Immune responses are modified by a diverse and abundant repertoire of carbohydrate structures on the cell surface, which is known as the glycome. In this study, we propose that a unique glycome that can be identified through the binding of galectin-4 is created on local, but not systemic, memory CD4+ T cells under diverse intestinal inflammatory conditions, but not in the healthy state. The colitis-associated glycome (CAG) represents an immature core 1–expressing O-glycan. Development of CAG may be mediated by down-regulation of the expression of core-2 β1,6-N-acetylgalactosaminytransferase (C2GnT) 1, a key enzyme responsible for the production of core-2 O-glycan branch through addition of N-acetylgalactosamine (GalNAc) to a core-1 O-glycan structure. Mechanistically, the CAG seems to contribute to super raft formation associated with the immunological synapse on colonic memory CD4+ T cells and to the consequent stabilization of protein kinase C ζ activation, resulting in the stimulation of memory CD4+ T cell expansion in the inflamed intestine. Functionally, CAG-mediated CD4+ T cell expansion contributes to the exacerbation of T cell–mediated experimental intestinal inflammations. Therefore, the CAG may be an attractive therapeutic target to specifically suppress the expansion of effector memory CD4+ T cells in intestinal inflammation such as that seen in inflammatory bowel disease.

The surface of all mammalian cells is covered by complex carbohydrate structures termed glycans (van Kooyk and Rabinovich, 2008). The glycan structure is determined by the enzymatic processes that produce glycosidic linkages of saccharides to other saccharides, and the expression profile of these glycan-modifying enzymes is altered by several factors, such as cell differentiation and activation, inflammatory insults, and the environment (Marth and Grewal, 2008; Baum and Crocker, 2009; Rabinovich and Toscano, 2009). The importance of the glycome in immune responses has been highlighted by its role in the control of cell homing, apoptosis, and microbial recognition (Marth and Grewal, 2008; van Kooyk and Rabinovich, 2008; Baum and Crocker, 2009; Rabinovich and Toscano, 2009). Consequently, there is a diverse and abundant repertoire of glycan structures on the cell surface, which is known as the glycome (Marth and Grewal, 2008; van Kooyk and Rabinovich, 2008; Rabinovich and Toscano, 2009). In addition, a recent human genetic study provides support for an alteration of the glycome in B cell signaling as a protective factor in some autoimmune diseases (Surolia et al., 2010). Therefore, understanding the functional role of each glycome motif in the immune response can potentially open up a new avenue for the treatment of immune-mediated diseases (Rabinovich and Toscano, 2009).

Inflammatory bowel disease (IBD) is a chronic intestinal inflammatory condition that develops in a genetically predisposed host. IBD is characterized by two major forms, Crohn’s disease (CD) and ulcerative colitis (UC), which are mediated by both common and distinct mechanisms (Xavier and Podolsky, 2007; Kaser et al., 2010; Mizoguchi and Mizoguchi, 2010). For example, Th1/Th17 responses have been implicated in the pathogenesis of CD, whereas UC has a significant contribution from Th2 cytokines (Xavier and Podolsky, 2007; Kaser et al., 2010; Mizoguchi and Mizoguchi, 2010). However, both diseases are characterized by a significant expansion of inflammatory memory CD4+ T cells in the inflamed intestine (Xavier and Podolsky, 2007; Kaser et al., 2010). Although much is known about the pathogenic effector mechanisms in these diseases, little information is currently available on how the carbohydrate structure of T cells contributes to these responses (Santucci et al., 2003; Hokama et al., 2004; Müller et al., 2006; Srikrishna et al., 2005). This is in contrast to the abundant amount of information available on the heavily O-glycosylated mucus that has been clearly demonstrated to play a protective role in IBD (An et al., 2007; Stone et al., 2009).

We herein demonstrate a colitis-associated glycome (CAG) on CD4+ T cells, which is characterized by immature core-1 O-glycan and induced through down-regulation of core-2 β1,6-N-acetylgalactosaminyltransferase (C2GnT) 1 expression under intestinal inflammatory conditions. We also propose that the inducible glycome motif contributes to the exacerbation of colitis by enhancing the expansion of effector memory CD4+ T cells through stabilization of protein kinase C (PKC) θ activation.

RESULTS
Colitis-associated T cell glycome
An endogenous glycan-binding protein family, the galectins, is composed of 15 members that recognize different carbohydrate epitopes and play different roles (e.g., anti- versus pro-inflammatory) in immune responses (Lowe, 2001; Baum and Crocker, 2009; Hsu et al., 2009; Rabinovich and Toscano, 2009). We previously demonstrated that an increased binding of galectin-4 is specifically seen on CD4+ T cells in the inflamed, but not normal, colon of Th2-mediated experimental colitis model (Hokama et al., 2004). We herein demonstrate that the binding of galectin-4 is also intensified on CD4+ T cells, but not CD4− cell populations, in the inflamed colon of Th1-mediated colitis model (CD45RB model) as compared with those in the normal colon of WT mice (Fig. 1 A). In contrast, intensified binding of galectin-4 was not observed on CD4+ T cells in other tissues (lung and liver) of this colitis model (Fig. 1 B). To see whether the intensified galectin-4 binding on CD4+ T cells is a specific feature of colitis or a common feature associated with any inflammatory conditions, we next examined a concanavalin A–induced hepatitis model. Interestingly, binding of galectin-4 on CD4+ T cells was decreased in the inflamed liver (Fig. 1 B, right).

