HIV-1 capsid engages nucleoporin NUP153 to promote viral nuclear entry

Abstract

Lentiviruses can infect non-dividing cells, and various cellular nuclear transport proteins provide crucial functions for lentiviral nuclear entry and integration. Genome-wide small interfering RNA screens previously identified nuclear pore complex component nucleoporin 153 (NUP153) as being important for infection by human immunodeficiency virus type 1 (HIV-1). We found that HIV-1 infection of NUP153 depleted cells resulted in normal levels of reverse transcription, a moderate reduction of 2-long terminal repeat circles, and a relatively large reduction in integrated proviruses, consistent with a role for NUP153 during nuclear entry of the HIV-1 pre-integration complex. We ascertained the capsid (CA) to be the major viral determinant for NUP153 dependence during infection, and accordingly observed a direct interaction between the CA N-terminal domain and the phenylalanine-glycine (FG)-repeat enriched NUP153 C-terminal domain (NUP153$_C$). NUP153$_C$ fused to the effector domains of the rhesus Trim5α restriction factor (Trim-NUP153$_C$) potently restricted HIV-1, providing an intracellular readout for the NUP153$_C$-CA interaction during retroviral infection. Primate lentiviruses and equine infectious anemia virus (EIAV) bound NUP153$_C$ under these conditions, results that correlated with direct binding between purified recombinant proteins in vitro. These binding phenotypes moreover correlated with the requirement for endogenous NUP153 function during infection. Mutagenesis experiments identified
NUP153$_C$ and CA residues important for binding, and different FG motifs within NUP153$_C$ mediated binding to HIV-1 versus EIAV CA proteins. HIV-1 CA binding mapped to residues that line a common alpha helix 3/4 hydrophobic pocket that also mediates binding to the small molecule PF-3450074 (PF74) inhibitor and cleavage and polyadenylation specific factor 6 (CPSF6) protein, with Asn57 (Asp58 in EIAV) playing a particularly important role. PF74 and CPSF6 each competed with NUP153$_C$ for binding to HIV-1 CA, and significantly higher concentrations of PF74 were needed to inhibit HIV-1 infection in the face of Trim-NUP153$_C$ expression or NUP153 knockdown. Correlation between CA mutant viral cell cycle and NUP153 dependencies moreover indicated that the NUP153$_C$-CA interaction underlies the ability of HIV-1 to infect non-dividing cells. We propose that HIV-1 CA binds NUP153 FG motifs to affect viral nuclear import, serving as a novel example of viral hijacking of a fundamental cellular process.
Acknowledgements

Foremost, I thank Professor Alan Engelman. Alan was an excellent mentor during my doctoral studies, and provided the right combination of advising – sometimes direct, sometimes hands-off – for me to grow as a research scientist. I hope to emulate his critical eye for details in my future work. I also thank the professors who oversaw the various stages of my dissertation work: Drs. Joseph Sodroski, Dana Gabuzda, and Karl Munger for serving on my dissertation advisory committee; Drs. Todd Allen, Welkin Johnson, and Jeremy Luban for serving as dissertation examiners. I would like to acknowledge Joe in particular, not only for serving as the chair of my advisory and examination committees, but also for his insightful comments throughout my studies.

I wish to thank my cohorts from the Harvard Virology Program: while we may have finished at different times, I still feel that we all went through the journey of graduate school together. I acknowledge Anna Bruchez in particular: besides being a fantastic partner in life, I cherish our mutual love of science. I look forward to our future, both in and out of the scientific realm.

Lastly, I would like to thank the individuals who were instrumental in my academic development leading up to my graduate studies. I dedicate this dissertation to my parents, Walter and Mineko Matreyek: not only are they great parents, but their innate interests in science were likely largely responsible for sparking my own appreciation of biology. I also thank Dr. Hector Aguilar-Carreno, who served as a fantastic mentor when I initially began scientific research, and Dr. Benhur Lee, whose lab provided a great environment to start virology research as an undergraduate.

Contributions: Alan Engelman and I both wrote the manuscript.
The HIV-1 replication cycle

Human immunodeficiency virus type 1 (HIV-1) is the causative agent of acquired immunodeficiency syndrome (AIDS) [1-3]. HIV/AIDS remains a global pandemic with ~34 million individuals infected as of 2010, and the virus was estimated to have caused ~1.8 million deaths in that same year [4]. There are currently no effective prophylactic or therapeutic vaccines for HIV-1 infection. Although the development of combined anti-retroviral therapy regimens have curtailed AIDS progression in HIV infected individuals in developed nations, these treatments are not widely available in either Sub-Saharan Africa or South and Southeast Asia, which are experiencing the greatest disease burden.

Aside from its epidemiological relevance, HIV-1 is the prototypical lentivirus, and provides a common model to understand the molecular processes undertaken by viruses of the family Retroviridae. Like all viruses, HIV-1 must initiate its replication cycle by first gaining entry into the target cell (Figure 1-1). HIV-1 initiates viral entry by binding the cell surface protein CD4 [5], which is expressed to high levels on a number of immune cells, including CD4 positive subsets of T-lymphocytes, macrophages, and dendritic cells. This binding event triggers conformational changes in the viral envelope protein, revealing its site for co-receptor binding. Binding to an HIV-1 co-receptor, most commonly proteins CCR5 [6-10] or CXCR4 [11-13], triggers a cascade of events resulting in the fusion of the viral and cellular membranes, releasing the viral core into the cell cytoplasm.
Figure 1-1. Schematic of the HIV-1 replication cycle. HIV-1 infection is initiated when the virion binds to receptor molecules on the target cell, which triggers fusion between the viral and cellular membranes (Entry). Reverse transcriptase (RT) housed within the capsid core then creates a double stranded DNA templated by the viral RNA genome (Reverse transcription). Upon trafficking into the nucleus, the viral DNA is integrated into a host chromosome by the viral integrase (IN) protein (Integration). This completes the first half of the HIV-1 replication cycle. The integrated provirus is next transcribed by host RNA polymerases to yielded viral transcripts (Transcription), which are alternatively spliced and later translated to create the various viral protein products (Translation). Unspliced genomic RNA, along with the viral structural proteins, traffick to sites of virion assembly at the plasma membrane (Assembly). Here, the developing virion buds from host membrane and releases (Budding). Lastly, the nascent HIV-1 particle must undergo a maturation step to form a fully infectious virion (Maturation). The viral particle is now ready to find its next target cell to begin a new round of its replication cycle.
While in the cytoplasm, HIV-1 reverse transcribes its genome, creating a double-stranded DNA templated by the RNA genomes packaged within its core [14]. Retroviruses such as HIV-1 differ from other animal viruses by requiring integration into host chromosomes as an obligate step of their life cycles. Accordingly, upon trafficking into the nucleus, the double stranded viral DNA is inserted into a host chromosome by the viral IN protein [15-17]. Once integrated, the virus is transcribed by host RNA polymerase II. The resulting RNA molecules are either left intact or alternatively spliced to yield blueprints for the full complement HIV-1 viral proteins [18]. Once translated, the resulting protein products assemble with the unspliced viral genomic RNA at the plasma membrane [19]. The viral particle buds from the plasma membrane until it completes its assembly process and releases [20]. After release, the HIV-1 protease (PR) cleaves the intravirion components of the immature virion, in a process termed maturation. The mature virion, now exhibiting the classical conical core morphology associated with HIV, is now fully infectious and ready to embark on another round of infection.

**General retroviral strategies for nuclear entry**

Although many of the molecular mechanisms that govern the steps of the replication cycle are now well characterized, the molecular processes HIV-1 undertakes to gain access to the host chromosomes are not well understood. Aside from the periods of time when animal cells are actively dividing, cell chromosomes and the associated nucleoplasm are separated from the cytoplasm by two sets of adjoining membranes, together referred to as the nuclear envelope. Seven retroviral genera, including α through ε, lenti-, and spuma-, comprise Retroviridae. The γ-retrovirus Moloney murine leukemia
virus (MLV) and lentivirus HIV-1 are historic model systems for the study of retroviral nuclear import due to their contrasting dependencies on the cycling state of the cells that they infect. MLV is highly dependent on cellular mitosis, and accordingly requires the dissolution of the nuclear envelope to gain access to host chromosomes [21]. Contrastingly, HIV-1 productively infects post-mitotic cell types [22], and accordingly possesses a mechanism to bypass an intact nuclear envelope to gain access to host chromosomes.

The classical mechanism of protein import through the nuclear pore

HIV-1 nucleoprotein complexes are believed to enter the nucleoplasm by passing through nuclear pore complexes (NPCs), which stably perforate the nuclear envelope during interphase and gate-keep the trafficking of molecules between the cell nucleus and cytoplasm (Figure 1-2). Each NPC is composed of ~ 30 different protein constituents called nucleoporins (NUPs) [23,24], which are found in various multiples of 8 to yield the ~ 120 MDa tubular structures found in animal cells [25]. Transport through the NPC is highly selective; molecules less than ~ 9 nm in diameter are able to passively diffuse through the channel, while those up to ~ 39 nm must be actively transported by interacting with specific carrier proteins [26]. Protein cargos are most often imported by members of the karyopherin (KPN) β superfamily [27]. These proteins pass through the pore by interacting with phenylalanine-glycine (FG) motifs that are found in highly flexible domains present in about one-third of the NUPs and line the inner channel of the NPC structure. Though the precise biophysical mechanism of nuclear transport is not
Figure 1-2. Schematic of the NPC and classical nuclear import pathway. (top) General NPC substructures and locations of NUPs that scored as potential HIV-1 co-factors in genome-wide RNA interference (RNAi) screens [28-31]. Asterisks denote NUPs that scored in more than one screen. (bottom) The Ran-based nuclear import cycle. Import protein cargo binds to a KPN $\beta$ protein, oftentimes bridged by a member of the KPN $\alpha$ protein family (KPN $\beta1$, which is also referred to as importin $\beta1$, and KPN $\alpha2$ or importin $\alpha1$, depicted, are canonical members of each protein family). KPN $\beta1$ ferries the complex through the NPC channel. The engagement of KPN $\beta1$ by Ran-GTP concentrated at the nuclear basket releases the KPN $\alpha$-cargo complex into the nucleus. KPN $\beta1$ becomes free to bind additional import cargo after Ran dissociates from it upon RanBP1 binding and Ran-GTP hydrolysis, stimulated by RanGAP concentrated at the cytoplasmic filaments.
completely understood, it is clear that transport is largely dictated by the properties exerted by these FG-containing domains [32].

