_i S^i_x \right) \]  

(2.6a)

\[ h^{LR}_z = \left( 2 - \frac{\Delta_x}{J} \right), \quad h^{UD}_z = \left( 2 - \frac{\Delta_y}{J} \right) \]  

(2.6b)

\[ h_x = 2\sqrt{2} \frac{t}{J} \]  

(2.6c)
where $\vec{S} = \frac{1}{2}\vec{\sigma}$. The second sum ($i \in LR$) is over all spins which reside on lines in horizontal direction, see Fig. [1] and the third sum ($i \in UD$) is over spins that reside on vertical lines. While the first three terms all commute with each other, the last term does not. It is this transverse field which makes this a quantum problem. The strong antiferromagnetic interaction and the strong longitudinal field are introduced to realize the constraint: having two neighboring spin down costs an energy of order $J$. The mapping becomes exact in the limit $J \to \infty$. As in one dimension, this is of course not a mapping of the full bosonic model to a spin model, but of the resonantly connected subspace.

We will phrase most of the following discussion in the language of the constrained five-state model, keeping in mind that the results can directly be applied to the frustrated Ising spin model.

### C. Limiting cases

We understand the system in the following limiting cases

1. $\lambda_x, \lambda_y \to \infty$, $\lambda_x/\lambda_y = 1$ (weak diagonal tilt): The parent Mott insulator is stable to a weak tilt, and so the dipole vacuum is the ground state in this limit. Dipole creation costs a large amount of energy, and so dipoles are only virtually created.

2. $\lambda_x, \lambda_y \to -\infty$, $\lambda_x/\lambda_y = 1$ (strong diagonal tilt): This is the quantum liquid state described in Ref. [4]. The number of dipoles is maximized, and the ground state is an equal amplitude superposition of all dipole product states that fulfill the constraint. As we have shown in Ref. [4] this is a disordered state; the ground state is unique and gapped.

3. $\lambda_y \to +\infty$; $\lambda_x/\lambda_y \to 0$: along this line vertical dipole states on links aligned in $y$ direction cannot be occupied, as they cost an infinite amount of energy, while horizontal dipoles along links in $x$ direction are accessible. In this limit the system decouples into a collection of horizontal one-dimensional chains. These chains are effectively one-dimensional, they undergo a phase transition in the Ising universality class at a critical value of $\lambda_y = -1.31$ (which is the same as in the one-dimensional case).

We expect the one-dimensional order within each chain to persist when $\lambda_y$ takes on finite values. Neighboring chains may then interact via dipole states aligned in $y$ direction, which might lead to a coupling between these chains, and thus to two-dimensional order.

---

1 The symmetry which is broken in the ordered phase is a reflection symmetry. The lattice does not have this translation symmetry unless $\Delta_x$ is strictly infinite
III. PHASE DIAGRAM OBTAINED FROM QUANTUM MONTE CARLO

Here we present results from a Quantum Monte Carlo study of the effective resonant subspace of the near-diagonally tilted decorated square lattice. We emphasize that we do not simulate the full bosonic Hamiltonian: QMC would then look for the absolute ground state, which means that all bosons follow the tilt and fall down to minus infinity. Instead we simulate the effective resonant subspace, which is described by the constrain five state model.

A. Order parameters

As we expect one-dimensional order to persist in some region of the phase diagram, we introduce order parameters which probe for 1D Ising order, as well as order parameters which probe for two-dimensional order.

Before introducing our order parameters, we begin by reviewing the order parameter of the one-dimensional system in Refs. 2,3: a staggered magnetization which breaks lattice symmetries (translation, inversion, and reflection symmetry). In the language of the spin mapping in Section II B, and Ref. 3 it is given by

\[ M = \frac{1}{L} \sum_{l} (-1)^{l} \sigma_{l}^{z}. \]

In the limit \( \lambda_y = \infty, \lambda_x/\lambda_y = 0 \) each unit cell of the decorated square lattice has only three states available, and we can directly translate this staggered magnetization to our notation. Each chain aligned along the \( x \) direction and at position \( y \) then has its own, independent order parameter

\[ M_{LR}(y) = \frac{1}{L_x} \sum_{x} (\hat{p}_\rightarrow - \hat{p}_\leftarrow)_{x,y} = \frac{1}{L_x} \sum_{x} m_{LR}(x,y), \]

