Abstract
Predicting organismal phenotypes from genotype data is important for plant and animal breeding, medicine, and evolutionary biology. Genomic-based phenotype prediction has been applied for single-nucleotide polymorphism (SNP) genotyping platforms, but not using complete genome sequences. Here, we report genomic prediction for starvation stress resistance and startle response in Drosophila melanogaster, using ~2.5 million SNPs determined by sequencing the Drosophila Genetic Reference Panel population of inbred lines. We constructed a genomic relationship matrix from the SNP data and used it in a genomic best linear unbiased prediction (GBLUP) model. We assessed predictive ability as the correlation between predicted genetic values and observed phenotypes by cross-validation, and found a predictive ability of 0.239 ± 0.008 (0.230 ± 0.012) for starvation resistance (startle response). The predictive ability of BayesB, a Bayesian method with internal SNP selection, was not greater than GBLUP. Selection of the 5% SNPs with either the highest absolute effect or variance explained did not improve predictive ability. Predictive ability decreased only when fewer than 150,000 SNPs were used to construct the genomic relationship matrix. We hypothesize that predictive power in this population stems from the SNP-based modeling of the subtle relationship structure caused by long-range linkage disequilibrium and not from population structure or SNPs in linkage disequilibrium with causal variants. We discuss the implications of these results for genomic prediction in other organisms.

Introduction
Most efforts to understand the genetic architecture of quantitative traits have focused on mapping the variants causing phenotypic variation in quantitative trait locus (QTL) mapping populations derived from crosses between lines genetically divergent for the trait, or in association mapping populations, with the goal of understanding the biological underpinnings of trait variation [1]. However, the ability to accurately predict quantitative trait phenotypes from information on genotypic variation in the absence of knowledge of causal variants will revolutionize evolutionary biology, medicine and human biology, and breeding of agriculturally important plant and animal species. The premise of personalized medicine is based on prediction of individual genetic risk to disease from genome-wide association studies [2,3], and the ability to select individuals or lines in animal and plant breeding programs based on genotypic information circumvents the costly process of progeny testing and reduces the generation interval in applied breeding programs, leading to greater efficiency [4,5].

In classical animal and plant breeding, the genetic quality of individuals or lines is predicted from phenotypic values of selection candidates and their relatives. The widely used Best Linear Unbiased Prediction (BLUP, [6]) method models the covariance structures between individuals via the numerator relationship matrix, which is constructed from known pedigree information and thus reflects expected relationships between individuals (i.e. the proportion of shared alleles of identical ancestral origin) given the pedigree. The advent of high-throughput genotyping platforms for many agronomic species [7] enabled genotyping large numbers of individuals for dense panels of single nucleotide polymorphisms (SNPs) spanning the genome. The expected, pedigree-based numerator relationship matrix can then be replaced by a realized, genome-based relationship matrix (often called the “genomic” relationship matrix, [8]). This approach is equivalent to a random regression approach in which all SNP genotypes are simulta-
Author Summary

The ability to accurately predict values of complex phenotypes from genotype data will revolutionize plant and animal breeding, personalized medicine, and evolutionary biology. To date, genomic prediction has utilized high-density single-nucleotide polymorphism (SNP) genotyping arrays, but the availability of sequence data opens new frontiers for genomic prediction methods. This article is the first application of genomic phenotype prediction using whole-genome sequence data in a substantial sample of a higher eukaryote. We use ~2.5 million SNPs with minor allele frequency greater than 2.5% derived from genomic sequences of the “Drosophila Genetic Reference Panel” to predict phenotypes for two traits, starvation resistance and startle-induced locomotor behavior. We systematically address prediction within versus across sexes, genomic best linear unbiased prediction (GBLUP) versus a Bayesian approach, and the effect of SNP density. We find that (i) genomic prediction can be efficiently implemented using sequence data via GBLUP, (ii) there is little gain in predictive ability if the number of SNPs is increased above 150,000, and (iii) neither implicit nor explicit marker selection substantially improves the predictive ability. Although the findings must be seen against the background of small sample sizes, the results illustrate both the potential of the approach and the challenges ahead.

Bayesian linear regression methods [10,21] or fully non-parametric approaches [22–25].

GBLUP approaches are based on a linear model for the phenotypic values, which encompasses a vector of random genetic values of individuals whose covariance structure is inferred from genomic data. The linear model underlying the RRBLUP approach includes a vector of random marker effects (instead of a vector of genetic values) which are assumed to be drawn from the same normal distribution and uncorrelated. The model primarily provides estimates of SNP effects, but estimated genetic values of individuals can be derived as linear combinations of the estimated SNP effects, yielding the same predictions of individual genotypic or phenotypic values as GBLUP. The BayesB method [10], on the other hand, fits only a small fraction of the available markers to conform with the assumption that most loci are expected to have zero effect on the phenotype, and the remaining non-zero marker effects are drawn from normal distributions with random variances.

It has been suggested [26] that differences between prediction methods will become more pronounced with the availability of full genome sequence data. According to a study with simulated data [26], RRBLUP and equivalent GBLUP procedures do not take full advantage of high-density marker data if the number of causal SNPs is small, while approaches with an implicit feature selection such as BayesB might be more accurate. If, on the other hand, the number of causal loci is large, RRBLUP or GBLUP methods may yield accurate predictions because the assumption that every SNP has an effect is closer to reality.

Implementing genomic prediction with full genome sequence data raises a number of questions. What is the most efficient way to incorporate the complete genomic information in prediction? How much predictive ability is gained by using whole genome sequence data compared to high density SNP panels? Is it possible to increase predictive ability by a pre-selection of SNPs or models with an internal feature selection? How comparable are the results of genomic prediction and genome wide association? Here, we address these questions empirically based on full genomic sequences of a population of Drosophila melanogaster inbred lines. The inbred lines have been sequenced, and constitute the Drosophila Genetics Reference Panel (DGRP), a new community resource for genetic studies of complex traits [27].

We report the results of a full sequence based genomic prediction for two quantitative traits, starvation stress resistance and locomotor startle response, both of which display considerable genetic variation in natural populations and respond rapidly to artificial selection [28–30]. We used whole-genome sequences determined on the Illumina platform for 157(155) DGRP-lines for starvation resistance (startle response) [27]. Our reference method is a GBLUP approach in which ~2.5 million polymorphic SNPs are used to derive a genomic relationship matrix [8]. We evaluated predictive ability via cross-validation (CV), and compared prediction within sexes, across sexes, various SNP densities, and training set sizes. We assessed whether BayesB is superior over GBLUP given full genome sequence data [26], and compared our genomic prediction results with those of GWAS conducted on the same DGRP lines [27].