Directionality of nuclear translocation is governed by the gradient of the small Ras-related nuclear (Ran) GTPase protein, which is established through the asymmetric distribution of two Ran co-factors on opposite sides of the nuclear envelope (Figure 1-2). Regulator of chromosome condensation (RCC) 1, which is also referred to as Ran guanine nucleotide exchange factor (RanGEF), achieves nuclear compartmentalization through its association with nucleosomes [33], while Ran GTPase activating protein (RanGAP) is found associated with NUP358 filaments emanating from the cytoplasmic face of the NPC [34]. The classical mechanism of protein nuclear import is governed by two features: Ran binds KPN β proteins when it is complexed with guanosine triphosphate (GTP) rather than guanosine diphosphate (GDP), and protein cargos undergoing nuclear import preferentially bind Ran-free KPN β proteins. Due to the Ran gradient, KPN β proteins bind their import cargos within the cytoplasm, and ferry their cargos through the nuclear pore by interacting with the FG barrier [35]. Once in the nucleus, abundantly present RanGTP binds the KPN β protein, freeing the protein cargo within the nucleus. RanGTP-bound KPN β proteins are able to transit back into the cytoplasm, where Ran binding protein (RanBP) 1 and RanGAP stimulate the conversion of RanGTP to RanGDP [36] and dissociate Ran from the KPN β protein, completing the import cycle. Protein nuclear export cargos differ by preferentially binding RanGTP-bound carrier proteins, such as exportin (XPO) 1, to form ternary complexes that are released into the cytoplasm when Ran is freed upon binding with RanBP1/2 [37,38].
The HIV-1 substrate for nucleocytoplasmic transport

Mature HIV-1 virions harbor a relatively full complement of viral proteins, including \textit{gag}- (matrix, MA; capsid, CA; nucleocapsid, NC; p6) and \textit{pol}- (PR; RT; IN) encoded proteins, as well as a handful of accessory proteins (Vif, Vpr, and Nef). CA is composed of two independently folded protein domains, the N-terminal domain (NTD) and C-terminal domain (CTD), which are separated by a flexible linker [39]. During particle maturation, approximately one-half of the complement of CA protein condenses into a conical shell that is predominantly comprised of hexameric CA rings; twelve pentameric rings afford shape declinations necessary to enclose retroviral CA shells [40-43]. The mature core shell encases the viral components that are necessary to complete the early steps of retroviral infection, which includes the two copies of the viral RNA in complex with NC, RT, and IN. The viral core undergoes its first step in a series of conformational and compositional changes that occur following its entry into the cytoplasm, when the virus begins to reverse transcribe its genome in the context of a subviral complex commonly referred to as the reverse transcription complex (RTC) [44]. DNA synthesis likely triggers CA shell disassembly, as prevention of reverse transcription can delay the steps of core uncoating [45]. As the CA core begins to disassemble, some viral proteins diffuse away from the now permeable CA shell [46]. The combination of CA core disassembly and additional host-protein recruitment increases the size of the RTC to an estimated \( \sim 100-250 \) nm in diameter [47-49]. The number of complete, or near-complete reverse transcribed genomes in a population of infected cells can be readily measured by quantitative PCR, most commonly with a primer pair that generates an amplicon spanning from the upstream long terminal repeat
Figure 1-3. PCR-based methods for detection of post-entry to viral DNA integration steps of HIV-1 infection. (A) Generalized replication intermediates and byproducts leading up to integration. (B) Order of viral trafficking and RT and IN enzymatic steps. (C) Summary of viral DNA species that serve as markers for the various infection intermediates and byproducts.
(LTR) to a sequence past the primer binding site, such as a sequence in the upstream region of the *gag* gene; the viral DNAs detected by such reactions are commonly referred to as late reverse transcription (LRT) products because they depend on the second template switch of reverse transcription for their formation [50,51]. Once reverse transcription is completed, IN hydrolyzes the extremities of the linear viral DNA adjacent to conserved cytosine-adenine dinucleotides located within the viral LTRs to generate reactive CA$_{OH}$-3’ ends [52,53]; the resulting 3’-hydroxyl groups are subsequently used by IN to cut target DNA to effect viral DNA joining [54]. By convention, the integration-competent nucleoprotein complex formed by IN 3’ processing activity is referred to as the preintegration complex (PIC). These preceding steps are believed to largely occur within the cytoplasm, as the virus traffics to the nuclear periphery along microtubules [49].

**Techniques for measurement of HIV-1 nuclear import**

The majority of HIV-1 particles are noninfectious [55], and it is accordingly challenging to observe HIV-1 PIC nuclear transport directly with certainty. Nuclear transport is routinely inferred through comparison of steady-state levels of readily detectable markers of the bulk infection (Figure 1-3). Arguably, the most direct method is quantitative assessment of LRT DNA in cytoplasmic versus nuclear fractions. Importantly, this requires careful validation of the fidelity of fractionation, using control protein or nucleic acid markers appropriate to represent the separate compartments [56,57]. While many fractionation procedures likely separate soluble cytoplasmic components adequately, protocols likely differ in their abilities to distinguish
nucleoplasmic viral DNA from PICs associated with the NPC, or strongly associated with
the cytoskeleton. Before successfully integrating into a host chromosome, a subset of
PICs [58] are instead diverted to form non-productive DNA products through the action
of host cell-mediated DNA repair pathways: 1-LTR circles can be produced by
homologous recombination [59] or from aberrant reverse transcription [60,61], while 2-
LTR circles are formed through non-homologous end joining of the viral DNA [62]. PCR
primers that amplify products that span the LTR-LTR circle junction provide a
convenient, albeit indirect measurement for assessing the competence of the virus to
reach the nuclear interior [61]. Due to the generation of reactive CA\textsubscript{OH} ends by IN 3’
processing activity, a fraction of PICs aberrantly integrate their LTR ends back into an
internal region of the viral DNA in a process referred to as autointegration [63-66].
Importantly, autointegrants formed by the insertion of one LTR end in the vicinity of the
second viral DNA end can score as positive in assays quantitating 2-LTR circles,
confounding the use of 2-LTR circle measures as readouts for nuclear viral DNA [66].
Specific aspects of PCR design, which take into account the DNA sequence at the LTR-
LTR circle junction, can accordingly help to mitigate this complication [66]. Absolute
and relative levels of integration can be measured through PCR reactions specific for
integrated proviral DNA [51,67], while the distribution of integration sites along
chromosomes are assessed by identifying sequences of viral-cellular DNA junctions
within the infected cell population [68,69]. Although continuous advancement of various
microscopy-based approaches provides an important additional avenue to assess HIV-1
nuclear import and integration [48,70,71], high-throughput, live-cell approaches capable
of kinetically witnessing individual nuclear import events are not yet available.
Various biochemical approaches have yielded insight into the viral proteins that remain as part of the viral nucleoprotein substrate for nuclear import. The RTC/PIC observed in the cytoplasm exceeds the diameter of the pore \([48,49]\), so only a fraction of the viral and cellular proteins that associate with the PIC in the cytoplasm likely enter the nucleus \([48]\). The double-stranded reverse-transcribed viral DNA and a tetramer of IN protein form the heart of the PIC, as they comprise the intasome nucleoprotein complex that drives integration \([72,73]\). Keeping in mind that only one functional PIC is formed per infectious event, the identities of other PIC-associated viral proteins have been difficult to identify precisely. MA, RT, and Vpr were repeatedly found to be components of viral nucleoprotein complexes isolated from nuclear fractions \([56,74-77]\). A handful of studies found NC and PR as well \([75,76,78]\), while CA was noticeably absent from many of these same studies \([56,74-78]\). In fact, CA was either observed to be absent \([44,77]\), or found in only scant amounts \([79]\) within viral complexes extracted from whole-cell or cytoplasmic extracts, prompting initial belief that the HIV-1 core uncoats completely prior to PIC formation. Subsequent microscopy studies have more readily observed CA in association with cytoplasmic nucleoprotein complexes \([48,49,80]\), though the duration of this association remains largely unknown. While some studies have detected CA in the nuclear fraction following HIV-1 infection \([81,82]\), it is not entirely clear how much of this signal represents intranuclear CA rather than CA protein associated with the nuclear envelope. It would therefore be instructive to determine how much of this signal co-fractionates with nuclear PICs.
Viral and cellular elements implicated in HIV-1 PIC nuclear import

Many of the viral elements found in association with the PIC have been proposed to be important for HIV-1 nuclear import. Nuclear localization signals (NLSs) present in MA [83,84] and IN [76,85], as well as various non-canonical karyophilic signals in Vpr [77,86-90], have each been proposed to recruit cellular nuclear transport proteins. Basic-type NLSs within IN have been proposed to recruit KPN α adaptor proteins importin α1 (Rch1) [76] and importin α3 (KPNA4) [91], which would presumably require additional binding to KPN β1 for function (Figure 1-2). IN can also directly interact with KPN β proteins importin 7 [92,93] and transportin 3 (TNPO3, TRN-SR2, or importin 12) [70,94], though the relevance of these interactions have been brought into question [95-97]. IN and Vpr are additionally proposed to bind NUPs directly to facilitate nuclear import without the need for adaptor KPN carrier proteins, which include interactions between IN and NUP153 [98], and Vpr with Pom121 [86] or hCG1 [99].

The reverse transcribed genome is suggested to be an important determinant of HIV-1 PIC nuclear import, primarily through a triple stranded DNA flap element generated through the action of the central polypurine tract (cPPT) and central termination signal (CTS) [100,101]. While this element is not absolutely required for either nuclear import or infection [102-104], numerous groups have confirmed that the DNA flap exerts a positive effect during infection [105-107]. DNA plus-strand extension from the cPPT primer likely decreases the overall duration of reverse transcription within the cell [106,108], which may indirectly influence viral nuclear import during instances of limiting nucleotide concentrations, for example. Such a kinetic advantage to reverse transcription conferred by the cPPT is consistent with its ability to reduce the time-frame
in which the viral single-stranded DNA is sensitive to the inhibitory activity of APOBEC3 cytosine deaminase restriction factors \[109-111\], and may similarly protect the RTC/PIC from other host defense proteins that could derail its trafficking.

While HIV-1 MA, IN, and Vpr NLSs can confer nuclear localization when fused to otherwise cytoplasmic proteins, some studies have refuted the importance of these signals in PIC nuclear import during infection \[103,106,112-114\]. Various features of HIV-1 biology can help to explain some of these discrepancies. Firstly, MA and IN in particular are not known to function as free proteins during the early phase of HIV-1 infection. Thus, studying MA or IN as recombinant proteins expressed in human cells may not uncover behaviors relevant to PIC biology. Secondly, many of the viral constituents of the PIC are multifunctional proteins, whereby mutations may result in multiple coincident defects to infection, obfuscating the targeted assessment of contributions to a particular phenotype. Lastly, there is little evidence to support that HIV-1 enters the nucleus during mitosis when its passage through the NPC is blocked \[115\]. Thus, the historical perspective that HIV-1 nuclear import mutants would specifically be blocked for infection of non-dividing target cell types would since appear to be largely misguided.

**CA functionally determines requirements for nuclear trafficking**

The field has more recently moved to view CA as the major viral protein that mediates HIV-1 nuclear import. Masahiro Yamashita and Michael Emerman demonstrated that infection by an HIV-1 chimeric virus that carried the MLV CA protein was cell cycle dependent \[116\], mimicking the property of parental MLV. The defect to
Figure 1-4. Schematic of HIV-1 CA and mutations. A single HIV-1 CA monomer (protein database code 3j34) is represented by a cartoon of the peptide backbone, as well as a semi-transparent surface: NTD, green; flexible linker, purple; CTD, red. A subset of CA residue side-chains that exhibit phenotypic differences in preintegrative steps of HIV-1 infection are shown as sticks and colored as follows: carbon, orange; nitrogen, blue; oxygen, red.
infection upon cell cycle arrest was at the step of nuclear import, as a decrease in the formation of 2-LTR circle DNAs relative to wild-type (WT) HIV-1 was observed [116]. They subsequently determined that certain point mutations in HIV-1 CA, including T54A/N57A and Q63A/Q67A (Figure 1-4), also imparted cell cycle dependence to HIV-1 [57]. Notably, the infection defect exhibited by the T54A/N57A mutant virus upon cell cycle arrest occurred after nuclear entry but before integration [57]. While this mutant was sensitive to cell cycle arrest in all cell lines tested, the growth arrest phenotypes of A92E and G94D CA mutant viruses, which are hypersensitive to the levels of CA-interacting host protein cyclophilin A (CypA) in certain cell lines (Hela and H9 cells), were restricted to these same cells [117,118]. Cell cycle arrest also inhibited these viruses after nuclear import, as both LRT and 2-LTR circle levels remained unchanged. While the infection defects experienced by these CA mutant viruses upon cell cycle arrest occur following HIV-1 nuclear entry, the Q63A/Q67A mutant virus appeared to be defective for nuclear import, as it exhibited decreased levels of 2-LTR circle formation as compared to WT virus in dividing cells [119]. Q63A/Q67A CA cores recovered from whole virions following detergent treatment were less stable than WT cores in vitro [120], but the mutant viral RTCs and PICs retained a greater complement of CA protein than did the WT virus during infection [45,57,119]. This apparent delay in Q63A/Q67A core uncoating appears related to the nuclear import and integration defects experienced by this mutant virus.