(3.1)

where \( \hat{p}_d \) is a projection operator that projects onto the dipole state \( d \). Note that this order parameter is normalized to take values in the interval \([-1, 1]\). The (staggered) magnetization of each unit cell has been defined for dipoles along left-right direction only as

\[ m_{LR}(x,y) = \hat{p}_\leftarrow - \hat{p}_\rightarrow \]

When \( \lambda_y \neq \infty \), each unit cell has two additional states available\(^2\). We can still use the above

\(^2\) This breaks the translation symmetry of the one-dimensional chain explicitly: There is no translation relating the state \(|\rightarrow\rangle\) to the state \(|\leftarrow\rangle\), under which the order parameter would change sign. There is, however, an inversion symmetry and a reflection symmetry left, which can be spontaneously broken by
definition, and add another component to the order parameter,

\[ m_{UD}(x, y) = \hat{p}_\downarrow - \hat{p}_\uparrow \]

the magnetization for dipoles aligned in \( y \) direction. We combine the two to a vector,

\[ \vec{m}(x, y) = \begin{pmatrix} m_{LR}(x, y) \\ m_{UD}(x, y) \end{pmatrix} \]

we will refer to this as the “magnetization” of a unit cell of our system. The magnetization \( \vec{m}(x, y) \) transforms as a vector and is odd under inversion. To probe for two-dimensional order in the system, we define the total magnetization

\[ \vec{M} = \frac{1}{L_x L_y} \sum_{x,y} \vec{m}(x, y). \] (3.2)

and measure \( \langle \vec{M}^2 \rangle \). If the chains are aligned ferromagnetically, then this order parameter is non-zero. To probe for antiferromagnetically aligned chains we define a total staggered magnetization

\[ \vec{M}_{\text{stagg,x}} = \frac{1}{L_x L_y} \sum_{x,y} (-1)^x \vec{m}(x, y), \]
\[ \vec{M}_{\text{stagg,y}} = \frac{1}{L_x L_y} \sum_{x,y} (-1)^y \vec{m}(x, y). \]

For an anisotropic tilt we expect the most important effect to be an order within each chain. These chains may or may not be coupled to form two-dimensional order. It is therefore useful to define order parameters which probe for one-dimensional order along \( x \) or \( y \) direction only. For this purpose we will use \( M_{LR}(y) \), Eq. 3.1, and average its square over all chains,

\[ \langle \langle M_{LR}^2 \rangle \rangle = \frac{1}{L_y} \sum_y \langle M_{LR}^2(y) \rangle = \frac{1}{L_x} \frac{1}{L_y^2} \sum_{x,y,y'} \langle m_{LR}(x, y)m_{LR}(x, y') \rangle \] (3.3)

and similarly for for chains aligned along \( y \), \( \langle \langle M_{UD}^2 \rangle \rangle = \frac{1}{L_x} \sum_x \langle M_{UD}^2(y) \rangle \).

an ordered state.
FIG. 4: Phase diagram obtained from QMC study. We find only one-dimensional order. The two-dimensional order parameters are zero everywhere. The phase boundary was obtained from crossing of the binder cumulant of the one-dimensional magnetization, Eq. (3.3). Square lattice of size $L_x = L_y = (4, 8, 16, 32, 64)$ the imaginary time slice thickness was $a = 0.04$, imaginary time direction was scaled with the linear system size, $M_\tau = (40, 80, 160, 320, 640)$, corresponding to temperatures $T = (0.625, 0.3125, 0.1562, 0.0781, 0.0391)$. Essentially the same phase diagram is obtained from order parameter scaling assuming the Ising exponent $\eta = 1/4$.

B. Phase diagram

Results of the QMC simulations are summarized in the phase diagram shown in Figure 4. The disordered dipole state for $\lambda_x, \lambda_y \to -\infty$ appers to be continuously connected to the parent Mott insulator at $\lambda_x, \lambda_y \to +\infty$. There is a critical line where the system undergoes a transition to an ordered state with one dimensional order along individual chains. For $\lambda_y < \lambda_x$ these chains are aligned in $y$ direction (lower right corner of the phase diagram in Fig. 4), and $\langle M_{\text{UD}}^2 \rangle \neq 0$, while $\langle M^2 \rangle = \langle M_{\text{stagg,x/y}}^2 \rangle = 0$. We will show below that
FIG. 5: Absence of two dimensional order in the QMC study. Here we show the scaling of the total magnetization with system size, $\langle M^2 \rangle \times L$. For randomly aligned magnetized chains we expect $\langle M^2 \rangle \propto 1/L$, while for perfectly aligned chains $\langle M^2 \rangle = \text{const}$ and for antiferromagnetic order in transverse direction $\langle M^2 \rangle = 0$. In the disordered phase $\langle M^2 \rangle \propto 1/(L_x L_y)$. This shows that in the ordered phase the system behaves as a collection of independent chains with one-dimensional order within each chain. Similar results are obtained for different cuts through the phase diagram.