To our knowledge, this is the first application of genomic prediction on empirical whole genome sequence in a substantial sample of a higher organism. However, this study, as well as all previous association studies, only assesses the effects of common SNPs, since the effects of rare alleles cannot be estimated due to the small sample of sequenced lines. The results illustrate both the potential of the approach and challenges to be addressed in the future.
Results
Genomic Best Linear Unbiased Prediction (GBLUP)
We constructed a genomic relationship matrix [8] from ~2.5 million SNPs for which the minor allele was present in at least four of the DGRP lines [27]. A histogram of the off-diagonal elements of this matrix for 157 DGRP lines used in the GBLUP analyses (Figure 1) and a corresponding heatmap (Figure 2) show that there were no large blocks of high genomic relationship among the lines. The average genomic relationship is close to zero, as expected, but there is considerable variance around this average (Figure 1), as indicated by two block of lines with average genomic relationships within each block of 0.25 and 0.34 (Figure 2). We performed genomic prediction for starvation stress resistance and locomotor startle response. The phenotypes used were the medians of many (40–52) individually tested males and females for each line, or the average of the male and female medians (Table S1). We used several cross-validation (CV) procedures for each trait (Table 1). In the 5-fold CV, predictive ability was 0.239 ± 0.008 for starvation resistance and 0.230 ± 0.012 for startle response. In human studies the efficiency of a predictor is reported as the squared correlation \( r^2 \) rather than \( r \) [31], so that in terms of variance explained the estimates were 0.074 ± 0.005 for starvation resistance and 0.080 ± 0.005 for startle response. The observed accuracy depends on the size of the training set (Figure 3), with decreasing accuracies obtained with smaller training sets. Predictive abilities are roughly halved for both traits when using only 20% instead of 80% of the data to train the model. Maximum likelihood estimates of narrow-sense heritabilities based on the GBLUP model using the genomic relationship matrix were 1.0 in all analyses (Table S2), reflecting the fact that phenotypes are averages over many replicates and thus residual variance is minimal. Hence, the phenotypes used represent the line genotypes with maximum accuracy, which is the ideal case for training the genomic model.

Using male performance data to train the model and using the results to predict the female performance (or vice versa) does not affect the predictive ability for startle response, but substantially reduces the predictive ability for starvation resistance, reflecting a higher degree of genotype by sex interaction in this trait [27], and see below). Prediction is more accurate in females than in males (0.254 vs. 0.203) for starvation resistance, while there is little difference for startle response.

A series of 5-fold CVs for starvation resistance using different SNP densities showed that predictive ability remained almost constant if every 16th SNP (~150,000 SNPs) was used to construct the genomic relationship matrix (Figure 4). The predictive ability began to deteriorate when fewer than 150,000 SNPs were used, but only vanished completely when as few as ~2,500 SNPs (every 1,024 SNP) were used. The corresponding LD distribution for SNP neighbors for different SNP densities is shown in Figure 5, illustrating the extreme short-range extent of LD in the D. melanogaster genome. The average LD between SNPs (after imputation) whose distance lay in the interval \([10,50],[100,200],[900,1000])\) bp was \( r^2 = 0.240(0.14,0.07) \) for the autosomes and \( r^2 = 0.380(0.23,0.10) \) for the X-chromosome. Long-range LD between pairs of loci at the opposite ends of chromosome arms or across different chromosome arms was on average 0.007 both for the autosomes and the X-chromosome.

For starvation resistance, the influence of the minor allele frequency of the SNPs used on the predictive ability was assessed with a series of 5-fold CVs using SNP sets with different average minor allele frequency. We find that the variability of the predictive ability increases when the average minor allele frequency of the SNPs used to construct the genomic relationship matrix is decreased (Figure S1). In 20 replicates of an additional 5-fold CV, in which we randomly chose 77,817 SNPs to build the genomic relationship matrix, an average predictive ability of 0.221 ± 0.009 was obtained, which is in the range obtained when every 32nd SNP (~77,817 SNPs) was used (0.211 ± 0.008, Figure 4). Running 20 replicates of a 5-fold CV using 10 randomly chosen blocks of adjacent SNPs (each block consisting of 7,781 SNPs) led to an average predictive ability of 0.210 ± 0.011.

To analyze whether the predictive ability is due to lines which are more highly related, we ran an additional 5-fold CV with 20 replicates in which the two groups of higher overall relatedness (Figure 2) were excluded. Here we found an average predictive ability of 0.290 ± 0.008 for starvation resistance, which is larger than the average predictive ability we obtained using all lines (0.239 ± 0.008). For startle response, excluding the two groups led to a decrease in predictive ability (0.168 ± 0.017 in comparison to 0.230 ± 0.012).

Effective population size derived from empirical accuracies of genomic prediction
The accuracy of genomic prediction is a function of a number of quantities, including the size of the training set and the effective population size \( N_e \) [20]. \( N_e \) has an effect on the number of independently segregating chromosome segments, \( M_s \), in a population (the larger \( N_e \), the larger \( M_s \)); and the predictive ability of GBLUP is higher when the number of segments is small. By varying the size of the training set in a series of CVs, we can estimate \( N_e \) by fitting a curve through the empirical accuracies obtained (Figure 3).

We estimated \( N_e = 8,748 \) for starvation resistance and \( N_e = 8,676 \) for startle response. The coefficient of determination of the fitted curve was \( R^2 = 0.70(0.44) \) for starvation resistance (startle response). The bias corrected empirical 95% confidence intervals for the \( N_e \) estimates obtained with bootstrapping [32] were [8,173; 9,474] for starvation resistance and [7,716; 9,925] for startle response.

The effective population size in the Raleigh population (from which the DGRP-lines were drawn) was estimated to be ~19,000 in 1984, with a massive fluctuation between years [33]. Our
estimates of \( N_e \sim 8,700 \) correspond to \( M_e = \frac{N_e L_f}{\ln(2N_e L_f)} \approx 2,000 \) independently segregating chromosome segments. In this formula \( L_f \) is the length of the female genome in Morgans (there is no recombination in male Drosophila). Since the sequenced animals resulted from 20 generations of full sib mating following the original sampling from the Raleigh population, the DGRP lines are not expected to have the same \( M_e \) as the original population and are consequently expected to have a different \( N_e \).

We can use the curves fitted through the empirical accuracies (Figure 3), to predict the expected accuracy of prediction for an arbitrarily large size of the training set: If 1,000 lines were available in the training set, the curve would predict accuracies of \( \sim 0.58 \) for starvation resistance and startle response. This value was obtained by using \( N_e \) and \( \hat{g}_{BLUP} = 1 \) as well as \( N_p = 1,000 \) and \( L_f = 2.451 \) in the modified formula of [20].

**Effective population size derived directly from linkage disequilibrium**

We also estimated the effective population size based on LD directly. For a distance bin of 0.02 Morgan we obtained average

---

**Figure 2. Heatmap of the genomic relationship matrix G.** The genomic relationship matrix \( G \) was calculated according to [8] using 157 lines and 2.5 million SNPs. The “S” after the line-ID indicates that the line belongs to the set of lines for which phenotypic records for startle response were also available (in addition to the phenotypic records of starvation resistance).