A number of additional CA-interacting host factors have been observed to affect HIV-1 nuclear import and integration. The rhesus Trim5α restriction factor normally restricts HIV-1 infection by targeting the viral core for disassembly and degradation prior
to the completion of reverse transcription [121,122]. Inhibition of cellular proteasome activity with the small molecule MG132 rescued reverse transcription while having no effect on the ultimate level of integration [123]. The MG132-rescued RTCs seemingly remain intact [124] and mature into integration-competent PICs [125]. These complexes also escape entrapment by proteasome-associated cytoplasmic bodies [126] yet accumulate fewer 2-LTR circles, consistent with a trafficking defect coincident with or shortly prior to nuclear import [123,125]. Various artificially engineered Trim-CypA fusion constructs have also been shown to cause defects to infection after reverse transcription, though these appear to occur after nuclear entry [127].

Perturbation of CA can also affect the post-reverse transcription steps of other retroviruses. Though MLV does not enter the nucleus via the NPC, it must also in large part dissolve its CA shell to effect IN-mediated integration. MLV CA is readily found in RTCs purified from infected cells, and remains stably associated with the PIC until it enters the nucleus [128]. MLV p12, a gag-encoded protein not found in HIV-1, is crucial for nuclear targeting as it tethers PICs to mitotic chromosomes [129-131]. While MLV CA dissociates from the PIC during mitosis, p12 mutants PM14 and S61A/S65A, which are defective for mitotic chromosomal tethering, each maintain CA in association with the PIC during mitosis [132]. Certain murine cells take advantage of RTC/PIC-associated CA to interrupt the MLV infection mechanism: the protein expressed from Friend virus susceptibility-1 (Fv1), which is a gag-related gene from a murine endogenous retroelement [133], is able to target MLV cores to inhibit infection [134-136]. Restricted MLV still reverse transcribes and forms PICs capable of integrating in vitro [137], yet does not form circular DNA byproducts [138,139]. The product of the Fv1 gene can also
inhibit HIV-1 infection when targeted to HIV-1 CA upon fusion to CypA, resulting in a quantifiable decrease in the number of integrated proviruses while leaving the accumulation of 2-LTR circles unchanged [140].

Together, these results show that the retroviral core shell is unlikely to passively fall apart upon viral entry, but instead functions at a critical juncture bridging reverse transcription and nuclear trafficking. Although premature CA disassembly and proteasomal targeting may exert their effects as early as reverse transcription, other perturbations to CA uncoating and CA-determined trafficking defects prevent PIC nuclear import, or even manifest as defects within the nucleus. MLV has specifically evolved to access chromosomes during mitosis, and accordingly, the combined functions exerted by MLV CA and p12 likely specifically link MLV uncoating and nuclear entry with mitosis. In the aforementioned chimeric HIV-1 encoding MLV gag, the PIC is likely forced into an MLV-type mechanism of nuclear entry. Contrastingly, the cell cycle dependence of HIV-1 CA missense mutations may be due to reasons stemming from various potential losses in function: for example, perturbed core engagement with host proteins may result in a virus blocked at one of many preintegrative steps of infection, and may require cellular rearrangements that occur during cell division to relieve this block. While the previously described phenotypes affecting CA reveal the effects the retroviral core may exert on the steps following reverse transcription, recent findings that CA protein physically associates with nuclear transport factors hints that CA takes a direct role in promoting the nuclear steps of HIV-1 infection.
RNA interference screens highlight specific nuclear transport proteins as HIV-1 host factors

A series of genome-wide RNAi screens [28-31] identified numerous nuclear transport factors as potential HIV-1 cofactors: TNPO3, NUP358/RANBP2, NUP155, NUP153, and NUP98 were each identified in two independent screens, while a number of additional NUPs (NUP50, NUP62, NUP85, NUP107, NUP133, NUP160, NUP210, NUP214, ELYS, and TPR) and soluble transporters (KPN β1, XPO1, and NXF1) each hit once [28-31,141] (Figure 1-2). The HIV-1 requirement for TNPO3, NUP358, and NUP153 were initially mapped to the nuclear steps of infection, either preceding or concomitant with integration [29].

TNPO3 (also referred to as Transportin-3 or Transportin-SR2) is a soluble transport receptor belonging to the KPN β superfamily. TNPO3 is responsible for the nuclear import of a subset of serine/arginine-rich host proteins required for pre-mRNA splicing, termed SR-proteins [142]. NUP358 (also referred to as RanBP2) is a large NUP that forms the cytoplasmic filaments which emanate from the cytoplasmic side of the nuclear pore complex [143-145]. The domains of this protein are involved in many different cellular functions: Ran-binding domains and FG repeats involved in controlling nucleocytoplasmic transport [146], zinc fingers required for nuclear envelope breakdown during mitosis [147], a SUMO E3 ligase domain necessary for sumoylation-based protein targeting [148], various domains for interacting with kinesins and microtubules to mediate organelle interaction with the cytoskeleton [149,150], and a C-terminal CypA homologous domain (CHD) likely involved in protein isomerization [151-153].
Nucleoporin NUP153 is a potential HIV-1 cofactor for HIV-1 PIC trafficking

My work has focused on NUP153, which is a relatively large (1475 amino acid) NUP found on the nuclear side of the NPC [154]. Its NTD is important for its localization and its functions in NPC scaffolding: it houses a nuclear localization signal [155], and it has separate regions involved in nuclear envelope binding [156], as well as protein interactions with nucleoporins NUP160, NUP50, and TPR [157-159]. Its central zinc-fingers bind Ran [160], but also recruit COPI for nuclear envelope breakdown during mitosis [147,161]. Most interestingly, NUP153 possesses a long, highly flexible CTD which reaches into the central channel [162] and can extend across to the cytoplasmic side of the NPC in a transport-dependent manner [163-165]. This domain contains 29 FG motifs of the patterns FG, FxF, or FxFG, and is involved in the nucleocytoplasmic transport of a variety of protein or nucleoprotein cargos [166,167].

In this thesis, I describe our investigation of the role of NUP153 during the process of HIV-1 ingress, particularly the postentry steps leading up to viral integration. I found that a direct interaction between the NUP153 FG motifs and the HIV-1 capsid protein underlie the viral requirement for NUP153 during its nuclear import, serving as a novel example of viral hijacking of a key feature of cellular nucleocytoplasmic transport. I propose that similar mechanisms of direct binding between viral capsids and host cell phenylalanine-glycine motifs extends to additional retroviruses, and may even extend to additional viral families.

Contributions: I performed all of the experiments described in this manuscript. Alan Engelman and I both wrote the manuscript.
Abstract

Lentiviruses likely infect nondividing cells by commandeering host nuclear transport factors to facilitate the passage of their PICs through NPCs within nuclear envelopes. Genome-wide small interfering RNA screens previously identified karyopherin β transportin-3 (TNPO3) and NPC component NUP153 as being important for infection by HIV-1. The knockdown of either protein significantly inhibited HIV-1 infectivity, while infection by the gammaretrovirus MLV was unaffected. Here, we establish that primate lentiviruses are particularly sensitive to NUP153 knockdown and investigate HIV-1-encoded elements that contribute to this dependency. Mutants lacking functional Vpr or the central DNA flap remained sensitive to NUP153 depletion, while MLV/HIV-1 chimera viruses carrying MLV MA, CA, or IN became less sensitive when the latter two elements were substituted. Two CA missense mutant viruses, N74D and P90A, were largely insensitive to NUP153 depletion, as was WT HIV-1 when CypA was depleted simultaneously or when infection was conducted in the presence of cyclosporine A. The codepletion of NUP153 and TNPO3 yielded synergistic effects that outweighed those calculated based on individual knockdowns, indicating potential interdependent roles for these factors during HIV-1 infection. Quantitative PCR revealed normal levels of late reverse transcripts, a moderate reduction of 2-LTR circles, and a relatively large reduction in integrated proviruses upon NUP153 knockdown. These results suggest that CA, likely by the qualities of its uncoating, determines whether HIV-1 requires cellular NUP153 for PIC nuclear import.
Introduction

The early steps of the retroviral life cycle occur within the context of nucleoprotein complexes that are derived from the core of the infecting viral particle. The RT enzyme converts genomic RNA into linear double stranded viral DNA (vDNA) within the confines of the RTC [44,128]. Soon thereafter, the IN enzyme catalyzes its initial activity, 3’ processing, whereby each vDNA 3’ end is cleaved adjacent to the conserved dinucleotide sequence CpA. This marks the transition from the RTC to the PIC, wherein IN catalyzes its second catalytic function, DNA strand transfer [168,169]. Concomitantly, the complexes undergo morphological transitions, such as the dissolution of the viral CA core, as they traffic from the cellular periphery to desired regions of host DNA within the nucleus [44,49,56,128]. Well-studied but still-unresolved aspects of these steps are the mechanisms by which retroviruses bypass the nuclear envelope, which physically separates the nuclear and cytoplasmic compartments of the cell (reviewed in [170]). Although certain viruses, such as the gammaretrovirus MLV, are believed to require the dissolution of the nuclear membrane during mitosis [21], lentiviruses such as HIV-1 are able to infect nondividing cells and thus are believed to traverse the nuclear membrane by passing through the NPC [115,171]. As the HIV-1 PIC has been estimated to have a stokes radius of 28 nm [79] and thus grossly exceeds the ~9-nm diffusion limit [172] of the NPC, lentiviruses theoretically possess at least one mechanism to hijack the nuclear transport machinery and actively transport their PICs through the pore.

A number of HIV-1 PIC components, including MA, Vpr, IN, and the central DNA flap formed during reverse transcription, have been proposed to function during
nuclear import, although significant roles for any of these components during this step have not been well corroborated. This may, at least in part, be reflective of redundant PIC nuclear import mechanisms, although viruses with these elements mutated in combination did not exhibit obvious cell cycle-dependent infectivity or nuclear import defects [106,173]. In contrast, CA can determine the ability of HIV-1 to infect nondividing cells, suggesting that viral core uncoating is a rate-limiting step of lentiviral PIC nuclear import [57,174].

