Abstract

A 2328-membered library of 2,3,4-trisubstituted tetrahydroquinolines was produced using a combination of solution- and solid-phase synthesis techniques. A tetrahydroquinoline (THQ) scaffold was prepared via an asymmetric Povarov reaction using cooperative catalysis to generate three contiguous stereogenic centers. A matrix of 4 stereoisomers of the THQ scaffold was prepared to enable the development of stereo/structure-activity relationships (SSAR) upon biological testing. A sparse matrix design strategy was employed to select library members to be synthesized with the goal of generating a diverse collection of tetrahydroquinolines with physicochemical properties suitable for downstream discovery.
Introduction

The acid-catalyzed [4+2] cycloaddition of N-aryl imines and electron-rich olefins, known as the Povarov reaction,\(^1\) is a powerful method for the synthesis of tetrahydroquinolines (THQ), a commonly occurring motif in a variety of natural products and biologically active compounds (Figure 1).\(^2\) Up to three contiguous stereocenters can be generated simultaneously in the Povarov reaction, and enantioselective catalytic variants of this reaction have been identified recently.\(^3\) As part of our ongoing efforts to develop new methods for producing collections of stereochemically and skeletally diverse small molecules,\(^4,5\) we were interested in applying the the chiral urea/ Brønsted acid co-catalyzed asymmetric Povarov reaction\(^3a\) (Figure 2) to the synthesis of a THQ-based library.

Figure 1. Examples of natural products and biologically active compounds featuring a tetrahydroquinoline core.

At the outset of the project we faced three synthetic challenges in the production of a diverse THQ-based library: (1) adaptation of the asymmetric Povarov reaction conditions to
multigram scale, (2) development of a practical strategy for accessing a matrix of stereoisomers and (3) optimization of solid-phase diversification reactions. In this paper, we describe successful solutions to these challenges in the context of the large-scale synthesis of a collection of stereoisomeric THQ scaffolds as well as the solid-phase production of a 2328-membered THQ library.

Figure 2. Asymmetric co-catalysis of the Povarov reaction using a Brønsted acid and a chiral urea.

Results and Discussion.

Scaffold Design. In designing a THQ scaffold for library synthesis, we required two key features: 1) a primary alcohol for loading onto solid support and 2) chemical handles for introducing appendage diversity. With these features in mind, we began by selecting the imino Diels-Alder partners for the asymmetric Povarov reaction. Use of an imine glyoxolate 5, obtained from condensation of aniline 6 and ethyl glyoxolate 7, as the 4-π component, was attractive for a number of reasons (Figure 3). The use of glyoxolate ester derivatives would
provide a low molecular weight scaffold bearing a functional handle for loading the products onto solid-phase supports. In addition, the primary products of the Povarov reaction (8) contain an epimerizable stereogenic center that could allow further diversification of the scaffold. Finally, excellent enantio- and diastereoselectivities have been demonstrated in the ureacatalyzed asymmetric Povarov reaction of glyoxylate imines.\textsuperscript{3a}

**Figure 3.** Retrosynthesis of THQ scaffold 8.

Various substituted anilines (4-methyl ester 6a, 4-((tert-butyl(dimethyl)silyl)oxy) 6b, 4-bromo 6c) were evaluated as imine precursors in the Povarov reaction with dihydrofuran as a model dienophile. The imine generated from 6a was unstable and resulted in a low yield on large scale in the Povarov reaction. Meanwhile, reactions of 6b were found to be poorly reproducible and became problematic with future protecting group manipulations. In contrast, 6c offered good reactivity and reproducibility in the imine formation on large scale. Furthermore, the aryl bromide could be used as a diversity site on solid phase for cross coupling reactions.\textsuperscript{7} It was
found that the Povarov adduct could be recrystallized and thus confirming the absolute configuration of the cycloaddition product with *endo* stereochemistry.\(^8\)

With the diene in hand, we moved on to study the dienophile partner 9. We focused on dienophiles featuring a handle for solid-phase diversification and those which showed good reactivity while retaining high levels of enantio- and diastereoselectivity in the Povarov reaction. As noted in previous reports, 2,3-dihydropyrrole derivative 10 is a versatile dienophile for the Povarov reaction.\(^{3a,9,10}\) We conducted a study (Table 1) to determine the most suitable protecting group for the pyrrole nitrogen under Povarov reaction conditions. As expected, a noticeable difference in reactivity was observed based on the nature of the protecting group. For example, the nosylated pyrrole 10a proved unreactive during the Povarov reaction mostly due to poor solubility in toluene at low temperatures (-60 °C) (entry 1). Meanwhile, use of Boc-protected pyrrole 10b led to an overall decrease in yield (38%) and diastereoselectivity (from 9:1 to 7:3 *dr*) (entry 2). However, it was found that Fmoc and Cbz carbamates, 10c and 10d gave more suitable results with up to 80% isolated yield of the corresponding cycloadduct and with good levels of diastereoselectivity (9:1 *dr*) and enantioselectivity (up to 93:7 *er*). Thus, dienophile 10c and 10d were selected for the scale up of the THQ scaffolds for library production.