¹(4:1)-CV means: r parts are used as training set and v parts are used as validation set.
²The average of the medians of male and female measurements was used to predict line phenotypes. Predicted phenotypes were then correlated with the averages of the medians of male and female measurements.
³Average correlation between predicted genetic values and observed phenotypes. Results are averages over 20 replicates. Standard errors of the means in parentheses.
⁴CV sex; sex² means: Medians of measurements of sex_0 were used in the training set, medians of sex_1 were used in the validation set.

LD-values of 0.010(0.009,0.008,0.011,0.008) for chromosome 2L (2R, 3L, 3R, X). These values correspond to an estimated effective population size of \( N_e = 3,415(5,541,10,663,2,811,9,710) \), approximately 25 generations ago. The average estimated effective population size is \( N_e = 6,428 \), which is in the range of the estimates based on the observed accuracies.

Genomic prediction with SNP selection

Genomic prediction might be improved if we only fit SNPs which are associated with variance in a trait, because we then concentrate on the biologically relevant genomic regions, and excluding SNPs which are not associated with the trait reduces statistical noise. We tested this hypothesis using the starvation resistance data. We identified the 5% SNPs with the highest absolute estimated effect or the highest estimated genetic variance, respectively, in the training set of the respective 80% of the folds in a 5-fold CV. We then used these subsets of selected SNPs to predict the phenotype in the remaining 20% of the fold. Predictive ability was improved by 3.3% over the reference scenario when using the 5% SNPs with largest effects (average predictive ability of 0.247±0.008 in comparison to 0.239±0.008). Using the 5% SNPs with greatest variance explained, predictive ability was improved by 2.1% (average predictive ability of 0.244±0.008). In both cases, the improvement is marginal and provides little support for the idea of SNP pre-selection.

We also compared our GBLUP results to those from a method which does not assume that all SNP effects are drawn from the same normal distribution and carries out an internal feature selection. We ran 20 replicates of a 5-fold CV for starvation resistance using BayesB [10]. In each round of the Markov Chain Monte Carlo based procedure (see Methods), 99.5% of the SNPs were assumed to have no effect and the effects of the remaining 0.5% of the SNPs were drawn from normal distribution with random variances. In most folds of each single CV and for all replicates of CV, the observed predictive abilities differed only marginally between BayesB and GBLUP (Figure 6). The average predictive ability obtained with BayesB was 0.238±0.008 which is not appreciably different from the result obtained with GBLUP (0.239±0.008).

Genomic prediction versus GWAS

Although genomic prediction follows a different paradigm than genome-wide association studies, it is informative to compare significant SNP positions from the GWAS to areas of large estimated SNP effects resulting from the GBLUP model. Previously [27], a GWAS of 168 DGRP lines (of which the material used here is a subset) identified 115 SNPs associated with...
starvation resistance and 75 SNPs associated with startle response at a nominal p-value $\leq 10^{-5}$ in the analyses of sex-averaged data. We estimated SNP effects using RRBLUP and compared them to the significant SNPs from the GWAS study (Figure S2, Figure S3). There is excellent concordance of signals from both approaches in some regions (e.g. the genome-wide largest SNP effects on chromosome 3L for starvation resistance and 2L for startle response), while concordance is poor in other regions, especially on the X chromosome.

We further investigated whether the most significant SNPs detected in the GWAS are reflected by large SNP effects in the GBLUP study using a different approach. For each significant SNP position from the GWAS we took the 100 neighboring SNPs (50 on each side) and calculated the sum of the absolute values of their estimated effects using the GBLUP model. To avoid an effect of different sample size, we used the 75 most significant loci from the GWAS for both traits. We compared these sums to the sums of the absolute values of estimated SNP effects in ~250,000 sliding windows spanning the whole genome (with each window containing 100 neighboring SNPs). We observed a clear separa-
tion of the density functions of these sums for both startle response and starvation resistance (Figure 7).

The density resulting from the sliding window approach reflects the overall distribution of the suggested statistic in the sample. For starvation resistance (startle response) a threshold value of 0.0076 (0.0046), cf. Figure 7, cuts off the upper 10% of the respective distribution. Applying the same threshold with the density function reflecting the statistic for the significant GWAS positions, 33.3% (25.3%) of the distribution exceeds the threshold, indicating that signals found in the GWAS are also associated with large estimates of the SNP effects in the genomic model.

Analyses of individual trait data
In addition to the line means we also analyzed individual records (104 ± 21 individual flies per line tested for starvation resistance and 80 ± 7 for startle response) to assess whether the variance between lines can be fully explained by additive gene effects or if non-additive mechanisms have an impact. This was done by modeling the covariance structure between lines based on the additive and additive × additive genomic relationship matrix and testing the goodness of fit of the respective models. Most applications of genomic prediction are for outbred populations, for which the additive genetic variance and corresponding narrow-sense heritability determine the extent to which phenotypes in the next generation can be predicted from information obtained on the current generation. However, the variance among DGRP lines is the total genetic variance, and is possibly inflated by additive by additive epistatic variance [34]. Therefore, we performed several analyses on measurements of individual flies to determine the nature of the total genetic variance, especially to what extent the presence of non-additive genetic variance might have affected predictive abilities. We fitted three different models to the individual phenotype data: Model 1 contained a random line effect, and lines were assumed to be unrelated. In Model 2, a random additive line effect $g$ was added, whose covariance structure was modeled via the genomic relationship matrix $G$. In Model 3, an additional random additive × additive epistatic effect $g \times g$ was included, whose covariance structure was modeled via the Hadamard product $G \cdot G$. Since the between line variance relates to inbred lines, while the additive and additive × additive variance component pertain to the non-inbred base population (or a hypothetical random mating $F_2$ produced from the inbred lines), the variance between inbred lines in Model 1 is expected to be twice the additive genetic variance in Model 2 or 3 under a fully additive model.

We estimated variance components for all three models pooled across sexes and separately for males and females (Table S3, Table S4). We find little evidence for non-additive genetic variance for these traits. The estimate of $\sigma^2_g$ from Model 2 is $\frac{1}{2} \sigma^2_{\text{line}}$ from Model 1, and Model 2 gave a significantly better fit than Model 1 when applying the likelihood ratio test, again indicating that the observed between line variance is due to additive gene action. Inclusion of the $g \times g$ component was not significant for either of the traits. We found significant sex by line interaction variance for starvation resistance, but not for startle response (Tables S3, S4), which is in accordance with the findings of the genomic prediction across sexes (Table 1) and previous analyses of these data [27].

Discussion
We report the first (to our knowledge) application of genomic prediction to a real set of full genomic sequencing data in a eukaryotic organism. Although predictive abilities obtained with starvation resistance and startle behavior are only moderate to low, and although we limited our analysis to SNPs that are common due to the small sample size of lines, this study can be seen as a proof of concept for this approach. There are several reasons for the limited predictive ability obtained in this study. First, the training set is small, with a maximum of ~120 observations in the 5-fold CV, and the accuracy of genomic prediction is a function of the size of the training set [20]. Using the curves fitted through the empirical accuracies (Figure 3), we predict accuracies of ~0.58 for starvation resistance and startle response, if 1,000 sequenced lines were available for the training set.
The second important factor affecting accuracy of prediction is the number of independently segregating chromosome segments, $M_r$ [20]. In our study we obtained $M_r \sim 2,000$. This is larger than usually observed for Holstein cattle ($M_r \sim 640$ with $N_r \sim 100$ and genome length $L \sim 30$ Morgans [35]), but is smaller than the corresponding value in the human genome ($M_r \sim 14,000$ with $N_r \sim 3,000$; $L \sim 30$ Morgans, [36]). (Note that in mammalian species, there is recombination in both sexes and $M_r = \frac{2N_e L}{\ln(4N_e L)}$ [9].)