Numerous studies also have examined the requirements for specific cellular proteins during lentiviral/HIV-1 PIC nuclear import, including nuclear transport proteins NUP98 [175], importin 7 [176], KPN α2 Rch1 [76], and importin α3 [91]. A series of three genome-wide siRNA screens [28-30] highlighted nuclear transport proteins whose depletion strongly inhibited the early steps of HIV-1 infection. This included TNPO3 or transportin-SR2, a member of the KPN β superfamily responsible for transporting splicing factors with SR motifs into the nucleus. The depletion of TNPO3 resulted in a sizable HIV-1 nuclear import defect [70] while infection by MLV or the lentivirus feline immunodeficiency virus (FIV) remained largely unaffected [96,177,178], suggesting TNPO3 dependence to be specific to, although perhaps not obligatorily required by, lentiviruses. The mechanism by which HIV-1 physically hijacks TNPO3 remains unsolved; even though TNPO3 can bind HIV-1 IN [70], comparable levels of binding to MLV and FIV INs were observed [96,178], and analyses of HIV-1 proteins relevant during the infection of TNPO3 knockdown cells implicated the CA protein as the genetic determinant of TNPO3 dependency [96].
In addition to TNPO3, two major constituent proteins of the NPC, nucleoporins NUP358/RanBP2 and NUP153, were identified in two of the siRNA screens [28,29]. NUP358 composes the large cytoplasmic filaments emanating from eukaryotic NPCs [144], the knockdown of which was recently confirmed to result in a defect of HIV-1 nuclear entry during infection [179]. NUP153 is localized within the nucleus, linking central NPC scaffolding subcomplexes with their corresponding nuclear basket substructure, as well as anchoring individual NPCs with the nuclear lamina [180]. Additionally, NUP153 dynamically shuttles between NPC-localized and nucleoplasmic populations [181]. Although NUP153 knockdown also was interpreted to result in a defect in HIV-1 nuclear import, the lack of clear correlation between an approximately 85% reduction in acute infection and 20% reduction in 2-long terminal repeat 2-LTR-containing DNA circle levels, a marker for PIC entry into the nucleus [29], suggested to us that other factors were at play. NUP153 has been reported to bind HIV-1 IN and Vpr [98,182], suggesting potential mechanistic clues for the role of this host factor during HIV-1 infection. To investigate how NUP153 facilitates HIV-1 infection, we analyzed viral determinants that render HIV-1 sensitive to NUP153 depletion and additionally performed qPCR analyses of the viral DNA species formed during the infection of NUP153 knockdown cells.
Depletion of NUP153 expression inhibits HIV-1 infection.

RNAi was used to knock down NUP153 expression and analyze the role of this host factor during HIV-1 infection. HeLa cells were transfected with one of two previously characterized NUP153-specific siRNAs [183,184] or a nontargeting siControl mismatch to siNUP153#1, and protein expression levels were measured 48 h later. Western blotting of whole-cell lysates showed NUP153 expression to be depleted greater than 8-fold by either siRNA (Figure 2-1A). NUP153 knockdown cells infected with HIV-1 or MLV revealed that siNUP153#1 and siNUP153#2 significantly reduced HIV-1 infectivity to 3.2 and 3.4% of siControl-treated cells, respectively (Figure 2-1B). MLV was less or not significantly inhibited in parallel infections. Because cells transfected with siNUP153#2 showed evidence of cytotoxicity (data not shown), siNUP153#1 was used for the remainder of the study.

To further address the specificity of NUP153 knockdown on HIV-1 infection, protein levels in depleted cells were restored via expression of an exogenously introduced siRNA-insensitive cDNA. siRNA-transfected HEK293T cells were retransfected with the inert pUC19 plasmid, an empty expression vector encoding an internal ribosome entry site (IRES)-controlled dsRed-Express fluorescent protein, or an engineered vector encoding NUP153 5’ of the IRES element. Western blot analysis of cells lysed at the time of infection showed more robust exogenous NUP153 expression than the endogenous protein in both knockdown and control cells (Figure 2-1C). As gross overexpression of NUP153 has been shown to distort the nuclear envelope [185], virus-infected green
Figure 2-1. NUP153 expression and HIV-1 infection. (A) Twofold dilutions of a whole-cell extract from control cells (lanes 1 to 4) compared to extracts from NUP153-depleted cells (lanes 5 and 6). NUP62 cross-reacted with the utilized anti-NUP153 antibody. (B) Percent infectivity of GFP reporter viruses in HeLa cells transfected with siNUP153#1 (dark gray) or siNUP153#2 (light gray) compared to control cells. Results are averages from three experiments, each performed in triplicate; error bars denote 95% confidence intervals. (C) HEK293T cells transfected with siControl or siNUP153#1 were retransfected with either control DNA (pUC19), empty IRES-dsRed-Express vector, or the vector expressing siRNA-resistant NUP153 protein. (D) Cells in panel C were gated for dim dsRed-Express expression, and the infectivities of GFP reporter viruses were normalized to those of cells transfected with the empty vector. Solid and hatched bars, cells transfected with siControl and siNUP153#1, respectively; dark and light gray bars, cells transfected with empty and NUP153 expression vectors, respectively. The results are averages from four experiments performed in duplicate, with error bars denoting 95% confidence intervals.
fluorescent protein (GFP)-positive cells were quantitated within cell populations gated for the dim fluorescence of the dsRed-Express protein. HIV-1 infection of NUP153 knockdown HEK293T cells was significantly inhibited compared to the infection of control cells, while exogenous NUP153 expression restored infection to levels similar to those of controls (Figure 2-1D). Although MLV in this experiment was partially affected by NUP153 knockdown, this effect was inert to NUP153 reexpression.

**Differential retroviral dependencies on cellular NUP153.**

We investigated whether NUP153 dependency was specific or common to lentiviruses by testing the infectivities of a panel of retroviral reporter constructs. To determine whether the stark infectivity defect observed with HIV-1 extended to other primate lentiviruses, GFP reporter viruses for HIV-2<sub>ROD</sub>, SIV<sub>MAC</sub>, SIV<sub>AGM</sub>Tan, and SIV<sub>AGM</sub>Sab were analyzed. NUP153 depletion significantly inhibited infection by each of these viruses, with values ranging from 3.3% for SIV<sub>AGM</sub>Tan to 10.6% for SIV<sub>MAC</sub>, while infection by MLV was slightly enhanced under these conditions (Figure 2-2A). In contrast, similar experiments showed more-divergent retroviruses to be less sensitive to NUP153 depletion (Figure 2-2B). NUP153 knockdown significantly inhibited equine infectious anemia virus (EIAV) infection, to 33.4% of the level for the control. The alpharetrovirus Rous sarcoma virus (RSV) and betaretrovirus Mason-Pfizer Monkey Virus (MPMV) also were significantly affected but to even lesser extents, at 53.7 and 38.7% of the control level, respectively (Figure 2-2B). Consistently with results of Lee et al. [177], infection by FIV was largely unaffected by NUP153 knockdown.
Figure 2-2. Retroviral susceptibilities to NUP153 knockdown. HeLa cells transfected with siNUP153#1 or siControl were infected with GFP reporter viruses specific to primate lentiviruses (A) or different types of retroviruses (B). Results are averages from at least three experiments performed in triplicate, with error bars denoting 95% confidence intervals.
Neither Vpr nor the central DNA flap play significant roles in NUP153 dependency during HIV-1 infection.

Viral elements implicated in HIV-1 nuclear import were analyzed to determine which ones might contribute to NUP153 dependency. Neither the central DNA flap nor Vpr are essential for HIV-1 infectivity, so mutations that completely abrogated function were analyzed here [114,186]. Reporter viruses with either or both elements mutated were applied to NUP153 or control knockdown cells at two levels of input: $5 \times 10^6$ or $5 \times 10^4$ RT-counts per minute (RTcpm). Similarly to previous observations, single and double mutant viral infectivities were comparable to that of the WT [106,114,186] (Figure 2-3A, dark gray bars). To determine whether sensitivity to NUP153 depletion was altered by these mutations, the infectivities of each mutant virus in knockdown cells were normalized to their corresponding control sample and regraphed (Figure 2-3B). Infections performed with either quantity of viral inocula were significantly decreased when NUP153 was knocked down, although as a group infections performed with less virus showed a slight, but not significant, increase in sensitivity to the knockdown. Although Vpr mutant viruses showed slight differences in sensitivity to the knockdown with both quantities of inocula, none of these values reached statistical significance.
Figure 2-3. NUP153 dependency during HIV-1 infection is independent of Vpr and the central DNA flap. (A) Viral infectivities were normalized to the level obtained with $5 \times 10^6$ RTcpm of WT virus (set to 100%). Dark gray, siControl; light gray, siNUP153#1. (B) Regraph of panel A results, with infectivities in knockdown cells expressed as percentages of control cells, which were set at 100%. Solid dark gray, WT virus; light gray, DNA flap mutant; hatched bars, Vpr mutant viruses. Results are averages from four experiments performed in duplicate, with error bars denoting 95% confidence intervals. RLU, relative light units.
Replacement of HIV-1 IN or CA with MLV counterparts influences NUP153 dependency, while MA does not.

Essential roles of MA, IN, and CA proteins during the early and/or late steps of HIV-1 replication precluded the use of deletion constructs in infectivity assays. Because NUP153 depletion resulted in dramatically different levels of MLV and HIV-1 infection [29] (Figure 2-1B), we instead tested a set of HIV-1-based chimera viruses containing differing amounts of MLV Gag and/or Pol proteins [116,173] (Figure 2-4A). Chimera viral names indicate the swapped MLV protein(s). For example, mMAnp12 carries MLV MA and p12, whereas mMAnp12CA additionally harbors MLV CA.

Upon NUP153 depletion, the infectivity of the parental HIV-1LaI isolate was significantly decreased to 2.1% of that of the control, while MLV remained unaffected at 112.1% (Figure 2-4B). The infectivity of mMAnp12 was indistinguishable from that of HIV-1LaI, while the addition of MLV CA reduced dependency on NUP153 about 10-fold, to 22.7% of that of the control. The separate replacement of the IN protein in mIN also yielded a significant, approximately 4-fold difference from HIV-1LaI to 9.1% of that of the control, although this sample exhibited greater experimental variability. The combination virus containing MLV MA, p12, CA, and IN was not inhibited by NUP153 depletion, exhibiting 149.6% infectivity compared to that of the control.
Figure 2-4. NUP153 dependencies of MLV / HIV-1 chimera viruses. (A) Illustration of constructs tested (not to scale), with major HIV-1 Gag and Pol proteins indicated in gray (NC, nucleocapsid; PR, protease) and MLV proteins in white. (B) Control or knockdown cells were infected with HIV-1_LAI, MLV, or HIV-1-derived MLV chimera viruses shown in panel A. Results are averages from three experiments performed in triplicate, with error bars denoting 95% confidence intervals.
Alteration of HIV-1 sensitivity to NUP153 depletion by CA missense mutations or cyclosporine treatment.

The preceding experiment revealed CA as a dominant determinant of NUP153 dependency, so we next surveyed a panel of previously characterized CA missense mutant viruses for NUP153 dependency during infection. Mutants of the CypA binding loop, encompassing HIV-1 residues His83 to Arg99, included G89V and P90A, which exhibit greatly diminished CypA binding [187], and A92E and G94D, whose infectivities are cell type specific [188,189]. Non-CypA loop mutants E45A and Q63A/Q67A, which exhibit altered core stability both in vitro and ex vivo [57,119,120,190], experience greatly decreased infectivities across cell types. A relatively large viral inoculum, 4 x 10^6 RTcpm, therefore was utilized to provide robust signals across the mutant virus set.