Large-scale reaction optimization. Having selected 5c as diene and 10c and 10d as dienophiles, we next evaluated the optimization for the asymmetric Povarov reaction on multigram scale to achieve high yield and optimal levels of enantio- and diastereoselectivity suitable for library production. In preliminary studies, we found that the manner in which the imine was generated was a critical parameter for obtaining consistent results on large scale. The imine formed in situ was found to be extremely sensitive to nucleophilic attack with an excess of aniline leading to side product formation. A practical procedure was developed involving formation of the imine via slow addition of aniline 6c into glyoxolate 7 in toluene at 0 °C, followed by isolation of the crude imine via solvent removal in vacuo.
Initially, when employing previously described conditions for the Povarov reaction\textsuperscript{3a} (4% mol of urea catalyst \textbf{1}, 2\% mol of NBSA as Brønsted acid in toluene at \(-60^\circ C\) in presence of 5Å MS, 1 mmol scale), we observed formation of the desired product \textbf{11} with good enantio- (9:1 \textit{er}) and diastereoselectivity (9:1 \textit{dr}) albeit in modest yield (40\%) (Table 2, entry 1). We hypothesized that residual amount of water from the Brønsted acid may hydrolyze the water-sensitive imine 5\textsuperscript{c}\textsuperscript{10,13} and therefore affect the overall isolated yield of \textbf{11} on large scale. After studying the effect of other Brønsted acids in the Povarov reaction, we found that the use of anhydrous \textit{p}-toluenesulfonic acid (PTSA)\textsuperscript{14} gave comparable results (yield and enantio- and diastereoselectivity) to NBSA (Table 2, entries 2 and 3). Anhydrous PTSA was found to be easy to use and could be stored for several weeks at room temperature in a desiccator. Thus, for practical reasons we decided to use PTSA for the remainder of our optimization experiments. This modification enable us to conduct the asymmetric Povarov reaction on large scale with up to 66 mmol of \textbf{5} (17 g) in presence of \textbf{10c} as the dienophile to give moderate yield and good enantiomeric ratio (65\%, 88:12 \textit{er}, entry 5). Similar yield and enantioselectivity of \textbf{11d} was obtained when \textbf{10d} was used as dienophile in the Povarov reaction. In addition, \textbf{11d} could be easily purified \textit{via} crystallization to give almost enantiomeric pure material. Gratifyingly, we observed no erosion of reactivity when using lower catalyst and Brønsted acid loading (2 mol\% of urea catalyst and 1 mol\% of PTSA (entries 3 and 4)). Similar results were obtained in the Povarov reaction when the enantiomer of the urea catalyst \textbf{1} was employed.\textsuperscript{15}
Epimerization studies. In order to obtain stereochemical diversity, a practical method to epimerize the stereogenic center adjacent to the ester was sought to convert the endo diastereomer 11c into the thermodynamically favored exo diastereoisomer 12c. Although there was precedent for a similar epimerization strategy via the corresponding aldehyde in the synthesis of the natural product martinelline,\(^6\) we were hoping to develop a synthetic sequence to access 12c directly and on large scale. After extensive screening of epimerization conditions,\(^7\) it was found that treatment with 0.1 M solution of sodium methoxide in methanol at 60 °C gave the desired epimerization product 14c in 70% yield. The endo methyl ester 13c that was recovered after purification could be resubjected to the same conditions to give 14c in 90% overall yield over two cycles.
**Library Scaffold Preparation.** For solid-phase library production, a protecting group manipulation was required to replace the incompatible Cbz group with Fmoc. To streamline the preparation of the final cores, we decided to utilize Fmoc-pyrrole 10d as the dienophile to generate *endo* diastereoisomers and Cbz-pyrrole 10c to generate the remaining *exo* diastereoisomers. After Povarov cycloaddition using Fmoc-pyrrole 10d with either 1 or its enantiomer, cycloadduct 11d was reduced using LiBH₄ to afford the corresponding primary alcohol 15d. Scaffold 15d could be easily recrystallized in a 9:1 mixture of benzene and dichloromethane to give enantioenriched compounds with excellent enantioselectivity (99:1 *er*). After epimerization of 11c to 14c, the *exo* Fmoc protected diastereoisomer was obtained via a step wise processes involving: 1) ester reduction using LiBH₄ and 2) protecting group exchange from the incompatible Cbz to Fmoc in order to afford 16d. Recrystallization of 16d afforded enrichment of enantiopure compound up to 97:3 *er*.