Accuracy of genomic prediction is thought to come from two sources: (i) SNPs in useful LD with causal loci; and (ii) SNPs reflecting the relationship structure between the training set and the set to be predicted [37]. Due to the very fast decay of LD in the *D. melanogaster* genome, few SNPs are in useful LD with any causal polymorphism. Even if we define “useful LD” very conservatively as $r^2 > 0.2$, then on average only a region of 120 bp around a causal polymorphism was in useful LD on an autosome (400 bp on the X chromosome). This means that on average 3 (6) SNPs were in useful LD with a causal autosomal (X-linked) polymorphism, as the average distance between neighboring SNPs was 45 bp (66 bp) on an autosome (X chromosome). If predictive ability was mainly driven by SNPs in LD with causal polymorphisms, reducing the SNP density should lead to a massive decay of predictive ability of the models, which was not observed. Little decrease in accuracy was seen, even if every 32nd SNP was used in the model, in which case hardly any SNP would be in useful LD with causal polymorphisms. The underlying mechanism therefore seems to depend on a sufficient number of SNPs being in low LD with causal polymorphisms, rather than few SNPs in close physical association and high LD. In the DGRP population, LD approaches a small but positive baseline level with increasing physical distance [27], so that even with large physical distances a minimum level of LD is maintained, which was on average $0.007 \sim \frac{1}{n}$ with $n = 157$ being the sample size.

The number of SNPs for maximal accuracy of genomic prediction with unrelated individuals has been estimated as $10N_e L$ [38], corresponding to $\sim 110,000$ SNPs in the present study.

For starvation resistance, we find that the empirical accuracy levels off when approximately every $16^{th}$ SNP is used, which is equivalent to $\sim 155,000$ or $7.3N_r L_r = 14.6N_e L$ SNPs. Adding more SNPs beyond this value does not lead to any improvement in the genomic prediction of starvation resistance, but also does not reduce accuracy, which one might expect when using more SNPs than actually needed. While fitting large numbers of “superfluous” SNPs may be considered as noise in the RRBLUP model, these SNPs can also be seen to provide a better basis to estimate the realized relationship matrix in the GBLUP model, which leads to a higher accuracy of the estimated realized relationships. Since both models are fully equivalent [9] no penalty is expected in the prediction of genomic values.

Since pedigree information for the founders of the inbred lines was not available, our estimates of heritability and genomic prediction are based on the actual degree of identity-by-descent sharing between relatives [39]. There is little pedigree structure in the DGRP lines, with the exception of two distinct blocks of higher relatedness, comprising 18 and 13 lines, respectively, with a genomic relationship within blocks of $\sim 0.25$ and 0.34. When these blocks were excluded from the data, predictive accuracy in a 5-fold CV increased (decreased) for starvation resistance (startle response), suggesting that prediction in the DGRP population does not rely on distinct family structures. Given this together with the short-range extent of LD in the *D. melanogaster* genome and the robustness of the accuracy of genomic prediction with reduced marker density, we conclude that the observed accuracy of prediction for starvation resistance and startle response is primarily due to the long-range LD in the population, or equivalently, the subtle relationship structure as reflected by the genomic relationship matrix.

We restricted our analyses to SNPs for which the minor allele was present in at least four DGRP lines (a minor allele frequency of 0.025). We applied this threshold to avoid computational limitations, especially when applying the BayesB method; and for consistency with the GWAS in the DGRP [27], which used the same filtering criterion. Thus, we did not utilize the $\sim 2$ million SNPs with minor allele frequencies less than this, nor did we take other forms of molecular variation into account.

Structural variations such as transposable elements have been repeatedly reported to be associated with phenotypic variation [40], therefore we must consider to what extent not including these variants in the models affected prediction accuracy. Given that we do not observe an increase in accuracy when increasing the number of SNPs from $\sim 150,000$ to 2.5 million, we do not expect that increasing the marker density by adding more SNPs and other variants will have a significant effect on predictive ability. Additionally, SNPs with low minor allele frequencies were shown to be highly variable in predictive ability, so that the potential amount of information possibly added by the 2 million low frequency SNPs is limited. However, accounting for all polymorphisms in the model means that some fraction of the genetic variants must causally affect the trait. Simulations [26] including the causal polymorphism in the model improves the predictive ability over models based only on neutral SNPs in LD with the causal variants. Further research is needed to understand these mechanisms in the context of genomic prediction based on empirical data.

The accuracy of BayesB has outperformed that of GBLUP in several simulation studies [10,37]. Simulation results have suggested that GBLUP did not take full advantage of genome sequence data, suggesting that Bayesian methods are needed to obtain maximum accuracy [26]. The superiority of BayesB over GBLUP is expected to increase with marker density, and decrease when the size of the training data set is increased [38]. However, we did not find that BayesB yielded a significantly higher predictive ability than GBLUP in the 20 replicates of 5-fold CV with starvation resistance implemented in the present study. We used a very high marker density and a small training set, and yet GBLUP performed as well as BayesB. These conclusions should be taken with caution, since the available size of the training set was extremely small in our study due to the limited availability of fully sequenced lines. In [20], BayesB yielded a higher accuracy than GBLUP, when the number of simulated QTL was low; but GBLUP slightly outperformed BayesB, when the number of QTL became large, since the GBLUP model is equivalent to RRBLUP, in which all SNPs are assumed to have an effect drawn from the same normal distribution. Although this model may not seem biologically plausible, it performed as well as BayesB in the present study, consistent with several studies on real data from dairy cattle for different traits [4,41].

The finding that BayesB did not outperform GBLUP in the present study is consistent with a quasi-infinitesimal genetic architecture; and results indicate that starvation resistance and startle response are complex traits with a highly polygenic genetic architecture rather than being driven by a few major causal genes. This is in agreement with previous studies stating that starvation resistance and startle response can be considered to be model traits with a complex (i.e. quasi-infinitesimal) genetic background [28–30]; and it is also in line with the results from the GWAS [27]. One reasonable conclusion might be that there are so many causal
polymorphisms, each with a small effect, that the ~2,000 effective chromosome segments are saturated with causal variants and the effects of segments follow a normal distribution. Under this circumstance, GBLUP is expected to perform as well as BayesB. However, these hypotheses clearly need further investigation. More systematic model comparisons based on the available data were not considered here due to the prohibitive computing time required for BayesB.