Galectins are structurally classified into three groups (prototype, chimera type, and tandem-repeat type), and galectin-4 belongs to the tandem-repeat type (Lowe, 2001; Baum and Crocker, 2009; Hsu et al., 2009; Rabinovich and Toscano, 2009). To test whether the inflammation-inducible binding on colonic CD4+ T cells is specific for galectin-4, we used another tandem-repeat galectin (galectin-8) and a prototype galectin (galectin-3). Unlike galectin-4, there was no difference in the binding pattern of galectin-8 on CD4+ T cells from inflamed versus normal colon (Fig. 1 C, left). The different binding pattern between galectin-4 and -8 may be caused by the ability of galectin-8 to interact with more diverse arrays of glycan structures as compared with galectin-4 (Vokhmyanina et al., 2012). In addition, no difference in the binding pattern of galectin-3 was observed when CD4+ T cells from inflamed versus normal colon were examined (Fig. 1 C, right). Because galectin-3 interacts with complex N-glycans (Lowe, 2001), it is possible that O-glycan, rather than N-glycan, on colonic CD4+ T cells is more susceptible to inflammation-induced alteration.

As observed in mouse models, CD4+ T cells from the inflamed colon of both UC and CD patients also exhibited increased galectin-4 binding in comparison to noninflammatory controls (Fig. 1 D). Interestingly, this binding was also observed with CD4+ T cells from the inflamed colon of patients with Campylobacter infection (Fig. 1 D). Flow cytometric analysis confirmed a more intensified binding of galectin-4 on CD4+ T cells isolated from the inflamed area of UC patients as compared with those from noninflamed area (Fig. 1 E). Interestingly, in UC patients, galectin-4-binding was rarely observed on CD8+ T cells from the inflamed colon or on CD4+ T cells from the peripheral blood (Fig. 1 E), which is consistent with a previous study showing no galectin-4 binding on peripheral mononuclear cells (Paclik et al., 2008). Collectively, these findings suggest that a common glycome, which can be identified by intensified galectin-4 binding, is created on colonic CD4+ T cells under intestinal inflammatory conditions in mice and humans.

Decreased C2GnT expression in colitis
Glycome is produced by the coordinated action of glycan-modifying enzymes (Marth and Grewal, 2008; van Kooyk and Rabinovich, 2008; Baum and Crocker, 2009; Rabinovich and Toscano, 2009). We therefore performed real-time, PCR-based preliminary screening to examine the expression profile of 63 major glycan-modifying enzymes in purified CD4+ T cells from inflamed versus normal colon (unpublished data). As the result, we found that core-2 β1,6-N-acetylgalactosaminyl transferase (C2GnT) 1 was commonly down-regulated in the CD4+ T cells obtained from the inflamed colon of various
glycome \( \text{CAG} \) represents the immature core-1 O-glycan. Indeed, an exogenous lectin peanut agglutinin (PNA), which interacts specifically with nonsialylated immature core-1 O-glycan (Toscano et al., 2007), was observed to bind to \( \text{CD4}^+ \) T cells derived from the inflamed, but not normal, colon (Fig. 2 B). Competition of C2GnT1 and ST3Gal1 sialyltransferase for sialylation of core-1 O-glycan has previously been shown to control thymic \( \text{CD8}^+ \) T cell homeostasis (Priatel et al., 2000). Therefore, we next examined the expression of ST3Gal-1 in colonic \( \text{CD4}^+ \) T cells. Interestingly, no significant change or rather decrease in the ST3Gal1 expression was observed in colonic \( \text{CD4}^+ \) T cells from inflamed colon as compared with those from normal colon (Fig. 2 C), suggesting that CAG may be created through a unique O-glycan biosynthesis pathway that favors generation of a nonsialylated immature core-1 O-glycan. As observed in mice, down-regulation of both C2GnT and ST3Gal1 expressions was seen in the purified \( \text{CD4}^+ \) T cells from the involved areas (colon) in comparison to those obtained from the non-involved areas of UC patients (Fig. 2 D).

colitis models as compared with \( \text{CD4}^+ \) T cells in the normal colon of WT mice (Fig. 2 A). The colitis models used include Th1-mediated colitis (CD45RB model) that was induced in RAG1\(^{-/-}\) mice by adoptive transfer of \( \text{CD4}^+ \) CD45RB\(^{\text{high}} \) naive T cells from WT spleen, Th2-mediated colitis that spontaneously develops in TCR\(\alpha^-/-\) mice, and memory T cell–induced colitis that was induced in TCR\(\beta^-/-\) and IL-2–deficient double KO (TBI–2 DKO) mice by adoptive transfer of \( \text{CD4}^+ \) CD45RB\(^{\text{low}} \) memory T cells from WT spleen, and acute intestinal injury that was induced by oral administration of 4% dextran sulfate sodium (DSS) for 4 d (Fig. 2 A).