During initial feasibility studies, it was found that the THQ aniline had limited reactivity upon treatment with various electrophiles, such as acyl chlorides and sulfonyl chlorides thus restricting its use as diversity site for solid-phase production. However, it was found that the aniline could be alkylated by reductive amination with a limited number of aldehydes. Formaldehyde was found to be the most reactive among the aldehydes tested. Scaffolds 15d and 16d were therefore methylated *via* reductive amination with excellent yields (90%) to give 17d and 18d. This strategy allowed us to generate eight different scaffolds, including both enantiomers of the NH and NMe *endo* and *exo* cores (Figure 3).
Scheme 2. Solution-phase synthesis of library scaffolds

Figure 3. Matrix of 4 stereoisomers for the NH and NMe THQ scaffolds.
**Solid-Phase Feasibility Studies.** With the NH and NMe THQ-scaffolds in hand, we turned our attention to the development of solid-phase methods for the introduction building blocks at the two diversity sites (secondary amine and aryl bromide). Amine capping at the first diversity site for both the NH and NMe sub-libraries involved screening with a variety of electrophiles, including isocyanates, sulfonyl chlorides, aldehydes and acids. Bis-capping was observed with the use of isocyanates in the presence of the free aniline and therefore removed from the design of the NH sub-library. While isocyanates performed well for the NMe sub-library, the use of aldehydes was problematic resulting in significant decomposition during reductive alkylation conditions. Therefore aldehydes were removed from the NMe sublibrary design. Acids and sulfonyl chlorides performed well for both sub-libraries.

Next, the feasibility of Pd-mediated cross coupling reactions at the aryl bromide was investigated. Both Sonogashira and Suzuki cross coupleings were explored. Initial screenings of the Sonogashira cross coupling led to poor conversion and produced a significant amount of side products. Therefore, we decided to focus solely on the Suzuki cross coupling for production purposes. Traditional Suzuki conditions on solid phase were attempted using 3-methoxybenzene boronic acid 19 and sulfonamides 20 and 21 as a model (Table 5, entry 1). Moderate conversion to the desired product was observed in addition to a significant amount of unknown byproduct formation, possibly due to a rapid protodeboronation step\(^9\) versus a slow oxidative insertion step. A variety of other conditions were screened including ligand (P(\(t\)-Bu))\(_3\), PEPPSI 26,\(^{20}\) S-Phos 24, Pd catalyst (PdCl\(_2\)(PPh\(_3\))\(_2\), Pd(dba)\(_2\)), bases (TEA, K\(_3\)PO\(_4\), Cs\(_2\)CO\(_3\)) and solvents (EtOH, PhMe, 1,4-dioxane, THF) in an attempt to increase the rate of oxidative insertion and potentially limit formation of side products without success (Table 5, entries 1-4). A recent publication
from the Buchwald lab highlights the use of X-phos ligand in a preformed catalyst. The use of such precatalyst was reported to increase the rate of boronic acid coupling versus its decomposition due to the use of milder reaction condition. Upon treatment with the Buchwald precatalyst 27 at room temperature, we were delighted to find formation of the desired cross coupling product in high conversion without the formation of undesired side products for both NH and NMe sub-libraries (entries 5 and 6).

*Conversion was measured by UPLC with UV detection at 210 nm.*
With this information in hand, a sparse matrix design strategy for each sub-library was implemented to select library members to be synthesized. First, a virtual library was constructed for both sub-libraries using all possible building block combinations at R_1 (amine) and R_2 (aryl bromide) using a master list of reagents (R_1 = sulfonyl chlorides, isocyanates, acids and aldehydes; R_2 = boronic acids). This resulted in ~2400 compounds per stereoisomer. Physicochemical property filters were then applied to eliminate building block combinations that led to products with undesirable properties. Property filters included the following: MW ≤500, ALogP -1 to 5, H-bond acceptors + donors ≤10, rotatable bonds ≤10 and TPSA ≤140. A total of 274 compounds per scaffold for the NH sub-library and 310 compounds per scaffold for the NH sub-library were selected from the remaining set using chemical similarity principles, maximizing diversity but retaining near neighbors for built-in SAR. The reagents selected for library production are shown below (Chart 1 and Chart 2). The same set of reagents was used for each stereoisomer thereby maintaining the ability to generate SSAR for each building block combination.