Consistently with previous reports, the infectivities of E45A and Q63A/Q67A were severely compromised, while G89V, A92E, and G94D yielded moderate defects and the N74D and P90A mutants infected HeLa cells at levels comparable to that of the WT (Figure 2-5A, dark gray bars). Comparison of infectivities in knockdown and control cells confirmed N74D to be insensitive to NUP153 depletion [177] (Figure 2-5A and 2-5B, light gray bars). E45A appeared moderately less sensitive to knockdown than the WT, while the Q63A/Q67A mutant was not distinguishable from the WT. A92E and G94D were at least as, if not more, sensitive to NUP153 depletion as the WT, while the CypA binding mutants G89V and P90A exhibited contrasting sensitivities: G89V was sensitive while P90A was resistant (Figure 2-5A and 2-5B, light gray bars). The P90A
Figure 2-5. WT and CA mutant viral infectivities and cyclosporine dependences in control and NUP153 knockdown cells. (A) Control (dark gray) or NUP153 knockdown (light gray) cells were left untreated (solid bars) or were treated with 5 µM cyclosporine (hatched bars) at the time of infection. All samples were normalized to the infectivity of WT virus in untreated control cells, which was set at 100%. The results are averages from three experiments, each performed in duplicate, with error bars denoting 95% confidence intervals. (B) Regraph of panel A results, with infectivities in knockdown cells expressed as percentages of the infectivity of control cells; hatched bars denote infections in the presence of CsA. The results are averages from six experiments performed in duplicate, with error bars denoting 95% confidence intervals. (C) Infectivities in NUP153 knockdown cells compared to that of control cells, with hatched bars denoting cells in which CypA was simultaneously depleted. Results are averages from two experiments performed in duplicate, with error bars denoting 95% confidence intervals.
phenotype appeared to be cell type specific, as partial sensitivity to NUP153 knockdown was observed in HEK293T and GHOST-CXCR4 cells (data not shown).

As the interaction of CA with CypA can govern HIV-1 uncoating [191], WT and CA mutant viral dependencies were evaluated in the presence of cyclosporine to disrupt this protein-protein interaction. As previously observed in HeLa cells [188,192], the WT was relatively unaffected by cyclosporine treatment, while E45A, Q63A/Q67A, A92E, and G94D witnessed approximately 5- to 10-fold increases in infectivity (Figure 2-5A, compare dark gray hatched and solid bars). Interestingly, cyclosporine treatment rendered the WT, A92E, and G94D viruses fully insensitive to NUP153 depletion (Figure 2-5A, dark gray hatched bars, and 2-5B, hatched bars). This effect was not observed with all NUP153-sensitive CA mutants, as the G89V mutant remained largely dependent on the host factor in the presence of the drug. Similar results were observed with CypA knockdown in place of cyclosporine treatment: CypA knockdown resulted in approximately 5- to 20-fold increases in the infectivities of E45A, Q63A/Q67A, A92E, and G94D mutant viruses (data not shown), and WT, A92E, and G94D viruses were rendered significantly less sensitive to NUP153 depletion when CypA was knocked down simultaneously (Figure 2-5C, compare hatched to solid bars).

**Interdependent requirement for NUP153 and TNPO3 during HIV-1 infection.**

Primate lentiviruses revealed strong dependencies on NUP153 and TNPO3, while MLV, FIV, and the N74D HIV-1 CA mutant virus were largely unaffected by either knockdown [96,177] (Figure 2-2). We therefore tested if these proteins would reveal evidence for interdependence during HIV-1 infection. Because Thys et al. [178] recently
Figure 2-6. Interdependence of NUP153 and TNPO3 during HIV-1 infection. (A) Whole-cell extracts of control, NUP153-depleted, TNPO3-depleted, and combinatorially depleted cells were blotted with the indicated primary antibodies. (B) Control (dark gray) or NUP153 knockdown (light gray) cells simultaneously depleted for TNPO3 (hatched bars) were infected with $2 \times 10^6$ or $2 \times 10^7$ RTcpm of vesicular stomatitis virus (VSV)-G or HIV-1 envelope pseudotyped viruses, respectively, yielding numbers of RLU in control cells that were within 1 log of each other (not shown). All samples were normalized to the infectivity of the WT virus in control cells, which was set at 100%. White bars show the multiplicative product of infectivity defects exhibited upon individual protein knockdowns, representing the theoretical maximum expected assuming independent function. Results are averages from three experiments, each performed in duplicate, with error bars denoting 95% confidence intervals.
showed that the route of N74D entry influenced the requirement for TNPO3, experiments were conducted in CD4-positive GHOST-CXCR4 cells to enable comparisons of VSV-G and HIV-1 envelope pseudotyped particles. NUP153 and TNPO3 were knocked down either individually or in combination (Figure 2-6A). WT viruses carrying either envelope exhibited 3- to 5-fold decreases in infectivity when NUP153 (Figure 2-6B, light gray bars) or TNPO3 (dark gray hatched bars) was knocked down, while N74D was largely, if not completely, insensitive. Interestingly, a 40-fold decrease in infection by VSV-G-pseudotyped WT virus was observed when both proteins were knocked down (Figure 2-6B, light gray hatched bar), far greater than the ~14-fold defect expected based on the product of individual knockdowns (Figure 2-6B, white bar). The N74D mutant showed no such effect, with the dual knockdown inhibiting this virus no more than the slight decrease observed with NUP153 knockdown alone. The results with the HIV-1 envelope pseudotypes were similar, although slightly exaggerated: WT virus exhibited an approximately 75-fold infection defect when both factors were knocked down, while the N74D mutant exhibited a much smaller, though noticeable, 3-fold decrease in infectivity.

**NUP153 depletion inhibits expression from an integration-defective reporter virus.**

HIV-1 reporter viruses harboring mutations of IN active-site residues are unable to catalyze vDNA integration but still can yield a reproducible level of reporter gene expression. N/N active-site mutant viruses carrying either WT or N74D CA therefore were produced to determine if the inhibitory effects of NUP153 depletion were conferred in the absence of integration. Infection with N/N mutant viruses yielded ~2 to 3% reporter expression compared to that of the WT IN viruses, and as expected, these gene
Figure 2-7. NUP153 dependencies of WT and IN active-site mutant viruses. (A) Relative differences in reporter expression of $5 \times 10^6$ RTcpm WT and N/N IN mutant, along with WT sequence or the CA N74D mutation, in the absence (dark gray) or presence (light gray) of 10 µM raltegravir. (B) Relative infectivities of WT and N/N mutant viruses in control (dark gray) or NUP153 knockdown cells (light gray), with WT infectivity ($5 \times 10^6$ RTcpm) set to 100%. Viruses harbored either WT (solid bars) or N74D (hatched bars) CA. (C) Regraph of panel B results, with infectivities in knockdown cells expressed as percentages of respective control cells; solid, hatched, and boldface hatched bars denote infections with $5 \times 10^6$, $5 \times 10^5$, and $5 \times 10^4$ RTcpm of WT IN virus, respectively, while light gray bars denote infection with N/N virus. Results are averages from five experiments performed in triplicate, with error bars denoting 95% confidence intervals.
expression levels were completely refractory to the addition of 10 μM strand transfer inhibitor raltegravir, a dose ~ 100-fold in excess of that required to inhibit 95% of WT viral infection [193] (Figure 2-7A). Control and NUP153 knockdown cells next were challenged with N/N viruses alongside 10-fold dilutions of WT IN viruses to establish a comparable level of endpoint reporter expression (Figure 2-7B). The N/N virus harboring WT CA was significantly inhibited by NUP153 depletion to a level indistinguishable from that of its integration-competent counterpart at all viral inocula tested (Figure 2-7C). Additionally, similarly to the effects of the N74D change on integrating virus, the N74D CA mutation rendered the N/N virus insensitive to NUP153 depletion.

**NUP153 depletion results in decreased 2-LTR circles and integrated proviruses.**

Although NUP153 depletion was previously concluded to result in an HIV-1 PIC nuclear import defect, this interpretation was based on an approximately 20% reduction in 2-LTR circle levels at 24 hpi alongside an 8-fold infectivity defect [29]. To more comprehensively address the block to HIV-1 infection upon NUP153 depletion, LRT, 2-LTR circle, and integrated proviral DNA levels were measured at multiple time points by qPCR following infection with either WT or N/N mutant virus. As expected [194], cells infected with N/N virus supported a level of LRT products similar to that of WT-infected cells at 8 hpi, with a corresponding ~ 9.6 fold increase in 2-LTR circle levels at 24 hpi (data not shown). WT and N/N mutant viral reverse transcription were insensitive to the amount of cellular NUP153, as peak levels at 8 hpi were similar in control and knockdown cells (Figure 2-8A and 2-8D). NUP153 depletion resulted in an
Figure 2-8. HIV-1 DNA species formed during acute infection of NUP153 knockdown cells. Viral DNAs were amplified from cells following infection with WT (A, B, and C) or N/N mutant (D and E) virus, with values from NUP153 knockdown cells (gray dashed line) normalized to peak LRT (8 hpi) (A and D), 2-LTR circle (24 hpi) (B and E), and integration (52 hpi) (C) values. (F) Levels of WT and N/N mutant virus infectivities upon NUP153 depletion, expressed as percent siControl-transfected cells (set at 100%). Results are averages from three experiments, with error bars denoting 95% confidence intervals.
approximately 4.7-fold decrease in N/N virus 2-LTR circle formation at 24 hpi, which leveled off somewhat, to 3.2-fold, by 52 hpi (Figure 2-8E). In contrast, NUP153-depleted cells infected with WT virus supported 2.1- and 2.3-fold lower 2-LTR circle levels than siControl transfected cells at 24 and 52 hpi, respectively (Figure 2-8B). WT viral integration was blocked more significantly than 2-LTR circles in NUP153 knockdown cells, about 5- and 7.2-fold lower than the levels of integrated proviruses in control cells at 24 and 52 hpi, respectively (Figure 2-8C). Comparison of luciferase activities at 52 hpi yielded approximately 9.3- and 10.7-fold reductions in WT and N/N mutant viral infectivities, respectively, upon NUP153 knockdown (Figure 2-8F).
Discussion

**NUP153 is likely required for HIV-1 nuclear entry.**

NUP153 expression has been shown to be required for HIV-1 infection [28,29], but its role(s) in this process has yet to be well characterized. Here, we show that NUP153 is required for efficient infection by primate lentiviruses and may play a role in infection by other retroviral genera (Figure 2-2). Our results with integration-defective N/N virus revealed NUP153 to be equally required for expression from integrated and unintegrated vDNA templates, implicating a step common to both processes. Our investigations tracking viral DNA accumulation in NUP153-depleted cells showed both WT and N/N IN mutant viral LRT levels similar to those of control cells, suggesting that NUP153 expression is not necessary for reverse transcription. In contrast, knockdown cells infected with the N/N mutant supported formation of about 5-fold fewer 2-LTR circles than NUP153-expressing cells (Figure 2-8). The nonhomologous end-joining machinery required for 2-LTR circle formation is expected to reside in the nucleus [61,62,195], which suggests that NUP153 is involved at a step(s) following reverse transcription which could precede or coincide with nuclear entry or a subsequent process that facilitates the formation and/or retention of 2-LTR circles. Because NUP153 is an NPC component, it seems most likely that the defect is at nuclear entry. Accordingly, knockdown cells infected with WT virus exhibited decreased levels of 2-LTR circles as well, albeit to a lesser extent than the N/N mutant. This discrepancy may be due to an overlying integration defect, which would be expected to contribute to the accumulation of vDNAs susceptible to circularization.
CA mutant viruses and cyclosporine treatment indicate a role for core uncoating in NUP153 dependency during HIV-1 infection.