Previously, gene centered multiple regression and partial least square (PLS) regression models were used to predict starvation resistance and startle response phenotypes from genotypic data [27]. In both cases only SNPs that had nominal significance levels of \(P<10^{-5}\) from the GWAS were used. The gene centered prediction models found that a few SNPs explained a large fraction of the genetic and phenotypic variance of the traits, while the PLS models found that the significant SNPs explained a high fraction of the phenotypic variance. The purpose of these studies was a comparison with human association studies, in which the fraction of the variance explained by significant variants in the entire sample is commonly quoted. These approaches are fundamentally different from the BLUP approach used in this study. The BLUP approach includes random components and their covariation structure in the model, whereas regression models do not incorporate random terms except from the residuals; and the BLUP approach does not rely on a pre-selection of SNPs based on a GWAS. Most critically, we evaluated the robustness of the BLUP predictions using 5-fold cross-validation; whereas the previous analyses only tested the explanatory power of the most significant associated SNPs using the entire sample. Had we done the same analysis using GBLUP, we would be able to predict 100% of the variance.

The imperfect concordance of the positions of the most significant SNPs from the GWAS and the largest estimates of SNP effects from RRBLUP is a consequence of the different objectives of the two approaches. A sequence-based GWAS is conducted to identify causal polymorphisms and provide estimates of allelic effects and frequencies. Also, the GWAS suffers from estimating one effect at a time and so does not necessarily position the QTL accurately. The goal of RRBLUP is to predict the phenotype using all available SNP information simultaneously. Here, estimated SNP effects are a by-product and mapping causal variants is not the primary objective. Given that the number of SNP effects to estimate is much larger than the number of observations, effects are estimated using penalized multiple regression approaches, shrinking estimated effect sizes towards zero. In addition, the magnitude of estimated SNP effects from RRBLUP is a function of the marker density. The higher the marker density, the more SNPs will be in LD with a causal mutation; therefore, the true allelic substitution effect of a causal polymorphism will be split up and assigned in parts to a series of SNPs in the respective haplotype block. This can mask both the effect size, because one large effect may come in many small pieces; and the mapping position, because any SNP in LD with the causal polymorphism may have a substantial estimated effect. Nevertheless, some of the largest SNP effects from RRBLUP are in the proximity of prominent SNPs identified in the GWAS, so that to some extent positional information can still be retrieved from the RRBLUP results.

A methodology combining the strengths of both approaches – unbiased effect estimates and high positional resolution of GWAS with the simultaneous analysis of all SNPs, high predictive power and quality control via CV of genomic approaches – still needs to be developed. Results obtained in our study cannot be directly compared to predictive abilities in human studies due to the extremely small training set size (120 in CV), and Drosophila has much larger \(N_e\) and rapid decline of LD compared to humans.

When genomic prediction in human studies was based on large training sets (thousands), substantial SNP panels (400k) and a highly heritable trait (\(h^2=0.80\)), predictive ability of genomic models was found to exceed what has been previously reported using a reduced number of markers pre-selected based on GWAS [31] and genomic prediction based on pre-selected SNPs was found to be of limited use in human studies of height [42].

In the near future individual whole genome sequences will become increasingly available for large numbers of individuals in many species [17,18], Sequence-based predictions will therefore be relevant for prediction of risk disease and individualized medicine in humans, and for genome-based selection in farm animals and crops. The main findings of our study are: (i) genomic prediction can be efficiently implemented via GBLUP with full genome sequence data; (ii) there is little, if any, gain in predictive ability if the number of SNPs is increased above 14.6N\(_L\) (equivalent to ~43,000 in Holstein cattle and 1,300,000 in humans); and (iii) approaches based on external or internal (BayesB) selection of subsets of SNPs were not found to provide a substantial gain in accuracy of prediction compared to GBLUP. All findings must be seen against the background of the small sample size and the specific genetic constellation, with almost unrelated inbred lines and highly accurate phenotypes. Nevertheless, these results provide a realistic assessment of the potential benefits of sequenced-based prediction applied to non-model organisms and indicate avenues for future research.

Materials and Methods

The Drosophila Genetic Reference Panel (DGRP) [27], a recently developed new community resource for genetic studies of complex traits, consists of 192 \(D.\) \textit{melanogaster} lines derived by 20 generations of full sib mating from wild-caught females from the Raleigh, North Carolina population. Whole genome sequence data of 168 DGRP lines (Freeze 1.0) have been obtained using a combination of Illumina and 454 next generation sequencing technology, which are available from the Baylor College of Medicine, http://www.hgsb.bcm.tmc.edu/project-species-id-GGRP_lines hgsc. We used the Illumina sequences for 157 DGRP lines in this study.

Data preprocessing

SNPs were called from the raw sequence data as described previously [27]. We used SNPs with a coverage greater than 2X but less than 30X, for which the minor allele frequency was present in at least four lines, and for which SNPs were called in at least 60 lines. This series of filters gave a total of 2,490,165 SNPs for this analysis; 582,024 on 2L, 478,218 on 2R, 563,094 on 3L, 534,979 on 3R and 331,850 on the \(X\) chromosome. We did not consider the few SNPs on the very short chromosome 4. In total there were 18,077,784 missing SNP genotypes (4.6%), which we imputed using Beagle Version 3.3.1 software [43].

Phenotypic values

Phenotypic measurements for starvation resistance were available for all 157 DGRP lines, and for startle response on 155 lines [27]. We used the average of the medians of measurements for each trait in males and females as the phenotypic value \(y_i\) of the \(i^{th}\) line, \(i.e.\) \(y_i = 0.5(\bar{y}_i^m + \bar{y}_i^f)\), where \(\bar{y}_i^m\) and \(\bar{y}_i^f\) are the medians of the measurements for female and male individuals of the \(i^{th}\) line. We used medians because of the skewed distribution of

\[
\begin{align*}
\hat{y}_i &= \beta_0 + \beta_1 x_i + \epsilon_i \\
\end{align*}
\]
traits; however, medians are highly correlated with line means. For
starvation resistance (starle response) there were on average
$52 \pm 11 (40 \pm 4)$ measurements for females, and $52 \pm 11 (40 \pm 4)$
measurements for males (Table S1). Measurements were taken in
several replicates for each trait [27].

Cross-validation

We used different cross-validation (CV) procedures [44–46] to
assess the predictive ability of different methods. In one replicate of
a CV, the lines are randomly divided into a training set, which is
used for parameter estimation; and a validation set, for which
genetic values are predicted. The CV procedures differ in the
ratios of the numbers of lines belonging to the training and
validation sets: In a $(t: v)$-CV (with integers $t$ and $v$), the lines are
randomly divided into $(t + v)$ groups. The $t$ groups build the
training set, and the remaining $v$ groups build the validation set.

For this classification, there are $\binom{t + v}{t}$ possibilities. For each of
these possibilities (“folds”), total genetic values for the lines of the
validation set are predicted and the corresponding predictive
ability is calculated. The $\binom{t + v}{t}$ predictive abilities are then
averaged to obtain one average correlation per CV replicate. For
example, one $(3:2)$-CV, consists of $\binom{3 + 2 + 2}{3} = 10$ CV folds, over
which predictive abilities are averaged. A $(t: 1)$-CV is also called
$(t + 1)$-fold CV.