C2GnT1 represents the key enzyme responsible for the production of core-2 O-glycan branch through addition of N-acetylgalactosamine (GlcNAc) to a core-1 O-glycan structure (Tsuboi and Fukuda, 1997, 1998; Lowe, 2001). Because galectin-4 has previously been demonstrated to interact with selected glycans, such as an immature (nonsialylated) core-1 O-glycan (Ideo et al., 2002; Blixt et al., 2004), this finding has prompted us to develop a hypothesis that colitis-associated glycome (CAG) represents the immature core-1 O-glycan. Indeed, an exogenous lectin peanut agglutinin (PNA), which interacts specifically with nonsialylated immature core-1 O-glycan (Toscano et al., 2007), was observed to bind to \( \text{CD4}^+ \) T cells derived from the inflamed, but not normal, colon (Fig. 2 B). Competition of C2GnT1 and ST3Gal1 sialyltransferase for sialylation of core-1 O-glycan has previously been shown to control thymic \( \text{CD8}^+ \) T cell homeostasis (Priatel et al., 2000). Therefore, we next examined the expression of ST3Gal1 in colonic \( \text{CD4}^+ \) T cells from inflamed colon as compared with those from normal colon (Fig. 2 C), suggesting that CAG may be created through a unique O-glycan biosynthesis pathway that favors generation of a nonsialylated immature core-1 O-glycan. As observed in mice, down-regulation of both C2GnT and ST3Gal1 expressions was seen in the purified \( \text{CD4}^+ \) T cells from the involved areas (colon) in comparison to those obtained from the non-involved areas of UC patients (Fig. 2 D).
To test whether the decreased C2GnT expression observed in mouse and human CD4+ T cells in the setting of inflammation is responsible for the development of CAG, we next restored C2GnT expression in CD4+ T cells by using T cell–specific C2GnT transgenic (T/C2GnT tg) mice that lack surface expression of core-1 O-glycan because of forced expression of this enzyme (Tsuboi and Fukuda, 1997, 1998). Indeed, PNA and galectin-4 were unable to bind to the C2GnT-expressing CD4+ T cells in the inflamed colon (Fig. 2 E, right). In addition, the restoration of C2GnT expression suppressed the binding of *Maackia amurensis* lectin II (MALII), which is capable of interacting with both sialylated and non-sialylated core 1 O-glycans (Geisler and Jarvis, 2011). Interestingly, binding of *Helix pomatia* lectin (HPA) and *Lycopersicon esculentum* lectin (LEL), which interact with other glycan structures, was intensified under inflammatory condition. However, the intensified binding on colonic CD4+ T cells was not suppressed by restoration of C2GnT expression (Fig. 2 E). Collectively, these findings suggest that down-regulation of C2GnT expression during inflammation is responsible for the generation of CAG recognized by galectin-4.

**Pathogenic role of CAG in colitis of CD45RB model**

To examine whether the expression of CAG on CD4+ T cells plays any role in colitis, we examined a naive T cell–induced colitis model (CD45RB model; Izcue et al., 2009). In brief, CD4+CD45RB<sup>high</sup> naive T cells were purified from the spleen of WT versus T/C2GnT tg mice and transferred into Rag<sup>1−/−</sup> mice lacking T and B cells, and the recipient mice were sacrificed at 8 wk after cell transfer. As previously demonstrated (Izcue et al., 2009), the donor T cells from WT mice induced the development of severe colitis in the recipients (Fig. 3 A, B) and expressed the CAG in the inflamed colon (Fig. 2 E). In contrast, CD4+ T cells with restored expression of C2GnT were significantly less able to induce the development of colitis (Fig. 3, A and B), consistent with their inability to express the CAG (Fig. 2 E). As predicted, no colitis was found in control WT mice (Fig. 3 A). The disease severity was further supported by the colonic expression level of an inflammatory cytokine; significantly increased IL-1β expression were observed in the colon of *Rag1<sup>1−/−</sup>* mice reconstituted with WT-derived CD4+ T cells as compared with those reconstituted with T/C2GnT tg–derived CD4+ T cells (Fig. 3 C). These findings demonstrate that ability of CD4+ T cells to express CAG is a significant contributor to the exacerbation of this naive T cell–induced colitis.

**Figure 2. Development of CAG by down-regulation of C2GnT expressions.** (A) Expression levels of C2GnT1 in purified CD4+ T cells from the normal colon of WT mice and from the inflamed colon of four kinds of colitis models were examined by real-time PCR. The colitis models include TCRα<sup>−/−</sup> mice, DSS model, CD45RB model, and BIL-2 DKO model, n = 6–7/each group, *P < 0.001. (B) Binding intensities of PNA on colonic CD4+ T cells from WT mice, TCRα<sup>−/−</sup> mice, and CD45RB model are shown. The results are one representation of 3–5 independent experiments. (C) Expression levels of ST3Gal1 in purified CD4+ T cells from the normal colon of WT mice and from the inflamed colon of TCRα<sup>−/−</sup> mice, CD45RB model, and BIL-2 DKO model are shown. The results are representative in 6–8 mice in each group, *P < 0.005. (D) Expression levels of C2GnT and ST3Gal1 in purified CD4+ T cells from noninflamed colon (inactive, n = 6) and from inflamed colon (active, n = 6) of UC patients are shown. ***, P < 0.005; *, P < 0.05. (E) FACS analysis shows the binding intensities of galectin-4, PNA, MALII, HPA, and LEL on colonic CD4+ T cells from WT mice (as control, left) and from recipient Rag<sup>1−/−</sup> mice that were reconstituted with WT-derived (middle) versus C2GnT tg–derived (right) naive T cells. The data are one representation of three independent experiments.

The data are one representation of three independent experiments.