Although the infection defect is likely at a nuclear step, the major functional determinant of NUP153 dependency identified thus far appears to be the CA protein [177] (Figure 2-4 to 2-6). It is possible that CA molecules associated with the PIC directly participate in steps at the NPC or within the nucleus, but because numerous point mutations across different faces of the HIV-1 CA monomer can dramatically alter NUP153 dependence, it is more likely that the dominant effects of CA are reflective of qualities conferred by a multimerized CA core. These results suggest that NUP153 dependency is an effect dictated by the manner in which the CA core uncoats in the cytoplasm or potentially at the nuclear pore itself [80]. Consistent with this interpretation, we found that the perturbation of cyclophilin binding, either by cyclosporine treatment or CypA knockdown, dictated the sensitivity of the WT and cyclosporine-dependent mutants A92E and G94D to NUP153 depletion (Figure 2-5). Thus, it appears as though the amount of CypA bound to the HIV-1 core is able to dictate whether the PIC undergoes downstream processes requiring NUP153, perhaps by altering the dynamics of uncoating [191].

Notably, this level of regulation by CypA does not appear to be a global requisite for infection, as SIVmac is highly sensitive to NUP153 knockdown in spite of its reported inability to bind CypA [196]. The route of cell entry taken by the N74D CA mutant, which has been documented to alter the requirement for TNPO3 during infection [178], may influence NUP153 dependency as well. Although the HIV-1-mediated entry of
N74D failed to reveal a requirement for NUP153 or TNPO3 in our hands, we did note a modest 3-fold effect upon the depletion of both proteins (Figure 2-6). Notably, there is precedence for a requirement of NUP153 and NUP153-like proteins during infection with other viruses and retrotransposons at a stage that interfaces capsid oligomerization with nuclear import. The *Saccharomyces pombe* ortholog Nup124p is important for the nuclear accumulation of the Tf1 retrotransposon [197,198]. Interestingly, residues adjacent to an N-terminal nuclear localization signal located in Tf1 Gag dictated whether Nup124p was necessary for Gag nuclear import, and this appeared to correlate with the ability of Gag to multimerize [199]. More recently, NUP153 was found to play a key role during hepatitis B virus nuclear import by signaling mature capsid proteins to dissociate within the NPC basket [200]. Interestingly, both Tf1 Gag and hepatitis B virus capsid have been demonstrated to directly bind their respective NUP153 orthologs. It therefore would be instructive to know if human NUP153 binds HIV-1 CA in an oligomerization-dependent manner.

**A potential role for IN in NUP153 dependency.**

Aside from the dominant effects conferred by CA, our functional studies of viral elements provide context to understand potential physical interactions relevant to NUP153 function during infection. Although NUP153 has been found to bind HIV-1 Vpr [182], viruses lacking virion-incorporated Vpr were not significantly altered in their NUP153 dependence compared to that of the WT virus, suggesting that this interaction is not relevant up to and including the nuclear import, integration, and early gene expression stages of infection (Figure 2-3). NUP153 also has been found to bind HIV-1
IN [98], and our results with MLV/HIV-1 chimera viruses support a role for HIV-1 IN during the infection of NUP153 knockdown cells (Figure 2-4). Additionally, the IN protein of FIV previously was found not to bind NUP153 [98], which appears to correlate with the insensitivity of this virus to NUP153 depletion (Figure 2-2B). As yet, the requirement for IN appears auxiliary to CA: despite carrying WT IN, HIV-1 CA mutants N74D and P90A were largely insensitive to NUP153 knockdown (Figure 2-5 and 2-6), while comparison between chimeras containing MLV IN or CA showed the replacement of CA to decrease the sensitivity of the virus to knockdown more than IN replacement (Figure 2-4).

Pleiotropic effects of NUP153 depletion.

It is currently unknown whether the effect of NUP153 knockdown on primate lentiviral infection is reliant on the cellular roles of NUP153 during nuclear transport or on other collateral pleiotropic effects caused by the depletion of this multifunctional protein. NUP153 is believed to be a major point of NPC interaction with translocating KPNs, including those for nuclear import via importin α/β and transportin, protein export via Crm1, and mRNA export via NXF1 (reviewed in [201]). Furthermore, NUP153 depletion has been shown to prevent the NPC from incorporating nucleoporins Tpr and NUP50 [159,184], and it also has been shown to perturb NUP62, NUP88, and NUP214 localization in certain contexts [184,202]. Thus, even if the disruption of a putative specific HIV-1 PIC-NUP153 interaction(s) is not the root cause of the infectivity defect, it may be due to the mislocalization of a subsequently required, potentially unidentified host factor. Furthermore, NUP153 can exert effects indirectly of nuclear transport, as its
depletion has been shown to disrupt the cytoskeleton [203], likely through the perturbation of the nuclear lamina, and it also has been found to delay cellular progression through mitosis [184,204]. Lastly, NUP153 is important during transcription and even has been found to be associated with large regions of transcriptionally active open chromosomes within the Drosophila genome [205]. Regardless, although NUP153 depletion is known to disrupt many processes within the cell, its overall relevance to HIV-1 infection must be relatively specific, as single point mutations in CA can render the virus completely unaffected (Figure 2-5).

It will be interesting to continue to determine the role of NUP153 in relation to other host factors implicated in HIV-1 nuclear transport, especially TNPO3 and NUP358. Numerous similarities have been observed upon the knockdown of individual components: HIV-1 exhibits a nuclear entry defect [29,70,179] (Figure 2-8), while MLV, FIV, and the N74D CA mutant virus are seemingly unaffected [28,29,70,96,177,178] (Figures 2-2, 2-5, and 2-6). Here, we determined that the simultaneous depletion of NUP153 and TNPO3 significantly enhanced the block to HIV-1 infection, suggesting interrelated functions. Perhaps these proteins represent multiple components of a concerted mechanism streamlining the early steps of HIV-1 infection, allowing for both optimal quantity and quality of proviral insertion into the host genome.
Materials and Methods

Plasmid constructs.

Infection assays utilized single-round viruses carrying either GFP or luciferase reporter genes. GFP-based constructs included: EIAV [206,207], HIV-1 [208], RSV [209] (Addgene plasmid 13878 obtained from Constance Cepko via Addgene), FIV [210,211], MLV [212,213], MPMV [214], HIV-2 strain ROD (HIV-2\textsubscript{ROD}), and simian immunodeficiency virus from \textit{Macaca mulatta} (SIV\textsubscript{MAC}), \textit{Chlorocebus sabaeus} (SIV\textsubscript{AGMSab}), and \textit{Chlorocebus tantalus} (SIV\textsubscript{AGMTan}) [215]. Luciferase-based viruses included MLV/HIV-1\textsubscript{LAI} chimeras [116,173] and HIV-1\textsubscript{NL4-3}-derived D64N/D116N (N/N) IN active site and Vpr and/or DNA flap mutants of pNLX.Luc [102,216]. VSV-G and HIV-1\textsubscript{NL4-3} glycoprotein expression vectors were as described [102,216].

HIV-1 CA mutations were generated through site-directed mutagenesis of the HIV-1\textsubscript{NL4-3}-based pHP-dI-N/A packaging plasmid [217] (AIDS Research and Reference Reagent Program [ARRRP]), which was co-transfected in conjunction with either pHI-vec2.GFP [218] or pHI-Luc [219] transfer vectors. Sequencing was used to verify PCR-mutated DNAs. NUP153 expression vector pIRES-dsRedExpress-NUP153 was created by digesting pCMV-Sport6-NUP153 (Open Biosystems) with Sal I and Bgl II, and ligating the resulting NUP153-coding fragment with Sal I/BamH I-digested pIRES-dsRedExpress (Clontech Laboratories).
Cells and siRNA transfections.

HEK293T and HeLa cells were cultured in Dulbecco’s modified Eagle’s medium supplemented to contain 10% fetal bovine serum, 100 IU/ml penicillin, and 100 µg/ml streptomycin, while GHOST cells expressing CD4 and the CXCR4 co-receptor (GHOST-CXCR4) [220] (ARRRP) were additionally cultured with 500 µg/ml G418, 100 µg/ml hygromycin, and 1 µg/ml puromycin. Approximately 75,000 HEK293T or 25,000 HeLa or GHOST-CXCR4 cells seeded per well of a 24-well plate were transfected the next day with a final concentration of 40 nM siNUP153#1 (GGACTTGTTAGATCTAGTT) [184], 10 nM siNUP153#2 (AGTGTTCAGTATGCTGTGTTTCT) [183], or 40 nM of mismatch control of siRNA #1, referred to as siControl (GGTCTTAATTGGAGCTAAATT; underlines indicate base mismatches with siNUP153#1)) (Dharmacon) using RNAiMax (Invitrogen) according to the manufacturers instructions. Simultaneous NUP153 and cyclophilin A (CypA) knockdown was performed by transfection with a final concentration of 20 nM siNUP153#1, 20 nM CypA siRNA (AAGGGTTTCCTGCTTCACAGA) [221], or the corresponding amount of siControl for a total siRNA concentration of 40 nM. Simultaneous NUP153 and TNPO3 knockdown was performed similarly, using siTNPO3 (CGACATTGCAGCTCGTGA) [96]. Media was exchanged the following day. NUP153 re-expression was performed by CaPO₄ transfection of 1 µg DNA immediately after siRNA transfection.

Virus production.

Vector particles were generated by transfecting HEK293T cells in 10-cm plates with 10 µg total of various ratios of the aforementioned virus production plasmids using
either CaPO₄ or Fugene 6 (Roche Molecular Biochemicals). The cells were washed 16 h after transfection, and supernatants collected 12 to 60 h thereafter were clarified at 300 x g, filtered through 0.45µm filters (Nalgene), and either allotted and frozen or concentrated by ultracentrifugation using an SW28 rotor at 53,000 x g for 2 h at 4°C before freezing. Concentrations of Vpr, DNA flap, and CA mutant viral stocks were determined alongside concomitantly produced WT viruses using an exogenous ³²P-based RT assay [222].

**Infectivity assays.**

Control and siRNA knockdown cells seeded onto 48-well plates were infected overnight with various reporter viruses 48 h post-siRNA transfection. Percentages of GFP-positive cells were determined 36 h post infection (hpi) using a FACSCanto flow cytometer (BD) equipped with FACSDIVA software. GFP reporter experiments were performed with virus inoculates adjusted to yield < 40% GFP-positive cells in control samples. Cells were infected with equal RTcpm of WT or mutant HIV-1 luciferase reporter viruses, while MLV chimera viruses were adjusted such that all infections were approximately within 2 log RLU/µg/sec of control cells. Where applicable, cyclosporin A (CsA) (Sigma) was added at the time of infection to the final concentration of 5 µM. Cells infected with luciferase reporter viruses were lysed 48 hpi unless otherwise noted, and resulting levels of luciferase activity were normalized to the corresponding levels of total protein in cell extracts as described previously [96].