We used $(4:1)$-, $(3:2)$-, $(2:3)$- and $(1:4)$-CVs to analyze the effect
of decreasing training set size. The CVs also differed in the
constellations of phenotypic records used for the training and
validation set. For example, the notation “$(4:1)$ male – female”
indicates that only the medians of male records were used in the
training set, and that the predicted genetic values were correlated
with the medians of female records of the validation set to obtain
the predictive ability in a $(4:1)$-CV. CVs were also run for different
marker densities, using every $2^k$-th SNP ($k = 0, 1, \ldots, 10$). Additionally,
5-fold CVs using only the 5% SNPs with the largest absolute values of estimated effects (obtained in the training set), or using only the 5% SNPs with the largest SNP variances (obtained in the
training set) were performed. The additive genetic variance marked by the $i$-th SNP was calculated as $4p_i (1 - p_i) \sigma_i^2$ with allele
frequency $p_i$ and estimated SNP effect $\hat{s}_i$. In another series of
5-fold CVs we randomly chose 77,817 SNPs to build the genomic
relationship matrix or we randomly chose 10 blocks of adjacent
SNPs (each block consisting of 7,781 SNPs). In an additional 5-
fold CV we excluded the lines in the two blocks of higher
relatedness (Figure 2) from the data. Each type of CV was
replicated 20 times, resulting in 20 average predictive abilities.

We also analyzed the influence of minor allele frequency on the
predictive ability by another series of 5-fold CV. For this, we
sorted all SNPs by their minor allele frequency and divided the
sorted vector into 32 blocks. For each block we ran 20 replicates
of a 5-fold CV using GBLUP and the corresponding $\sim 78,000$ SNPs.

Predictive ability and accuracy

Predictive ability was measured in terms of correlation between
predicted genetic values and observed phenotypic values. The

---

**Genomic prediction with GBLUP**

The underlying statistical model is

$$y = \mathbf{W}\mu + \mathbf{Z}\mathbf{g} + \mathbf{e}.$$  (1)

In this model, the $i$-th component of the $q$-vector $y$ is the
phenotypic value of the $i$-th line that is used for prediction, i.e. the
average of the medians of the phenotypic measurements for males
and females for this line. Moreover, $\mathbf{W} = (1, \ldots, 1)^T$, it is the
overall mean; $\mathbf{g} \sim \mathcal{N}(0, \sigma_g^2 \mathbf{I})$ is assumed to be multivariate normal,
with $\mathbf{G}$ the genomic relationship matrix of all $n$ lines [8] and $\sigma_g^2$ the
additive genetic variance among lines. The matrix $\mathbf{Z}$ is an $(q \times n)$-
inclusion matrix, whose rows consist of unit vectors with one
component being 1 and all the others zero, indicating the
respective positions of lines used for prediction in the $\mathbf{g}$-vector
of genetic values of all lines. $\mathbf{e} \sim \mathcal{N}(0, \sigma_e^2 \mathbf{I})$ is the residual term, where $\sigma_e^2$ is the residual variance.
Following the approach of [8], $\mathbf{G}$ was defined as

$$\mathbf{G} = \frac{(\mathbf{M} - \mathbf{P})(\mathbf{M} - \mathbf{P})^T}{2 \sum_{j=1}^n p_j (1 - p_j)}.$$  

where $\mathbf{M}$ is the $(n \times n)$-matrix of SNP genotype vectors for the $n$
lines with the $s$ SNPs coded as $-1, 1$ and the $j$-th column of $\mathbf{P}$ is
$(2(p_j - 0.5), \ldots, 2(p_j - 0.5))^T$, where $p_j$ is the frequency of the
second allele at locus $j$.

Variance components were estimated via maximum likelihood
(ML) using the R-package “RandomFields”, Version 2.0.46
(http://CRAN.R-project.org/package=RandomFields), and its
function “fitvario”. The BLUP approach to obtain the vector of
genetic values is equivalent to solving the so-called Mixed Model
Equations (MME):

$$\begin{bmatrix} \mathbf{W}^T \mathbf{W} & \mathbf{W}^T \mathbf{Z} \\ \mathbf{Z}^T \mathbf{W} & \mathbf{Z}^T \mathbf{Z} + \frac{\sigma_G^2}{\sigma_e^2} \mathbf{G} \end{bmatrix}^{-1} \begin{bmatrix} \mu \\ \mathbf{g} \end{bmatrix} = \begin{bmatrix} \mathbf{W}^T \mathbf{y} \\ \mathbf{Z}^T \mathbf{y} \end{bmatrix}.$$  

A narrow-sense heritability based on the GBLUP model (1) was
calculated as

$$\hat{h}_{\text{GBLUP}}^2 = \frac{\sigma_g^2}{\sigma_g^2 + \sigma_e^2}.$$  

Estimation of SNP effects

The GBLUP model (1) is equivalent to the following linear
model in which all SNPs are assumed to have an effect drawn from
the same normal distribution [9]:

$$y = \mathbf{W}\mu + \mathbf{Z}(\mathbf{M} - \mathbf{P})\mathbf{s} + \mathbf{e},$$

where $\mathbf{Z}, \mathbf{M}$ and $\mathbf{P}$ are as described above and $\mathbf{s} \sim \mathcal{N}(0, \sigma_s^2 \mathbf{I})$ is the
vector of SNP effects with $\sigma_s^2 = \frac{\sigma_g^2}{2 \sum_{j=1}^n p_j (1 - p_j)}$. Using this
equivalence, the SNP effects can be predicted as

---

[44-46] are references to the literature cited in the document.}
\[ s = \sigma^2_t (M - P)^T Z (\sigma^2_t Z (M - P) (M - P)^T Z + \sigma^2_t^2 I)^{-1} (y - W\mu) \]
\[ = \frac{\sigma^2_t^2}{2 \sum_{j=1} p_j (1 - p_j)} (M - P)^T Z (\sigma^2_t Z G Z^T + \sigma^2_t^2 I)^{-1} (y - W\mu). \]

To estimate the SNP effects resulting from GBLUP for a single trait, we used all of the available lines, i.e. \( y \) in model (1) contained the phenotypic values of all lines so that \( Z = 1 \) in the corresponding formulas. Note that only the inversion of a matrix of size equal to the number of sequenced lines is required.