**Pathogenic role of CAG in colitis of CD45RB model**

To examine whether the expression of CAG on CD4+ T cells plays any role in colitis, we examined a naive T cell–induced colitis model (CD45RB model; Izcue et al., 2009). In brief, CD4+CD45RB<sup>high</sup> naive T cells were purified from the spleen of WT versus T/C2GnT tg mice and transferred into Rag<sup>1−/−</sup> mice lacking T and B cells, and the recipient mice were sacrificed at 8 wk after cell transfer. As previously demonstrated (Izcue et al., 2009), the donor T cells from WT mice induced the development of severe colitis in the recipients (Fig. 3 A, B) and expressed the CAG in the inflamed colon (Fig. 2 E). In contrast, CD4+ T cells with restored expression of C2GnT were significantly less able to induce the development of colitis (Fig. 3, A and B), consistent with their inability to express the CAG (Fig. 2 E). As predicted, no colitis was found in control WT mice (Fig. 3 A). The disease severity was further supported by the colonic expression level of an inflammatory cytokine; significantly increased IL-1β expression were observed in the colon of *Rag1<sup>1−/−</sup>* mice reconstituted with WT-derived CD4+ T cells as compared with those reconstituted with T/C2GnT tg–derived CD4+ T cells (Fig. 3 C). These findings demonstrate that ability of CD4+ T cells to express CAG is a significant contributor to the exacerbation of this naive T cell–induced colitis.

**Contribution of CAG for T cell proliferation**

In the next series of studies, we examined the effect of CAG on colonic CD4+ T cell function during inflammation. We first noted that the improvement of colitis observed as a consequence of restored C2GnT expression was associated with a significant decrease in the absolute number of CD4+ T cells in the colon (Fig. 4 A). Indeed, in comparison to WT-derived
CD4+ T cells, T/C2GnT tg–derived CD4+ T cells exhibited significantly less proliferation as judged by BrdU incorporation in the colonic CD4+ T cells from WT mice and from Rag1−/− mice. The recipients were sacrificed at 8 wk after transfer. Absolute numbers of colonic CD4+ T cells in the recipient colon are shown in A. Proliferative responses as judged by BrdU incorporation in the colonic CD4+ T cells are shown in B. The absolute number of colonic BrdU+ CD4+ T cells is summarized in C. The mean of the percentage of BrdU+ cells in the GFP+ versus C2GnT Tg mice was co-transferred into Rag1−/− mice. The proliferative response of reconstituted GFP− CD4+ (WT-derived) versus GFP− CD4+ (C2GnT tg-derived) cells in the same recipient colon are shown in D; n = 5. The mean of the percentage of BrdU+ cells in the GFP+ versus GFP− CD4+ T cells is summarized in E. (F) Purified CD4+C45RBlow memory T cells from the spleen of WT versus GFP-expressing C2GnT double Tg mice were co-transferred into Rag1−/− mice. The proliferative response of reconstituted GFP− CD4+ (WT-derived) versus GFP− CD4+ (C2GnT tg-derived) cells in the same recipient colon are shown. Data shown are one representation of three independent experiments. *, P < 0.01; **, P < 0.0001.

These findings propose that the expression of CAG directly contributes to the enhancement of colonic CD4+ T cell expansion under intestinal inflammatory condition.

**Deleterious effect of CAG on memory T cell–induced colitis**

A previous study has suggested that the initial priming of T cells necessary for maturation from naive to memory stages is impaired in T/C2GnT tg mice (Tsuboi and Fukuda, 1998). This finding raised the possibility that the decreased proliferation/expansion observed in T cells from T/C2GnT tg mice, and, consequently, protection from colitis, was a result of insufficient priming of the adoptively transferred naive T cells. To test this possibility, we next used another mouse model system in which colitis can be induced by adoptive transfer of memory CD4+ T cells (Nagahama et al., 2008). In brief, CD4+ C45RBlow memory T cells were purified from the spleen of WT versus T/C2GnT tg mice, and they were adoptively transferred into TCRβ and βIL−2 DKO mice.

As previously demonstrated (Nagahama et al., 2008), WT memory CD4+ T cells induced severe colitis in the recipient mice at 8 wk after cell transfer (Fig. 5, A and C),
and the reconstituted donor CD4+ T cells in the recipient colon all exhibited memory phenotype (Fig. 5 D). The development of severe colitis was further supported by the increased expression of colonic IL-1β (Fig. 5 E). Similar to the results obtained with adoptive transfer of naive T cells, CAG was observed on the memory-derived donor CD4+ T cells in the recipient colon (Fig. 5 F, middle panel). In contrast, T/C2GnT Tg–derived memory CD4+ T cells induced significantly less severe colitis (Fig. 5 B and C), and they did not express CAG (Fig. 5 F, right panel). These findings suggest that CAG, which is expressed on memory CD4+ T cells, has the ability to exacerbate colitis.

**Effect of CAG on memory T cell proliferation**

Consistent with the colitis severity, absolute numbers (Fig. 6 A) and proliferative responses (Fig. 6 B) of colonic CD4+ T cells were significantly lower in βIL-2 DKO recipient mice that received C2GnT Tg–derived memory CD4+ T cells in comparison to those mice that received WT-derived memory CD4+ T cells. Co-transfer experiments of memory CD4+ T cells from GFP-reporter mice and from T/C2GnT Tg mice into βIL-2 DKO mice confirmed that WT-derived memory T cells (GFP+) were more proliferative than C2GnT Tg–derived memory T cells (GFP−) when examined in the same colons (Fig. 6 C). Another set of co-transfer experiments using memory CD4+ T cells from WT mice and from GFP-expressing T/C2GnT Tg mice further confirmed the higher proliferative ability of WT-derived memory CD4+ T cells (GFP+) as compared with C2GnT Tg–derived memory CD4+ T cells (GFP−) in the same individual colon of βIL-2 DKO mouse (Fig. 6 D).