The system indeed seems to be disordered in the transverse direction; each chain appears to have a two-fold degenerate ground state, which is independent of the order parameters of the neighboring chains, and so the two-dimensional system has a ground state degeneracy $2^{L_x}$, where $L_x$ is the linear system size in $x$ direction, i.e. the number of chains. Correlations in the $x$ direction decay exponentially with a correlation length which is smaller than the lattice spacing, $\xi_x \ll a$. There is no region in the phase diagram where either $\langle M^2 \rangle$, Eq. 3.2, or $\langle M_{\text{stagg},x}^2 \rangle$ or $\langle M_{\text{stagg},y}^2 \rangle$ takes a non-zero value.

We probe for two-dimensional order by measuring $\langle M^2 \rangle$. This quantity scales with system size exactly as it would for a collection randomly aligned magnetized one-dimensional chains. This suggests that there is no two-dimensional order: while in some regions of the phase diagram there is long range order along individual chains, there is no correlation between these chains, see Figure 5.
We find good data collapse with the critical exponents of the 2D classical Ising model (Onsager exponents), see Appendix. This further supports the observation that individual chains behave as independent 1d Ising systems.

IV. INTER CHAIN COUPLING: EXACT DIAGONALIZATION STUDY

Quantum Monte Carlo results describe a system which decouples into a collection of one-dimensional chains, while on symmetry grounds one would expect that a coupling between the chains should be generated. The following scenarios might explain this disagreement

- **hidden symmetry**: there could be a subtle microscopic symmetry which forbids any coupling between the order parameters of the chains. The next relevant term is then the energy-energy coupling, which leads to a change of the critical exponent $\nu$ but no ordering of the chains; or

- **finite size effects**: the coupling between the chains could be present, but is too small to have an observable effect for the system sizes studied with QMC. Simulating larger lattices should then, in principle, find a phase with two-dimensional order.

Here we resolve this question by an exact diagonalization study of a toy model, which consists of two chains and qualitatively captures the interchain constraint, and thus the coupling.

We find that a coupling between two neighboring chains is indeed present: it is antiferromagnetic in sign and very small in magnitude. It appears only in 20th order in perturbation theory in $t/|U - E|$ within the bosonic model, and is thus not observable for realistic system sizes, neither in QMC nor in cold-atomic quantum simulation experiments.

A. Toy model

We use a simplified model with only two chains. We reduce the Hilbert space further by only keeping the three most relevant dipole states in each unit cell, see Figure 6. The state without dipole has been integrated out\(^3\), while one of the vertical dipole states is missing: this enhances the coupling and reduces the size of the Hilbert space, which enables us to study longer chains. We expect this toy model to qualitatively describe the interchain coupling of our system.

The Hamiltonian for each of a single unit cell reads

\[
H_{\text{site}} = \begin{pmatrix}
\Delta_b & -t_b & -t_b \\
-t_b & \Delta_a & -t_a \\
-t_b & -t_a & \Delta_a
\end{pmatrix}
\]

\(^3\) this of course only works for $\Delta_x, \Delta_y < 0$
where $\Delta_a$ is the energy cost for a dipole along chain direction, and $\Delta_b$ is the energy cost for a dipole in direction transverse to the chains. The effective hopping elements $t_a$, and $t_b$ are obtained from second order perturbation theory, and they both have a negative sign (since $\Delta_a < \Delta_b < 0$).

$$t_b = t^2 \left( \frac{1}{\Delta_a} + \frac{1}{\Delta_b} \right), \tag{4.1}$$

$$t_a = \frac{2t^2}{\Delta_a}, \tag{4.2}$$

In addition to the single site Hamiltonian, there is the hard-core constraint forbidding two central sites from pointing toward each other. This constraint reduces the size of the Hilbert space. The size of the Hilbert space for any chain length $L$ can be computed exactly using transfer matrices. For long chains it grows as $\dim(H) \sim 5.35^L$.