**Distribution of linkage disequilibrium**

We used \( r^2 \) [48] as a measure of LD between a pair of loci. With two biallelic loci \( A \) and \( B \) with alleles \( A_1, A_2, B_1 \), and \( B_2 \) and frequencies \( f_{A_1}, f_{A_2}, f_{B_1}, \) and \( f_{B_2} \), we denote the frequencies of the genotypes \( A_1 B_1, A_1 B_2, A_2 B_1, \) and \( A_2 B_2 \) as \( f_{11}, f_{12}, f_{21}, \) and \( f_{22} \) respectively. Then,
\[ r^2 = \frac{(f_{11} f_{22} - f_{12} f_{21})^2}{f_{A_1} f_{A_2} f_{B_1} f_{B_2}}. \]

We performed the LD analyses using the imputed SNP matrix of 2.5 million SNPs for the 157 lines. We calculated the distribution of LD between all pairs of neighboring SNPs for different marker densities, using every \( 2^k \)-th SNP \((k = 0, 1, \ldots, 10)\). The extent of long-range LD was calculated for 20,000 pairs of SNPs randomly sampled from the first and the last 50,000 SNPs per chromosome arm. Moreover, the average LD was calculated between SNPs on different chromosome arms, by sampling 10,000 pairs of SNPs for each combination of chromosome arms.

**Effective population size derived from empirical accuracies of genomic prediction**

We modified the formula [20] for the expected accuracy, \( \mathbb{E}(\rho) \), of GBLUP given different population parameters (see Text S1 for more details on the derivation in the case of \( D. \) melanogaster);
\[ \mathbb{E}(\rho) = \frac{N_p h^2}{\sqrt{N_p h^2 + \frac{N_{e} L_{f}}{\ln(2N_e L_f)}}}. \]

\( N_{e} \) is the effective population size, \( N_p \) is the size of the training set, \( L_f \) is the length of the female genome in Morgans and \( h^2 \) is the narrow-sense heritability of the trait estimated from model (1). The term \( M_{e} = \frac{N_{e} L_{f}}{\ln(2N_e L_f)} \) describes the number of independently segregating genome segments [9].

We ran CVs with different numbers of lines \( (N_{p, 1} = 31.4, N_{p, 2} = 62.8, N_{p, 3} = 94.2, N_{p, 4} = 125.6 \) for starvariance and \( N_{p, 1} = 31.4, N_{p, 2} = 62.8, N_{p, 3} = 93.5, N_{p, 4} = 124 \) for starl response) in the training set (20 replicates each). Average numbers of lines in the training set are reported, which are non-integer values for starvariance because in a \((t + v)\)-CV, division of 157 lines into \( t + v \) groups may give unequal numbers of lines in the different partitions. Given the corresponding average accuracies \( \rho_{p, t} = 1, \ldots, 4j = 1, \ldots, 20 \) for the CV replicates, we estimated \( N_{e} \) by fitting a curve to the points \( (N_{p, t}, \rho_{p, t}) \). To fit the curve, we chose \( N_{e} \) such that the sum of the squared differences of the observed accuracies and the accuracies obtained by (2) was minimized:

\[ N_{e} = \arg \min_{N_{e}} \sum_{ij} \left( \rho_{ij} - \frac{N_{p, h^2}^2}{N_{p, h^2}^2 + \frac{N_{e} L_{f}}{\ln(2N_e L_f)}} \right)^2, \]

using \( h^2 = h_{\text{BLUP}}^2 = 1 \) and \( L_{f} = 2.451 \) Morgan. We calculated the length of the female genome in Morgans by summing the lengths of the chromosomes in base-pairs \((23.0, 21.4, 24.4, 28.0, 21.8)\) Mbp for chromosome 2L, \((2R, 3L, 3R, X)\) [19] and multiplying by the average recombination rates of females for the different chromosomes in Morgans per base-pair [50].

After performing bootstrapping (1,000 replicates), the bias corrected empirical 95% confidence intervals (2.5% error in each tail) for the \( N_{e} \) estimates [32,51] were calculated as
\[ \left[ G^{-1}(\Phi(2z_0 + z^{(0)})), G^{-1}(\Phi(2z_0 + z^{(1-z)})) \right], \]
where \( G^{-1}(z) \) is the 100z-percentage of the bootstrap cumulative distribution function, \( z^{(0)} \) is the 100z-percentage of the standard normal distribution function \( \Phi, z = 0.025 \) and \( z_0 = \Phi^{-1}(G(N_{e})) \).

**Effective population size derived directly from linkage disequilibrium**

To estimate the effective population size based on LD, the following formula was used [52]:
\[ \mathbb{E}(r^2) = \frac{1}{1 + 2N_{c} e_{r}} \frac{1}{n} \Rightarrow \frac{1}{\mathbb{E}(r^2)} = \frac{n}{1 - 1/2c_{r}}, \]
where \( n \) is the number of lines and \( c_{r} \) is the recombination rate in female individuals, cf. Text S1 for more details on this formula.

**Genomic prediction with BayesB**

The underlying model for the Markov Chain Monte Carlo based BayesB [10] method is
\[ y = W\mu + M\mathbf{s} + \mathbf{e}, \]
where \( y, W\mu, M \) and \( e \) are as defined previously and \( \mathbf{s} \) is the vector of normally distributed and independent SNP effects. The variance of the \( p \)th SNP effect, \( \sigma^2_{s_p} \), is assigned an informative prior. The prior distribution of the genetic variances aims to resemble a situation where there are many loci with zero variance and only some loci with variance not equal to zero. Therefore, the prior distribution of the variance of a marker effect is a mixture of distributions which is given by
\[ \sigma^2_{s_p} \sim \chi^{-2}(v, 5) \quad \text{with probability} (1 - \pi) \]
\[ = 0 \quad \text{with probability} \ \pi \]
Note that this implies that the unconditional distribution of each single marker effect is a mixture of a point mass at 0 (with probability \( 1 - \pi \)) and of a \( \chi^2 \)-distribution with zero mean, \( v \) degrees of freedom and scale parameter \( 5 \) [21], i.e. BayesB assigns the same unconditional prior distribution to each marker effect.

In our studies, we used \( v = 4 \) and the scale parameter \( 5 \) was calibrated as.
S = (y - 2)\sigma^2_{\text{genetic}} / (1 - \pi) \sum_{j=1}^{\infty} 2p_j (1 - p_j).

We chose \( \pi = 0.995 \), such that approximately 125,000 markers were contributing to the additive genetic variance. For the residual variance, \( \sigma^2_{\text{res}} \), the prior distribution was \( \chi^2(V_{\text{res}}, \Sigma_{\text{res}}) \), with \( V_{\text{res}} = 10 \) and

\[ S_{\text{res}} = (V_{\text{res}} - 2)\sigma^2_{\text{res}} / V_{\text{res}}. \]

Values for \( \sigma^2_{\text{genetic}} \) and \( \sigma^2_{\text{res}} \) were chosen in the order of magnitude of the variance components of the GBLUP model [1], which were estimated using all lines and “flyvario”. The BayesB procedure is described in detail in [10]. It consists of running a Gibbs chain, where additionally a Metropolis-Hastings algorithm (10 iterations) is used to sample from \( p(\sigma^2_{\text{genetic}} | y^*) \), where \( y^* \) denotes the data \( y \) corrected for the mean \( \mu \) and all genetic effects other than the marker effect \( s_j \). Following graphical inspection, we ran BayesB with a chain length of 40,000 iterations including a burn in of 5,000 iterations that were discarded. To perform the BayesB approach, we used the software “GenSel”, Version 2.36, by R. Fernando and D. Garrick (cf. http://taurus.anisci.iastate.edu/Site/Welcome.html), which is implemented in C++. BayesB is computationally very intensive. The analyses were run on a Mac Pro 2 × 2.93 GHz 6-Core Intel Xeon with 64 GB RAM running Mac OS X Server 10.6.7. One fold of a 5-fold CV for starvation resistance took approximately 70 hours.