To test whether CAG promotes the expansion of selected T helper (Th) subset, colonic cells from βIL-2 DKO mice reconstituted with C2GnT Tg–derived versus WT-derived memory CD4+ T cells were stimulated ex vivo with phorbol-12,13-dibutyrate/ionomycin and subjected to intracellular staining of IFN-γ, IL-17A, IL-10, and IL-4. Interestingly, although absolute number of CD4+ T cells in the inflamed colon was significantly reduced by restoration of C2GnT expression (Fig. 6 E, left), there was no proportional difference in Th1 (IFN-γ), Th17 (IL-17A), Tr1 (IL-10), and Th2 (IL-4) subsets among the colonic CD4+ T cell population (Fig. 6 E). Indeed, restoration of C2GnT expression did not alter the expression level of T-bet, RORγt, GATA3, or c-Maf in the purified colonic CD4+ T cells (Fig. 6 F). Collectively, these findings demonstrate the ability of CAG to directly enhance the proliferative response of memory CD4+ T cells but not the differentiation of specific Th subsets.

**Contribution of CAG to raft integrity**

Galectin-4 has previously been demonstrated to stabilize lipid rafts on epithelial cells for generation of super rafts (Braccia et al., 2003). The immunological synapse (IS), which is built on the lipid raft characterized by detergent insolubility, serves as a key component providing signals for T cell-mediated colitis. Galectin-4, which is expressed on memory CD4+ T cells, has the ability to exacerbate colitis.

![Figure 5](http://example.com/f5.png)

**Figure 5.** Pathogenic role of CAG in memory CD4+ T cell-mediated colitis. CD4+CD45RBhigh memory T cells were purified from the spleen of WT (WT>βIL-2, n = 20) versus T/C2GnT Tg (C2GnT>βIL-2, n = 18) mice, and they were adoptively transferred i.v. into βIL-2 DKO mice. The recipients were sacrificed at 8 wk after T cell transfer. (A and B) Representative histology of recipient colons with transfer of WT (A) versus C2GnT Tg (B) CD4+ T cells are shown. Bars, 200 µm. (C) The disease scores are summarized. (D) Flow cytometric analysis shows the expressions of CD4 versus CD62L on splenic cells of WT mouse (left panel, as control) and colonic lamina propria cells from recipient βIL-2 DKO mice after transfer of memory CD4+ T cells from the spleen of WT (middle panel) or C2GnT Tg (right panel) mice. Data are representative in 3 independent experiments. (E) Expression levels of IL-1β in colonic tissues from WT mice and from βIL-2 DKO mice with transfer of WT-derived (WT>βIL-2, n = 6) versus T/C2GnT Tg–derived (C2GnT>βIL-2, n = 6) CD4+ T cells are shown. (F) Binding intensities of galectin-4 (Gal4) on colonic CD4+ T cells in WT mice (left, as control) and the recipients with transfer of WT-derived (middle) versus C2GnT Tg–derived (right) memory CD4+ T cells are shown. Data shown are one representation of five independent experiments. **, P < 0.0001; *, P < 0.005.
which have been identified to localize within the IS (Gomez et al., 2007; Nolz et al., 2007). Interestingly, galectin-4 also precipitated Fam62a (five-C2 domain-containing protein); we confirmed Fam62a has accumulated within the IS by confocal microscopy (Fig. 7 A). These findings indicate that galectin-4 interacts with CAG in the detergent-insoluble region of the cell membrane (lipid raft) that is in association with the IS.

We next examined whether the lack of CAG alters the formation of lipid raft/IS. To do so, CD4+ T cells from GFP mice and T/C2GnT tg mice were co-transferred into BIL-2 DKO mice, and the binding of cholera toxin (CT; a marker of lipid rafts) to the GFP+ (WT-derived) versus GFP− (T/C2GnT tg-derived) CD4+ T cells from the same inflamed colon was examined by flow cytometry. Interestingly, significantly more intense binding of CT was observed on WT-derived CD4+ T cells in comparison to that observed on the cell surface of T/C2GnT-derived CD4+ T cells (Fig. 7 B). These findings propose a contribution of CAG in the generation of super rafts on CD4+ T cells during the course of intestinal inflammation.