### B. Results

We diagonalized this system for a chains of up to length nine, with periodic boundary conditions. In analyzing the results, it is useful to compare the spectrum to that of a simple model of two decoupled Ising chains in the ordered phase. For systems of finite length, this model would give four low-energy states, whose splitting vanishes exponentially with the system size in the thermodynamic limit.

\[^4\text{ while we can diagonalize chains of length nine in all regions of the phase diagram, in some regions the splitting between the lowest eigenvalues seems to become smaller than machine precision, this limits our analysis.}\]
Fig. 7 shows the energy of the three lowest excited states relative to the ground state, as a function of the system size. At first glance, these results are consistent with the model of completely decoupled chains, since the energy splitting to the three lowest excited states appears to vanish exponentially. However, for certain parameters and for the longest systems (fig. 7b), we observe a deviation from the decoupled chain model. Two of the low-energy states remain nearly degenerate, while the gap to the other two starts deviating from exponential. This behavior is consistent with having a small but non-zero inter-chain coupling.

FIG. 7: Strong finite-size effects: Logarithmic plot for energy of the first three excited states relative to the ground state as a function of system length, for (a) $\Delta_a = -5, \Delta_b = -4$ (b) $\Delta_a = -7, \Delta_b = -1$. The lines $E_1 - E_0$ and $E_2 - E_0$ appear on top of each other. At first sight this suggests that there are four ground states in the thermodynamic limit and that thus the order parameters of the chains are not coupled. However there is a small splitting between the first two levels above the ground state. This splitting grows linearly with system size and eventually dominates over the finite size gap for long enough chains.

1. Estimate of the order parameter coupling

The following observations further support the existence of a small coupling between the order parameters of the two chains:

1. There is a splitting between the first and the second excited state, $E_2 - E_1$. This splitting is too small to be visible in Fig. 7a. We present it in Fig. 8. Although the magnitude of the splitting is very small, it grows approximately linearly with system size, consistent with a finite energy density associated with an inter-chain order parameter coupling.
FIG. 8: Splitting between first and second excited state grows linearly with system size. This suggests that there is indeed a coupling between the order parameters of these two chain.

2. We can show that there is no hidden symmetry forbidding order parameter coupling: if we fix the boundary conditions\(^5\) to make the chains either aligned or anti-aligned, there is a difference in ground state energy of these two systems which grows linearly with system size, see Fig. 9. We can use the slope of this curve as an estimate for the coupling of the order parameters per unit cell.

The slopes of both curves in Fig. 7, 9 agree approximately, giving us a good estimate for the order parameter coupling of the chains. For the system sizes we studied, however, this coupling is smaller than the effective tunneling element between the different ground states, i.e. smaller than the finite size gap. For larger chains this order parameter coupling will start to dominate over the tunneling, and then there will only be two ground state. The coupling between two chains is antiferromagnetic.

\(^5\) We can view the segment under consideration as a part of a very long system, which is aligned either ferromagnetically or antiferromagnetically. The remainder of the long system provides the boundary conditions for the segment.
FIG. 9: The inter-chain coupling is antiferromagnetic, which we show by fixing the boundary conditions so that the chains are forced to be either aligned or anti-aligned. The energy difference grows linearly with system size and antiferromagnetic boundary conditions are energetically favorable.

2. Estimate of order in perturbation theory for coupling

We now estimate the order in perturbation theory in which the antiferromagnetic coupling is generated. To this end, we set $t_a = t_b = 1$ and use $\Delta = \Delta_b - \Delta_a$ as our only tuning parameter. Let $E_c$ be the energy per unit length of the antiferromagnetic coupling

$$E_c = \frac{E_2 - E_1}{N}$$

(here $N$ is the chain length). If the antiferromagnetic coupling appears in $n$th order in perturbation theory, then

$$E_c \propto |\Delta|^{1-n} \quad (4.3)$$

$$\log (E_c) = (1 - n) \log (|\Delta|) + \text{const} \quad (4.4)$$

We plot $\log E_c$ versus $\log(|\Delta|)$ and obtain $n = 10$ from a linear fit (see Fig. 10). This suggests that the antiferromagnetic inter-chain coupling is generated in 10th order in perturbation theory within this toy model, and in 20th order in perturbation theory within the bosonic model.
C. Mechanism for inter-chain coupling

Having established that, in the ordered phase, the chains couple antiferromagnetically, it is natural to ask what is the microscopic mechanism responsible for this coupling. Below, we give a qualitative argument for the generation of inter-chain coupling in high orders in $t/\Delta$, which predicts that the sign of the coupling should be antiferromagnetic.