Comparing areas with large SNP effects with significant SNP positions

A genome-wide association study (GWAS) revealed 203(90) significant SNP positions for starvation resistance (starle response) [27], where a SNP position was considered significant if at least one of the three p-values, obtained using only male, only female or sex-pooled phenotypic records, was \( \leq 10^{-5} \). We considered the subset of SNPs for which p-values of SNP effects of pooled data were \( \leq 10^{-5} \), to be more conservative and to be consistent with the previous analyses, leading to 115(75) significant SNPs for starvation resistance (starle response).

We compared genomic regions for which GBLUP estimated large SNP effects to these significant SNP positions of the GWAS. To avoid an effect of different sample sizes, we chose the 75 most significant SNPs from the GWAS analysis for each trait. For each of these SNPs, we chose the 100 closest (neighboring) SNPs (50 on each side) and calculated the sums of absolute values of the corresponding 100 SNP effects (resulting from the GBLUP model). We compared the distribution of these sums to the distribution of the sums of the absolute values of estimated SNP effects in \( \sim 250,000 \) windows of 100 neighboring SNPs covering the whole genome by plotting the corresponding density functions. To obtain the sums of the absolute values of estimated SNP effects covering the whole genome, the windows were overlapping displaced by 10 SNP positions. If the genomic regions for which GBLUP estimated large SNP effects coincide with the significant SNP positions of the GWAS, we expect the density functions to be separated.

Variance component estimation using ASReml and individual trait records

For each trait, we fitted three different models using individual trait records. The first model included a fixed sex effect, a random line effect, a random line-sex-interaction term and a random term accounting for the different replicates in which measurements of the traits were taken:

\[ \text{phenotype} = \mu + \text{sex} + \text{line} + \text{sex} \times \text{line} + \text{replicate} + \text{sex} \times \text{line} + \text{replicate} \times \text{line} \times \text{line} \times \text{replicate} 
+ \text{residual} \]  
(Model 1)

In the second model, an additional random genetic effect \( g \) was added for each line. The variance-covariance matrix of the vector of these genetic effects was assumed to be given by the genomic relationship matrix \( G \) of [8]:

\[ \text{phenotype} = \mu + \text{sex} + \text{line} + \text{sex} \times \text{line} + g + \text{residual} \]  
(Model 2)

In the third model, an additional random additive × additive epistatic effect \( g \times g \) was included for each line. The variance-covariance matrix of the vector of these genetic effects was given by the Hadamard product \( G \times G \) [53] of the genomic relationship matrix \( G \) of [8]:

\[ \text{phenotype} = \mu + \text{sex} + \text{line} + \text{sex} \times \text{line} + g + \text{g} \times \text{g} + \text{residual} \]  
(Model 3)

Heritabilities

The broad-sense heritability for Model 1 was calculated as

\[ h^2_{\text{Model1}} = \frac{\sigma^2_{\text{line}} + \sigma^2_{\text{sex-line}} + \sigma^2_{\text{residual}}}{\sigma^2_{\text{line}} + \sigma^2_{\text{sex-line}} + \sigma^2_{\text{residual}}}, \]

cf. [28]. Narrow sense heritabilities for Models 2 and 3 were calculated as

\[ h^2_{\text{Model2}} = \frac{\sigma^2_g}{\sigma^2_{\text{line}} + \sigma^2_{\text{sex-line}} + \sigma^2_g + \sigma^2_{\text{residual}}} \]

and

\[ h^2_{\text{Model3}} = \frac{\sigma^2_g}{\sigma^2_{\text{line}} + \sigma^2_{\text{sex-line}} + \sigma^2_g + \sigma^2_g + \sigma^2_{\text{residual}}}. \]

These heritabilities are based on individual trait records. Unless stated otherwise, all statistical analyses were performed using R software [55]. The R-package “ff”, Version 2.2-1 (http://CRAN.R-project.org/package=ff), was used to handle the large amount of SNP data efficiently in terms of memory capacity.

Supporting Information

Figure S1 Predictive ability of 5-fold CV with GBLUP for starvation resistance using different set of SNPs with different average minor allele frequencies. Each boxplot shows the average
predictive abilities for 20 replicates of 5-fold CV using GBLUP and SNPs with different average minor allele frequencies. The different average minor allele frequencies are plotted as green dots. To choose the SNPs for each bin of minor allele frequency the SNPs were sorted by minor allele frequency and then divided into 32 blocks, i.e. each bin contained ~77,817 SNPs. The horizontal green line indicates the average accuracy obtained using every 32nd SNP (resulting in 77,817 SNPs as well), which was 0.212 ± 0.008.

**Figure S2** Manhattan plot of the estimated SNP effects for starvation resistance for different chromosomes. The SNP effects were estimated using the GBLUP approach and sex-averaged phenotypic values of 157 lines. Vertical lines indicate the 115 significant SNP positions according to the GWAS of [27] using sex-pooled records.

**Figure S3** Manhattan plot of the estimated SNP effects for starlate response for different chromosomes. The SNP effects were estimated using the GBLUP approach and sex-averaged phenotypic values of 155 lines. Vertical lines indicate the 75 significant SNP positions according to the GWAS of [27] using sex-pooled records.

**Table S1** Mean and standard deviation of phenotypic values and of the number of individual records per line.

**Table S2** Variance components and heritabilities estimated from GBLUP using all lines. Variance components were estimated by maximum likelihood using the R-package “RandomFields” and its function “fitvario.”

**References**

**Table S3** Results of variance component estimation using ASReml for starvation resistance. Different linear models for individual trait records were investigated.

**Table S4** Results of variance component estimation using ASReml for starlate response. Different linear models for individual trait records were investigated.

**Text S1** We give more details on the formula of [52] for the expected linkage disequilibrium as well as the derivation of the number of independently segregating chromosome segments \( M \) and the expected accuracy of prediction \( E(\rho) \) in the case of \( D. melanogaster \). We also derive the expected value of the genomic relationship matrix \( G \) of [9] and show that \( E(G) = A \), where \( A \) is the numerator relationship matrix.

**Acknowledgments**

We thank Stephanie M. Rollman and Michael M. Magwire for collecting the starvation resistance data and Katherine W. Jordan for collecting the starlate response data. We thank three anonymous reviewers for their valuable comments on previous versions of the manuscript.

**Author Contributions**

Conceived and designed the experiments: HS TFCM MS. Performed the experiments: RAG. Analyzed the data: UO. Contributed reagents/materials/analysis tools: UO JFA EAS CS MS TFCM. Wrote the paper: UO HS TFCM DG MS. Sequencing management: SR. DGRP sequencing bioinformatics: DZ. DGRP sequencing PI: RAG.