**Solid-Phase Library Production.** With the solid-phase feasibility studies complete, we turned our attention to library production. Immobilization of the scaffold onto solid support was achieved via activation of the SynPhase Lanterns (L-series) with triflic acid followed by treatment with scaffolds 15-18 in the presence of excess 2,6-luditine (Scheme 3). The average loading levels obtained were 17 µmol/Lantern for the NH sub-library and 13.3 µmol/Lantern for the NMe sub-library. Removal of the Fmoc protecting group under standard conditions followed by capping with the appropriate electrophilic building blocks for NH and NMe sub-libraries yielded compounds 12{1-42} and 13{8-54}. Subsequent Pd-mediated cross coupling utilizing the Suzuki reaction afforded compounds 14{1-42, 1-14} and 15{8-54, 1-14}. Once the reaction sequence was complete, the Lanterns were subjected an aqueous sodium cyanide wash (1:1 1.0 M NaCN in water:THF solution) in order to remove any residual Pd. Release of the final compounds (16{1-42, 1-14} and 17{8-54, 1-14}) from solid support was achieved via treatment with HF/pyridine. All library products were analyzed by ultra-performance liquid chromatography, and compound purity was assessed by UV detection at 210 nm. The average
purity of the THQ NH library (1088 compounds) was 78%, with 71% of the library being >75% pure, while the average purity of the THQ NMe library (1240 compounds) was 75%, with 68% of the library being >75% pure. A full purity analysis is provided in Figure 5. Of note, certain nitrogen containing building blocks proved problematic during the amine capping for the NH sub-library, including acids 12, 24, 29 and 30, while the trans-1-propenylboronic acid (1) generally did not perform well for either sub-library.

Scheme 3. Solid-phase synthesis of THQ library on SynPhase Lanterns
Figure 5. Purity analysis for THQ library (UPLC analysis with UV detection at 210 nm).

Library members are displayed as blocks of 4 stereoisomers (see legend) for both the NH and NMe sub-libraries. Reagents used for solid-phase diversification are shown on the x- and y-axes. (See Charts 1 and 2 for detailed list of reagents).
**Library Analysis.** Analysis of the THQ library (Table 1 and Figure 6) reveals that the calculated physicochemical property profile for the compound set is within the intended range for the library design (*vide supra*). Meanwhile, the structural diversity of the THQ library was analyzed in comparison to the NIH Molecular Library Repository (MLSMR) as we intended to submit a subset of these compounds to the collection at the time of the analysis. We employed multifusion similarity (MFS) maps for the comparison of each collection using extended connectivity fingerprints (ECFP_4) for molecular representation and Tanimoto coefficient as the similarity measure. In this method, each molecule in the test set (THQ library) is compared to every molecule in the reference set (2011 MLSMR) and the largest similarity score and the mean similarity score to the reference set is obtained. The resulting mean similarity (x-axis) and maximum similarity (y-axis) values are plotted in two dimensions as a scatter plot facilitating the visual characterization and comparison. Figure 6 shows the MFS map comparing the THQ library to the MLSMR. Each data point in the map depicts a compound from the test set and its location was influenced by the reference set. (The reference compounds themselves do not appear on the plot). The maximum mean similarity of the THQ library is 0.13 (Tc) indicative of the overall structural diversity with the respect to the MLSMR reference set. Furthermore, there are no compounds with maximal similarity equal or greater than 0.57 (Tc) in the MLSMR, illustrating that these compounds represent regions of unoccupied chemical space within this collection.

Conclusions

In summary a 2328-membered library of tetrahydroquinolines was successfully prepared using the asymmetric Brønsted acid/urea-catayzed Povarov reaction$^{3a}$ as a key step. Adaptation of the Povarov reaction for large scale synthesis led to the use of anhydrous PTSA as the Brønsted acid in place of NBSA and optimization of the imime formation step. These
modifications enabled the large scale (>5 g) preparation of 4 stereoisomers of two THQ scaffolds with two functional handles for solid-phase diversification. *In silico* library design followed by production on SynPhase Lanterns afforded a diverse library of functionalized tetrahydroquinolines with properties suitable for downstream discovery.

12. This side product was identified as the aminal adduct.

13. NBSA is commercially available only as the hydrate (containing x molecules of water). To remove residual amounts of water, NBSA was dissolved in a minimum amount of dry THF and azeotroped with toluene. This sequence was repeated three times until a dark brown viscous oil was obtained. The light sensitive oil was dried under high vacuum over CaCl₂ and stored in the dark.

14. p-Toluenesulfonic acid was dehydrated by azeotropic distillation with toluene using a Dean-Stark apparatus. The residue was then crystallized from benzene.

15. The SSS enantiomer urea catalyst was obtained from Astatech, Inc.