Normalized infectivity data were log transformed, and statistical analyses were performed by paired two-tailed Student’s t-test. Mean infectivity values were then back
transformed for graphical representation, with error bars denoting 95% confidence intervals.

**Western blot analysis.**

At the time of infection, siRNA treated cells were lysed with radioligand immunoprecipitation assay buffer (20 mM HEPES [pH 7.5], 150 mM NaCl, 1% NP-40, 1% sodium deoxycholate, 0.1% sodium dodecyl sulfate, 0.5 M EDTA, Complete protease inhibitor [Roche Molecular Biochemicals]). Following determination of protein concentration by Bradford assay, 60 µg or two-fold dilutions of each lysate were fractionated through 9% Tris-glycine gels, and proteins were transferred onto a polyvinylidene fluoride membrane. NUP153 and NUP62 were detected using a 1:2,500 dilution of mouse mAb414 antibody (Abcam Inc.), while TNPO3 was detected using a 1:150 dilution of mouse anti-TNPO3 antibody ab54353 (Abcam Inc.). A 1:5,000 dilution of rabbit anti-mouse horseradish peroxidase-conjugated served as secondary antibody (Dako North America Inc.), and a 1:5,000 dilution of mouse anti-α-tubulin antibody (Abcam Inc.) was used for loading control. Blots were developed using the ECL Plus detection reagent (GE Healthcare).

**QPCR.**

siNUP153#1 or siControl-transfected cells (500,000) were infected with ~2x10^7 RTcpm of DNase-treated WT or N/N mutant virus, with parallel infections conducted in the presence 100 µM azidothymidine (AZT) to define residual plasmid DNA levels potentially carried over from transfection. Two hours later, infected cells washed with
phosphate-buffered saline were re-plated into individual 24-wells. Cells were collected at various time points, and DNA was extracted with a QIAamp DNA Mini Kit as recommended by the manufacturer (Qiagen). Each sample was analyzed in triplicate by qPCR to determine levels of HIV-1 LRT-products, 2-LTR containing circles, and integrated proviruses via nested Alu-PCR essentially as described previously [51,223]. LRT and 2-LTR circle values were normalized to qPCR values for β-globin DNA performed in parallel, while all input DNAs for first-round Alu-PCRs were adjusted for equal β-globin amplification. Values obtained from corresponding AZT-treated samples, which averaged 2.6% of peak LRT and 2.5% of peak 2-LTR circles, were subtracted from non drug-treated values.

Plasmid pNLX.luc.R- was used to generate LRT standard curves while pUC19.2LTR was used for 2-LTR circles [216]. The integration standard was prepared by infecting HeLa cells at relatively low multiplicity of infection with the pH1-puro transfer vector [219], passage for two weeks in 2 µg/ml puromycin to permit loss of unintegrated HIV-1 DNA forms, and extraction of total DNA using the QIAamp DNA Mini Kit. Two-fold dilutions of infected cell DNA were mixed with complementary amounts of DNA prepared from uninfected HeLa cells to form the standard curve. Two-fold dilutions of uninfected cell DNA were used as the standard for β-globin.

QPCR primers and probes were: MH531, MH532, and MH535 for LRT [51]; 2-LTR circle junction [224]; AE3014, AE1066, AE3013, AE990, and AE995 for Alu-PCR [223,225]; and β-globin+ and β-globin- for HeLa genomic DNA [65]. SYBR green was used to measure β-globin amplification.

Abstract

Lentiviruses can infect non-dividing cells, and various cellular transport proteins provide crucial functions for lentiviral nuclear entry and integration. We previously showed that the viral CA protein mediated the dependency on cellular NUP153 during HIV-1 infection, and now demonstrate a direct interaction between the CA N-terminal domain and the phenylalanine-glycine (FG)-repeat enriched NUP153 C-terminal domain (NUP153\textsubscript{C}). NUP153\textsubscript{C} fused to the effector domains of the rhesus Trim5\textalpha{} restriction factor (Trim-NUP153\textsubscript{C}) potently restricted HIV-1, providing an intracellular readout for the NUP153\textsubscript{C}-CA interaction during retroviral infection. Primate lentiviruses and EIAV bound NUP153\textsubscript{C} under these conditions, results that correlated with direct binding between purified proteins in vitro. These binding phenotypes moreover correlated with the requirement for endogenous NUP153 protein during virus infection. Mutagenesis experiments concordantly identified NUP153\textsubscript{C} and CA residues important for binding and lentiviral infectivity. Different FG motifs within NUP153\textsubscript{C} mediated binding to HIV-1 versus EIAV capsids. HIV-1 CA binding mapped to residues that line the common alpha helix 3/4 hydrophobic pocket that also mediates binding to the small molecule PF-3450074 (PF74) inhibitor and cleavage and polyadenylation specific factor 6 (CPSF6) protein, with Asn57 (Asp58 in EIAV) playing a particularly important role. PF74 and CPSF6 accordingly each competed with NUP153\textsubscript{C} for binding to the HIV-1 CA pocket, and significantly higher concentrations of PF74 were needed to inhibit HIV-1 infection in the face of Trim-NUP153\textsubscript{C} expression or NUP153 knockdown. Correlation between CA mutant viral cell cycle and NUP153 dependencies moreover indicates that the NUP153\textsubscript{C}-CA interaction underlies the ability of HIV-1 to infect non-dividing cells. Our results
highlight similar mechanisms of binding for disparate host factors to the same region of HIV-1 CA during viral ingress. We conclude that a subset of lentiviral CA proteins directly engage FG-motifs present on NUP153 to affect viral nuclear import.
Introduction

Retroviruses integrate their reverse transcribed genomes into host cell chromosomes to provide a permanent vantage from which to amplify themselves for subsequent transmission. As the nuclear envelope physically separates the host chromosomes from the cytoplasm during interphase, retroviruses have evolved mechanisms to bypass this natural barrier to the nuclear compartment. The γ-retrovirus MLV is believed to await the dissolution of the nuclear envelope during mitosis, a mechanism that limits infection by this virus to actively dividing target cells [21,132,171]. Lentiviruses such as HIV-1 infect post-mitotic cell subtypes during the establishment of host systemic infection, and correspondingly harbor mechanisms to infect cells during interphase, likely circumventing the nuclear envelope by passing through the channel present in the NPC [22,226].

The vertebrate NPC is a large ~ 120 MDa macrostructure, composed of ~ 30 different proteins called nucleoporins (NUPs) that stack in rings of eight-fold symmetry to form the tubular pore as well as the attached cytoplasmic filaments and nuclear basket substructures [227,228]. Approximately one-third of the NUPs harbor domains rich in phenylalanine-glycine (FG) motifs, commonly observed as FxF, FxFG, or GLFG patterns [32]. These FG-rich domains line the central channel of the NPC, as well as the cytoplasmic and nuclear openings [229], and dictate the selective passage of macromolecules through the pore; small molecules are able to passively diffuse, while molecules greater than ~ 9 nm in diameter need to be ferried by specialized carrier proteins capable of interacting with the FG-based permeability barrier [230].
The HIV-1 nucleoprotein substrate for proviral integration, called the PIC, is estimated at ~ 56 nm in diameter [79], and thus requires active translocation into the nucleus. While initial studies suggested that HIV-1 IN, MA, and Vpr proteins, as well as a triple-stranded DNA structure of the reverse transcribed genome called the DNA flap, were key viral elements required for PIC nuclear import, subsequent studies found none of these factors to be essential [173]. Contrastingly, the viral CA protein was shown to be the major viral determinant for infecting non-dividing cells [57,116]. Various host proteins have also been shown to play roles in HIV-1 nuclear import, with perhaps the most promising candidates emerging from a series of genome-wide RNAi screens; factors identified in more than one of these screens include transportin-3 (TNPO3 or TRN-SR2), NUP358, and NUP153 [28,29,141]. We have been particularly interested in NUP153, which plays an important CA-dependent role in HIV-1 PIC nuclear import [177,231].

NUP153 is a FG nucleoporin that predominantly locates to the nuclear side of the NPC and exchanges dynamically with a nucleoplasmic population [181]. While NUP153 is anchored to the nuclear rim of the NPC through its N-terminal domain [156], its C-terminal FG enriched domain (referred to as NUP153c herein) is natively unfolded and highly flexible [162]. The ~ 200 nm long NUP153c potentially reaches through to the cytoplasmic side of the NPC channel [164], shifting in spatial distribution in a transport-dependent manner [163,165]. Human NUP153c contains 29 FG motifs (FxF, FG, and FxFG patterns), which provide a vital role in NUP153-mediated nucleocytoplasmic transport [166,167,185].
While numerous studies have demonstrated the functional significance of CA for HIV-1 nuclear import and integration, the mechanistic details for these connections are incompletely understood. Retroviral CA proteins are composed of two $\alpha$-helical domains, the N-terminal domain (NTD) and C-terminal domain (CTD), separated by a short flexible linker. CA multimerizes into hexameric arrays during particle maturation, while twelve interspersed pentamers dictate the overall shape of the condensed viral core [40-43]. While relatively intact cores enter the cell upon viral-cell membrane fusion, little if any CA remains associated with the PIC within the nucleus [56,74,75,77,81]. The precise location and mechanism of CA core disassembly remains controversial: while initial steps of core uncoating are tied to reverse transcription [45], subsequent events may involve binding to host proteins. This may involve CypA and the NUP358 cyclophilin homologous domain (CHD), both of which bind the cyclophilin binding loop protruding from the top of the CA NTD [232,233], or CPSF6, which binds a hydrophobic pocket [234] located between $\alpha$-helices 3 and 4 within the NTD. The small molecule PF-3450074 (PF74), which inhibits HIV-1 infection by destabilizing incoming CA cores, also engages this same pocket [235]. CA-containing protein complexes have been observed alongside the nuclear envelope [80], suggesting that the ultimate steps of core uncoating may occur at the nuclear periphery and/or during PIC nuclear transport.

Here, we find that the CA proteins from numerous lentiviruses, including HIV-1 and EIAV, directly bind NUP153$_C$, with subsequent mapping demonstrating the importance of individual FG-motifs themselves. A panel of HIV-1 CA mutants highlights the importance of side-chains lining the CA NTD helix 3/4 hydrophobic pocket, and competition with both CPSF6 and PF74 support this as the site of NUP153$_C$ binding.
Correlation between NUP153 binding and dependence on endogenous NUP153 expression additionally support the relevance of this interaction during infection. HIV-1 CA mutant viruses N57A and N57D were defective for NUP153$_C$ binding and acutely sensitive to the arrest of the cell-division cycle, with a significant correlation between cell cycle and NUP153 dependencies observed among an expanded set of CA mutant viruses. Our data support a model whereby partially uncoated cores directly engage NUP153 FG-motifs within the NPC to affect HIV-1 PIC nuclear import.
Results

**NUP153\textsubscript{C} binds the NTDs of a subset of retroviral CA proteins**

As we previously found CA to be the dominant viral determinant of the requirement for NUP153 during HIV-1 infection [231], we tested whether a physical interaction between NUP153 and HIV-1 CA exists. Our initial assay utilized a recombinant viral fusion protein consisting of HIV-1 CA and nucleocapsid (NC) proteins, which when assembled in vitro in the presence of high salt and single stranded nucleic acid forms large tube-like structures that readily pellet through cushions of sucrose [40]. In this way, CA-interacting proteins can co-sediment with the tube structures [122,177]. Full length or various fragments of HA-tagged NUP153 expression constructs were transfected into 293T cells, and the resulting proteins were tested for their ability to co-sediment with CA-NC assemblies. Full-length NUP153 (residues 1-1475) pelleted through the sucrose cushion in a CA-NC dependent manner (Figure 3-1A and 3-1B). The NUP153 N-terminal domain (residues 1-650) failed to bind CA-NC under conditions that supported efficient NUP153\textsubscript{C} (residues 896-1475) binding. The C-terminal NUP153 deletion mutant comprised of residues 1-1198 failed to bind, confirming the importance of the NUP153 FG-repeat domain in binding, and mapping the interaction to residues 1199-1475 of the full length protein.