We begin by the observation that in the Ising ordered phase, there are two distinct types of domain wall fluctuations, a kink and an anti-kink (see Fig. 11(a,b)). Kink-anti kink pairs can be generated virtually, lowering the kinetic energy. We note also that the two domain walls have a parametrically different effective mass: the kink (Fig. 11a) can hop via a process of order $t_b^2/(|\Delta_a - \Delta_b|)$, while the anti-kink (Fig. 11b) is much lighter, hopping via a process of order $t_a$. Therefore, the anti-kinks are more delocalized. We note also that kink-anti-kink pairs in a fully ordered configuration are always created in the same orientation, see Fig. 11c. If the order parameter of a chain points to the left, then each kink is on the right side of its anti-kink partner. As a consequence, worlds lines of kinks curve in the opposite direction than world lines of anti-kinks; and which way they curve is determined by the sign of the order parameter. Some typical space-time paths of fluctuating kink-anti kink pairs are shown schematically in Fig. 11c.
FIG. 11: A kink (a) and anti-kink (b) configuration. Kinks in different chains cannot reside on the same rung, because of the hard-core constraint; no such restriction exists for the anti-kinks. c) Schematic space-time trajectories for kink-anti kink pairs. The kinks (anti-kinks) are represented by solid (dashed) lines, respectively. The arrows represent the direction of the Ising order parameter. The average order parameter is assumed to be pointing to the left. In this configuration, the kinks are typically to the right of the anti-kinks, and their world lines typically curve left. Since the two chains couple only through the kinks, this provides a mechanism for coupling the order parameters of the two chains; if the order parameters are anti-aligned, there is a larger “phase space” for kink-anti kink fluctuations (since the world lines of kinks in the two chains curve in opposite directions), reducing the kinetic energy.

The order parameters of two neighboring chains are not coupled directly; i.e., in a classical, fully ordered configuration (which is the ground state in the limit $t_{a,b} = 0$), there is no energy difference between an aligned and an anti-aligned configuration. However, in the presence of quantum fluctuations, the two chains become coupled. For instance, in our two-chain model, kinks cannot occur simultaneously on both chains, because of the constraint preventing two dipoles to point towards each other. Note that there is no such constraint for anti-kinks; configurations in which anti-kinks in the two chains occur on the same rung are allowed.

This hard-core interaction between kinks provides a mechanism for coupling the order parameters of the two chains. Consider the kink space-time configuration in Fig. 11: In this configuration the world lines of kinks tend to curve to the right. The repulsive interaction between kinks on the two chains reduces the “phase space” available for quantum fluctuations. However, one can imagine that if the two order parameters are anti-aligned, the phase space for fluctuations is slightly larger than in the opposite case, since then the space-time trajectories of the kinks on the upper and lower chains tend to curve in opposite ways, allowing one to fit more quantum fluctuations in a given space-time “volume” (thus lowering the kinetic energy). This “order by disorder” mechanism explains how the repulsion between anti-kinks can generate a coupling between the order parameters of the two chains to high order in $t_{a,b}/|\Delta_a - \Delta_b|$. Moreover, it predicts that the coupling is antiferromagnetic, consistently with the ED findings described above.
V. CONCLUSIONS

We have proposed a setup to simulate frustrated quantum Ising spins with cold atoms in a tilted optical lattice, by generalizing an idea which has been successfully applied experimentally in one dimension. We have studied the phase diagram of the resulting model and found that it has strong finite size effects. While for realistic systems it decouples into a collection of one dimensional Ising chains, a coupling between the chains is present in the thermodynamic limit. A quantum simulator of ultracold atoms would however, be limited in the system size. We therefore expect it to observe a one-dimensional transition to ordered chains, just as we did in QMC.