Sustained PKCθ activation through CAG

PKCθ, which represents a proximal molecule in IS-mediated signaling, exists diffusely within the cytoplasm of resting CD4+ T cells and is accumulated within the IS after TCR activation (Arendt et al., 2002). Therefore, we next examined whether absence of CAG altered the inflammation-induced activation of PKCθ. To do so, CD4+ T cells were purified from the inflamed colon of βIL-2 DKO mice with transfer of WT versus C2GnT tg-derived memory CD4+ T cells. After cell lysis, lipid rafts were precipitated with CT-coupled beads, and the precipitant subjected to immune-blot with an anti-PKCθ antibody. As shown in Fig. 7 C (top), more PKCθ could be detected in association with the precipitated detergent-insoluble lipid rafts obtained from the fresh WT-derived CD4+ T cells in comparison to that observed from the C2GnT-expressing CD4+ T cells. Coomassie blue staining of the precipitates showed that this in vivo data. To do so, purified CD4+ T cells from the
inflamed colon were stimulated for 30 min with anti-CD3 and anti-CD28–coupled magnetic beads. After removal of the beads, the activated cells were cultured again in the presence of galectin-4 for 1 or 3 h, and then lysed. The accumulation of PKCθ within the lipid rafts was then assessed as described in Fig. 7 C. Interestingly, at 3 h after stimulation, activation of PKCθ (as indicated by the association within CT-precipitated lipid rafts) was lower in C2GnT tg–derived CD4+ T cells in comparison to WT-derived CD4+ T cells (Fig. 7 D, right). Indeed, significant capping of PKCθ was observed on the WT-derived CD4+ T cells as compared with C2GnT tg–derived CD4+ T cells (Fig. 7 E). In contrast, such differences in PKCθ activation were not detectable between CD4+ T cells from WT and C2GnT tg mice at 1 h after stimulation (Fig. 7 D, left). These findings suggest that CAG has the ability to sustain, but not initiate, the activation of PKCθ in colonic memory CD4+ T cells.

**PKCθ-dependent proliferation of CAG–expressing T cells**

In a final set of experiments, we examined whether the sustained PKCθ activation in colonic CD4+ T cells by CAG development promotes the proliferative response. To do so, colonic memory CD4+ T cells were stimulated as shown in Fig. 7 D, and the activated cells were cultured again in the presence of galectin-4 for 1 or 3 h. At 1 h before analysis, cells were pulsed with BrdU. As shown in Fig. 8 (A and C), similar levels of proliferation were observed in WT- versus C2GnT tg–derived CD4+ T cells at 1 h after stimulation. However, at 3 h after stimulation, much less proliferation was seen in C2GnT tg–derived CD4+ T cells compared with WT-derived CD4+ T cells (Fig. 8, B and C). In addition, the proliferative response of WT-derived CD4+ T cells was reduced when galectin-4 was omitted from the culture (Fig. 8, B and C).

We next examined whether the sustained proliferative response through development of CAG depends on PKCθ. To do so, colonic CD4+ T cells used in Fig. 8 B were pre-treated with rotterin (an inhibitor of Ca2+-dependent PKC including PKCθ). As shown in Fig. 8 D, inhibition of PKCθ suppressed the galectin-4/CAG-induced proliferative response of colonic CD4+ T cells (Fig. 8 D, top right). In contrast, pretreatment with KT5720 (an inhibitor of PKA) had no effect on the proliferative response (Fig. 8 D, top left). In addition, these treatments did not alter the galectin-4 binding on the CD4+ T cells (Fig. 8 D, bottom). To further confirm the in vitro finding, in vivo co-transfer experiment using PKCθ−/− mice (Sun et al., 2000) was next conducted. To do so, CD4+CD45RBlow memory T cells were purified from the spleen of PKCθ+/− mice versus GFP-reporter mice, and they were co-transferred into βIL-2 DKO mice. In the same individual recipient colon, PKCθ–intact and PKCθ–deficient CD4+ T cells both developed CAG (Fig. 8 E). However, PKCθ–deficient CD4+ T cells (as indicated by GFP−) expressed CAG, exhibited significantly less proliferative response as compared with PKCθ–intact CD4+ T cells (as indicated by GFP+; Fig. 8 F). Collectively, these findings suggest that CAG-mediated expansion of memory CD4+ T cells depends on the activation of PKCθ.

**DISCUSSION**

In this manuscript, we propose that an inducible CAG, which can be identified by galectin-4 binding, is created on local memory CD4+ T cells under diverse intestinal inflammatory conditions that range from IBD to infection but not in...
It has been previously shown that CD4+ T cells contribute significantly to the exacerbation, but not induction, of colitis. The data would thus indicate that impairment of O-glycan maturation in CD4+ T cells plays a deleterious role for progression of colitis and supports a previous notion that N-glycan maturation (branching) can safeguard against some autoimmune diseases (Green et al., 2007). Consistent with this, galectin-4, which interacts with immature glycan structures (Ideo et al., 2002; Blixt et al., 2004), has been shown to exacerbate an experimental chronic colitis (Hokama et al., 2004). In contrast, galectins–1 and –3, which interact with more mature glycan structures (Lowe, 2001; Baum and Crocker, 2009), contribute to the suppression of colitis (Santucci et al., 2003; Müller et al., 2006). Thus, during the course of inflammation, changes in the glycan structures that decorate pathogenic memory T cells results in alterations in cell surface interactions that further control intestinal inflammation. Alternatively, administration of galectin-4 delayed the recovery from DSS-induced colitis (Hokama et al., 2004), whereas the administration ameliorated the acute phase of this colitis (Paclik et al., 2008). DSS-induced acute colitis is mediated by innate immune response, and adaptive immune responses then participate in the recovery process from this colitis (Mizoguchi, 2012). Therefore, it is possible that the role of galectin-4 in colitis differs depending on innate versus adaptive immune responses involved. This possibility is supported by a recent report demonstrating the ability of galectin-4 to suppress innate immune response by killing blood group antigen-expressing bacteria (Stowell et al., 2010).