Appendix A: Details on the QMC study

a. Binder cumulant

The binder cumulant gives a good estimate for the critical point, and it does not depend on critical exponents. For an Ising order parameter, $M$, the binder cumulant is defined as

$$U = 1 - \frac{\langle M^4 \rangle}{3 \langle M^2 \rangle^2}.$$ 

When the binder cumulant is plotted for different system sizes, all curves should cross at the critical point for the following reason. While for an infinite system the magnetization vanishes at the critical point as

$$M \propto (-\tau)\beta,$$

where $\tau$ is the reduced temperature $\tau = T/T_c - 1$, $\beta$ is the critical exponent of the magnetization. For a finite system there are corrections to scaling, described by a scaling function $\phi$, which only depends on $\xi/L$,

$$M = (-\tau)\beta \phi(\xi/L) = (-\tau)\beta \tilde{\phi}(\tau L^{1/\nu}),$$

where $\xi$ is the correlation length, and $\nu$ is the correlation length exponent. We used $\xi = \tau^{-\nu}$ to rewrite the scaling function for a different argument. The average magnetization squared,
and raised to the fourth power, have different scaling functions,

\[ \langle M^2 \rangle = (-\tau)^{2\beta} u_2 (\tau L^{1/\nu}) \]
\[ \langle M^4 \rangle = (-\tau)^{4\beta} u_4 (\tau L^{1/\nu}) \]

and so the binder cumulant is a function of this same argument, \( \tau L^{1/\nu} \)

\[ U(\tau, L) = 1 - \frac{u_4 (\tau L^{1/\nu})}{3 (u_2 (\tau L^{1/\nu}))^2} = f (\tau L^{1/\nu}) , \quad (A1) \]

At the critical point we have \( \tau = 0 \), and so the binder cumulant at this point should not depend on system size. In the thermodynamic limit for an Ising system in the ordered phase \( U \to \frac{2}{3} \), and \( U \to 0 \) in the disordered phase. Fig. 12 shows the binder cumulant of the one-dimensional order parameters \( \langle \langle M^2_{LR} \rangle \rangle \) and \( \langle \langle M^2_{UD} \rangle \rangle \) for different cuts through the phase diagram.

\[ b. \quad \text{Order parameter scaling and the critical exponent} \ \eta \]

The phase transition point can also be found from order parameter scaling. This will depend on the correlation length exponent, \( \eta \). Let \( M \) again be an Ising order parameter, at the critical point the correlation decays as a power law,

\[ \langle M(r)M(0) \rangle \propto |r|^{-(d+z-2+\eta)} \quad (A2) \]

\( z \) is the dynamic critical exponent, which is \( z = 1 \) in case of the Ising model. We define \( M \) as the (normalized) total magnetization \( M = 1/L \int M(r)dr \), and for a one dimensional system (\( d = 1 \)) we have

\[ \langle M^2 \rangle \propto L^{-\eta} \quad (A3) \]

The correlation length exponent for the 2D classical Ising model is \( \eta = 1/4 \). In Figure 14 we plot \( \langle \langle M^2_{LR} \rangle \rangle L^{-1/4} \) and \( \langle \langle M^2_{UD} \rangle \rangle L^{-1/4} \) for different system sizes. The crossing point of these lines gives us the phase boundary which agrees with the one found from the binder cumulant.

\[ c. \quad \text{Critical exponent} \ \nu \]

If we rescale the \( x \) axis for the binder cumulant, and plot it as a function of \( (\lambda - \lambda_c) L^{1/\nu} \), then the data points for all system sizes should collapse. We indeed observe a good data collapse for the correlation length exponent of the classical two-dimensional Ising model,
FIG. 12: Binder cumulant for order parameters $\langle M^2_{LR} \rangle$ and $\langle M^2_{UD} \rangle$ for a horizontal cut through the phase diagram, keeping $\Delta_x = -5$ fixed, plotted for different system sizes, $L_x = L_y = 4, 8, 16, 32, 64$. 

mBinderLR; $\Delta_x = -5$

mBinderUD; $\Delta_x = -5$
FIG. 13: Binder cumulant of $\langle M^2_{UD} \rangle$ along different cuts through the phase diagram: here $\Delta_x = 10$ and $\Delta_x = -2$. 
FIG. 14: Order parameter scaling, assuming the correlation length exponent $\eta = 1/4$ of the classical two-dimensional Ising model. Good agreement of the crossing points, also with the ones found from the binder cumulant.
FIG. 15: Data collapse for the critical exponent $\nu = 1$ of the classical two-dimensional Ising model. The $x$ axis is centered around the critical point and rescaled by $L^{1/\nu}$

$\nu = 1$, see Fig. 15