Galectin-4 has previously been demonstrated to promote the formation of super rafts on non–T cells (Braccia et al., 2003). Alternatively, as shown here, during intestinal inflammation from a variety of different causes and mechanistic pathways, a characteristic CAG is detectable that is functionally associated with promoting the inflammatory process. Therefore, intestinal inflammatory insults may further modify the Th-specific glycomes, creating a local inflammation-specific glycome. Interestingly, unlike intestinal inflammation, hepatic inflammation did not induce the development of CAG. Because host–microbial interaction is significantly enhanced in intestinal, but not hepatic, inflammation (Sartor, 2008), this raises a possibility that some microbial-derived factors may contribute to the development of CAG.

We show that the CAG can be recognized by galectin–4 that has previously been shown to interact with specific carbohydrate epitopes such as an immature (nonsialylated) core-1 O-glycan (Ideo et al., 2002; Blixt et al., 2004). In addition, we show that CAG development was abolished by restoration of C2GnT expression, an enzyme responsible for initiating the maturation (branching) of O-glycans from core-1 to core-2 (Tsuboi and Fukuda, 1997, 1998). Collectively, these findings propose that the CAG observed reflects an immature core-1 O-glycan caused by a down-regulation of expression of the responsible enzyme during inflammation from a variety of different causes. An important observation in our study is that the CAG observed on CD4+ T cells contributes significantly to the exacerbation, but not induction, of colitis.
this, we show that formation of CAG led to sustained activation of PKCθ; a key proximal element in the IS-induced signaling machinery (Arendt et al., 2002). PKCθ is primarily responsible for the activation and proliferation of memory, but not naive, CD4+ T cells through consequent NF-κB activation (Sun et al., 2000). In addition, we have previously demonstrated that absence of PKCθ suppresses both Th1 and Th2 responses in the inflamed colon by reducing memory CD4+ T cell proliferation rather than by inhibiting the differentiation of naive T cells into Th1, Th17, or Th2 cells (Nagahama et al., 2008). Consistent with this, we herein show that the absence of CAG suppressed the proliferative responses of colonic memory CD4+ T cells, but it did not affect the differentiation of Th subsets in the inflamed colon. Therefore, our studies propose that formation of CAG serves to sustain PKCθ activation, resulting in enhanced expansion of memory CD4+ T cells in the inflamed colon. However, our current dataset may be unable to rule out a possibility that an alteration of retention/homing of CD4+ T cells is also involved in the CAG-mediated expansion in the inflamed colon.

PKCθ has been proposed as an attractive therapeutic target in IBD (Baier and Wagner, 2009). PKCθ-mediated signaling leading to consequent activation of NF-κB is used primarily by memory CD4+ T cells but not by naive CD4+ T cells, CD8+ T cells, or other cell types (Arendt et al., 2002; Kingeter and Schaefer, 2008). This is consistent with our observations that CAG is expressed by memory CD4+ T cells in the inflamed colon but not in other organs associated with models of colitis (Hokama et al., 2004). Interestingly, a recent study has suggested that PKCθ is not recruited to the IS of CD4+ Foxp3 regulatory T cells, but rather inhibits the regulatory function of these cells (Znin-Zhorov et al., 2010). Thus, collectively, blockade of CAG formation for inhibition of PKCθ activity may represent a specific therapeutic strategy to target colitogenic memory CD4+ T cells without affecting other T cell populations.

In summary, we propose that intestinal inflammation is associated with the formation of an inducible colitis-associated glycome (CAG) on local memory CD4+ T cells, which contributes to the exacerbation of intestinal inflammation, presumably by stimulating their expansion through prolonged PKCθ activation. This mechanistic pathway may provide a rationale to specifically target effector memory CD4+ T cells in the inflamed intestine.

**MATERIALS AND METHODS**

**Mice.** Sperm of a transgenic mouse strain carrying human C2GnT gene under control of Lck promoter (Tsuibo and Fukuda, 1997) was obtained from M. Fukuda (Burnham Institute, San Diego, CA), and the mice were recovered through in vitro fertilization with the help of Charles River Laboratory. The recovered T cell–specific C2GnT (T/C2GnT) tg mice were further backcrossed to C57BL/6 mice five times. GFP+ Tg mice were then backcrossed to C57BL/6 (Nagahama et al., 2008; Shimomura et al., 2008). GFP-expressing T/C2GnT Tg mice were grown by crossing T/C2GnT Tg mice with GFP tg mice. All mice were maintained under specific pathogen–free facility at Massachusetts General Hospital. All experiments were approved by the subcommittee on Research Animal Care of Massachusetts General Hospital.

**Human samples.** Diagnosis for IBD was based on conventional clinical and endoscopic criteria. Surgically resected or biopsy specimens were obtained with informed consent from patients who had active or inactive UC, active CD, *Campylobacter* infection, or polyps (as healthy control). All experiments were approved by local Ethics Committees of Shiga University of Medical Science and Keio University School of Medicine.

**Induction and evaluation of colitis.** For CD45RB model, T cells were first enriched from the spleen using T cell enrichment column (R&D Systems). After staining with FITC–anti-CD4 and PE–anti-CD45RB mAbs, CD4+CD45RBhigh T cells were purified using flow cytometric sorting. The purity was >98%. CD4+CD45RBhigh T cells (5 x 10^6) were intravenously administrated into RAG^{-/-} mice, and the recipients were euthanized at 8 wk after cell transfer. For memory CD4+ T cell–induced colitis model, T cells enriched through T cell–enrichment column were stained with FITC–anti-CD4 and PE–anti-CD45RB mAbs, and CD4+CD45RBhigh T cells were then purified using flow cytometric sorting. The purity was >99%. CD4+CD45RBhigh T cells (5 x 10^6) were intravenously administrated into BLI-2 DKO mice, and the recipients were euthanized at 8 wk after cell transfer. The disease score of both models was assessed by a combination of gross and histological examinations as previously described (Nagahama et al., 2008).

**Cell isolation and flow cytometric analysis.** In humans, lamina propria mononuclear cells were isolated as previously described (Okazawa et al., 2002; Kamada et al., 2008). In brief, dissected mucosa was incubated with 30 mM EDTA for 20 min, followed by incubation in medium containing 1.5 mg/ml collagenase type IV (Sigma–Aldrich) and 0.1 mg/ml DNase I (Roche) for 60 min at 37°C. After passing glass wool column, cells were subjected to Ficoll density gradient, and CD4+ cells were magnetically separated using IMag CD4 MicroBeads (BD). Colon LP cells from mice were isolated as previously described (Shimomura et al., 2008). They were blocked, stained, and analyzed using FACSCalibur (BD) and FlowJo software (Tree Star). For mice, FITC–anti-CD3ε (clone 145-2C11; BD), PE–anti-CD4 (clone RM4-4; eBioscience), FITC–PNA (Vector Laboratories), Biotinylated-MALII (Vector Laboratories)/Alexa Fluor 488–conjugated streptavidin (Invitrogen), Alexa Fluor 488–HPA (Invitrogen), and FITC–LEL (Vector Laboratories) were used. For humans, Alexa Fluor 488–human galectin-4, APC–anti–human CD4 (clone RPA-T4; BD), and APC–anti–human CD8 (clone SK1; BD) were used.

**Recombinant galectins.** Human and mouse recombinant galectin-4 and galectin-3 were generated previously (Hokama et al., 2004). Full-length cDNA of mouse galectin-8 was synthesized by GenScript Inc. and subcloned into pGEX–6P vector (GE Healthcare). BL-21 star carrying pGEX–6P was cultured in the presence of 0.1 mM IPTG. Fusion protein was purified with glutathione Sepharose 4B, and recombinant protein was separated from the GST moiety by using PreScission protease (GE Healthcare). After removal of endotoxin using endotoxin removal gel (Thermo Fisher Scientific), the protein was dialyzed to PBS and concentrated. 1 mg of galectin was labeled with Alexa Fluor 488 or Alexa Fluor 594 according to the manufacturer’s instruction (Invitrogen).

**Confocal microscopic analysis.** Human colon tissues were snap-frozen in O.C.T. compound, and 5 μm (in thickness) cryosections were prepared. After fixation with acetone for 5 min at 4°C and subsequent blocking with 2% BSA and 1% gelatin, sections were subjected to double staining with Alexa Fluor 594–conjugated recombinant galectin-4 and FITC–conjugated anti–human CD4 (BioLegend). The staining was analyzed using FV1000 confocal laser microscopy (Olympus) immediately after immunostaining.

For mouse cells, purified CD4+ T cells were incubated with rabbit anti-Fam62a antibody, which was generated by help from Affinity BioReagents.
After washing, they were fixed with 4% paraformaldehyde and permeabilized with 0.1% saponin in PBS. The cells were incubated with primary antibodies against various markers, followed by secondary antibodies conjugated to Alexa Fluor (Invitrogen). The stained cells were analyzed using a FACSCalibur flow cytometer (BD Biosciences).

**Intracellular cytokine staining.** Colonic cells were stimulated with phorbol-12,13-dibutyrate and ionomycin (10 μM each) for 5 hours at 37°C in the presence of monensin (GolgiStop, BD Biosciences). The cells were then washed and fixed with Cytofix/Cytoperm buffer (BD Biosciences). After permeabilization with ice-cold 90% methanol, the cells were stained with antibodies against intracellular markers, such as nuclear β-actin and cytokine proteins (e.g., IFN-γ, IL-17, IL-10, and IL-4). The stained cells were analyzed using a FACSCalibur flow cytometer (BD Biosciences).

**Real-time PCR analysis.** After stimulation with FITC–anti-CD3e antibody (εBioscience) for 24 hours, the cells were harvested and subjected to real-time PCR analysis using the LightCycler 480 system (Roche). The mRNA levels were normalized to the expression of GAPDH. The primer sets used for real-time PCR were as follows: IFN-γ (forward: 5'-GATTCCAAGGATGGGAAGG-3', reverse: 5'-GACATCATGCAGCACATGC-3'), IL-17 (forward: 5'-GATGACGCTGCGTGGTCTA-3', reverse: 5'-GCATGGTCTGCCTCTTCCT-3'), and GAPDH (forward: 5'-GGTGAAGTCGGGAGAGG-3', reverse: 5'-CACACTTGTTGTTTGGGTG-3').

**Immunoprecipitation.** Purified CD4+ T cells from the colon were stimulated with anti-CD3e and anti-CD28 antibodies (Miltenyi Biotec) for 24 hours. After stimulation, the cells were lysed in lysis buffer containing protease inhibitors. The lysates were then subjected to immunoprecipitation using anti-CD3e antibody (εBioscience). The immunoprecipitated proteins were analyzed by Western blotting using antibodies against various markers, such as phosphorylated Akt and p38 MAPK.

**Statistical analysis.** The data were analyzed using statistics software (SPSS). The differences between groups were assessed using one-way or two-way analysis of variance (ANOVA). The significance level was set at p < 0.05.