We addressed whether the NUP153–CA-NC interaction was the result of direct protein binding through the use of purified, recombinant NUP153 protein. We attempted to express full-length NUP153 fused to glutathione \(\text{S}\)-transferase (GST) in bacteria, but despite extensive effort, were unable to define conditions that yielded usable quantities of
Figure 3-1. **NUP153C directly binds the HIV-1 CA N-terminal domain.** (A) Schematic of NUP153 protein, with residue numbers of domain boundaries indicated. (B) Full length or truncated fragments of HA-tagged NUP153 extracted from 293T cells were tested for binding to HIV-1 CA-NC. Pelleted proteins were resolved by SDS-PAGE and visualized by western blotting with anti-HA antibody 3F10 (top), or by Coomassie stain (bottom). Input, 20% of binding reaction. CA-NC was included in the binding reactions as indicated. (C) Recombinant, tag-free NUP153C and GST purified from *E. coli* were similarly tested for binding to CA-NC; proteins were detected with Coomassie stain. (D) Recombinant NUP153C pulled down with full length his-tagged wild-type (WT) or W184A/M185A HIV-1 CA, and detected with Coomassie stain. (E) Recombinant NUP153C pulled down with his-tagged CA_N, and detected with Coomassie stain. Each experiment was repeated at least 3 times, with a single representative result shown.
GST-NUP153 protein. Based on our preliminary binding data (Figure 3-1B), we instead expressed and affinity purified GST-NUP153C. NUP153C was liberated from the GST tag by site-specific proteolysis, with the remaining CA binding studies utilizing tag-free NUP153C protein. Approximately 40% of the input recombinant NUP153C protein was recovered during co-sedimentation under conditions where binding of a negative control GST protein was undetected (Figure 3-1C). To test whether NUP153C binds CA in the absence of NC and nucleic acid, his-tagged HIV-1 CA expressed and purified from E. coli was utilized in Ni-nitritriacetic acid (NTA) pulldown assays. Approximately 30% of input NUP153C was pulled down by his-tagged HIV-1 CA protein. Notably, this interaction is likely independent of CA oligomerization, as double mutant W184A/M185A CA, which is unable to dimerize and form higher-ordered assemblies [236], pulled-down comparable amounts of NUP153C (Figure 3-1D). The isolated CA NTD (CA_N) was expressed as a his-tagged protein and purified to next probe the binding region within HIV-1 CA; CA_N pulled down ~30% of input NUP153C protein (Figure 3-1E). Although these data do not quantitatively address potential CA oligomerization-based affects on NUP153C binding, the relatively robust interaction with CA_N suggests that NUP153 may efficiently engage monomeric CA during HIV-1 infection.

The preceding results established a direct interaction between NUP153 and HIV-1 CA proteins in vitro. We next examined whether an assay could be constructed to visualize the interaction in the context of HIV-1 infection. We scored for potential intracellular interaction by relying upon the potent capability of rhesus Trim5α (rhTrim5α) to inhibit HIV-1 infection. RhTrim5α is a cytoplasmically localized restriction factor, capable of blocking HIV-1 infection at an early post-entry step [121].
Figure 3-2. Restriction of HIV-1 infection by Trim5-NUP153\textsubscript{C} fusion proteins. (A) Schematic of Trim-NUP153\textsubscript{C} fusion and control constructs. Color code: Trim5 RBCC, brown; rhTrim5\textsubscript{α} SPRY, auburn; HA-tag, blue; NUP153\textsubscript{C}, orange. (B) Western blot of HOS cells stably transduced with HA-tagged Trim-NUP153\textsubscript{C} fusion or control constructs, detected with antibody 3F10. (C) Western-blot detection of Trim-NUP153\textsubscript{C} fusion proteins with anti-HA monoclonal antibodies 3F10 and 16b12. Antibody 3F10 detects full-length Trim-NUP153\textsubscript{C}-HA whereas antibody 16b12 more faithfully detects full-length Trim-HA-NUP153\textsubscript{C}. (D) Infectivity of various doses of HIV-1 (left) or MLV (right) GFP reporter viruses on HOS cells stably expressing various Trim-based constructs. The results are an average of two experiments, with error bars denoting standard error. Asterisks in panels B and C mark bands that correspond to the expected mobilities of full length Trim-NUP153\textsubscript{C} constructs.

While the C-terminal B30.2 (SPRY) domain recognizes patterns present on the surface of retroviral CA cores [237,238], the N-terminal RING, B-box 2, and coiled coil (RBCC) effector domains block infection by eliciting a combination of inhibitory activities, including premature disassembly of the viral core [122], proteasomal targeting [123], and triggering of innate immune signaling [239]. Both naturally occurring, as well as artificially engineered variants of Trim5 have been discovered wherein the SPRY domain is replaced by heterologous coding sequences, retaining viral restriction while changing the method by which the viral core is recognized [233,240,241]. In this vein we tested for intracellular recognition between NUP153C and HIV-1 CA by replacing the SPRY domain of rhTrim5α with NUP153C, concomitantly introducing either an internal- or C-terminal HA epitope tag to enable detection of the fusion proteins by western blotting (Figure 3-2A). These constructs, as well as control constructs encoding only the epitope-tagged rhTrim5 RBCC or NUP153C, were stably introduced into human osteosarcoma (HOS) cells (Figure 3-2B). While a single species of C-terminally HA tagged Trim-NUP153C of the expected molecular weight was detected by western blot, the internally tagged construct revealed the protein susceptible to degradation, with the full-length protein representing only a minority of the expressed products at steady state (Figure 3-2B and 3-2C). Regardless, Trim-NUP153C expressing cells potently restricted HIV-1 infection, yielding consistent 5-10 fold reductions in viral titer (Figure 3-2D). The combination of both rhTrim5 RBCC and NUP153C domains was necessary, as neither domain expressed alone inhibited HIV-1 infection. Knockdown of endogenous NUP153 acutely attenuates HIV-1 infection with little or no effect on MLV [231]. Importantly, the observed attenuation of HIV-1 infection by Trim-NUP153C expression was specific, as
Figure 3-3. Trim-NUP153c localizes to the cell cytoplasm and restricts HIV-1 reverse transcription. (A) Immunofluorescence confocal microscopy of HOS cells transduced with empty vector or the indicated HA-tagged construct. Hoechst 33342 stains DNA and therefore highlights cell nuclei. (B) Fractionation of rhTrim5α-HA, Trim-HA-NUP153c, and HA-NUP153c expressing cells. Gels were probed with antibodies against the HA tag (top panels), histone H3, α-tubulin, or NUP62 (bottom panels). Cytoplasmic α-tubulin and nucleus-associated NUP62 and histone H3 marker proteins were predominantly found in fractions 1 and 3, respectively. Asterisks mark bands that correspond to the expected mobilities of full length constructs. (C-E) Levels of R-U5 DNA synthesis (early reverse transcripts) (C), U5-gag DNA synthesis (late reverse transcripts) (D), and 2-LTR circle formation (E), in cells transduced with empty vector, rhTrim5α-HA, or Trim-HA-NUP153c expressing constructs at 1, 6, 24, and 48 h post HIV-1 infection, as detected by qPCR. Results (averages of three experiments, with error bars denoting standard error) were normalized to levels of peak DNA amplification, which was set at 100%. (F) Corresponding infectivity of GFP reporter viruses, measured 48 h post infection. Data were normalized to infectivity in cells transduced with empty expression vector. Results are an average of three experiments, with error bars denoting standard error.

infection by an MLV reporter virus was unaffected (Figure 3-2D). Similar to parental rhTrim5α, Trim-NUP153C located to the cell cytoplasm (Figure 3-3A and 3-3B) and prevented HIV-1 from completing reverse transcription (Figure 3-3C-F), suggesting that it likely recognizes the HIV-1 CA core in the cytoplasm shortly after viral entry. We conclude that although NUP153C in the context of the Trim5 protein likely engages HIV-1 CA earlier than endogenous NUP153 protein, the novel fusion nonetheless affords the analysis of the NUP153-CA interaction in the context of HIV-1 infection. Due to the marginally greater level of restriction imparted by the internally tagged construct, the Trim-HA-NUP153C variant was used in subsequent experiments.

The readout for intracellular CA core recognition was further validated by subjecting a panel of divergent retroviral reporter viruses to Trim-NUP153C inhibition. Primate lentiviruses SIVmac, SIVagmSab, SIVagmTan, and HIV-2 were similarly sensitive to Trim-NUP153C inhibition (Figure 3-4A). Though EIAV was also sensitive, not all lentiviruses were: neither bovine immunodeficiency virus (BIV) nor FIV was inhibited by Trim-NUP153C. The more distantly related α-retrovirus RSV was also unresponsive. To correlate the results of Trim-mediated restriction of virus infection to direct protein binding, a subset of the sensitive (EIAV) and nonresponsive (MLV and FIV) CA\textsubscript{N} proteins were purified following their expression in bacteria. EIAV CA\textsubscript{N} bound NUP153C as efficiently as HIV-1 CA\textsubscript{N}, whereas binding to either MLV or FIV CA\textsubscript{N} was significantly less efficient ($P < 0.01$) (Figure 3-4B and 3-4C). Reliance on NUP153 during retroviral infection was compared with CA-NUP153C binding (Figure 3-4A) by correlating percent infectivity in the face of NUP153 knockdown [231] (repeated here using HOS cells; Figure 3-4D).
Figure 3-4. Diverse lentiviruses bind NUP153C. (A) Transduction efficiencies of retroviral GFP reporter viruses in Trim-NUP153C expressing cells normalized to infection in mock transduced cells, which were set to 100%. The results are the geometric mean of at least 4 experiments, with error bars denoting 95% confidence intervals. (right) Western blot detection of control or NUP153 knockdown HOS cells with antibody mab414. (E) Scatter plot comparing relative retroviral infectivities under each condition.
The resulting Spearman rank coefficient of 0.673 was statistically significant \( P = 0.039 \) (Figure 3-4E).

**FG motifs within NUP153 dictate CA binding**

Mutations within NUP153\textsubscript{C} were made to decipher the components of NUP153 critical for binding. As the HIV-1 restriction assay was higher throughput than the expression and purification of separate NUP153\textsubscript{C} proteins, we first engineered mutations within the Trim-NUP153\textsubscript{C} fusion construct. Since the starting fusion construct contained the entire \( \sim 580 \) amino acid NUP153\textsubscript{C}, we generated cell lines stably expressing Trim fusion proteins with roughly quarter-size deletions of NUP153\textsubscript{C}, and determined the extent to which these constructs inhibited HIV-1 and EIAV infection, using MLV and FIV as negative controls (Figure 3-5A and 3-5B). Relative levels of HIV-1 and EIAV infection were compared to ease the interpretation of results to Trim-NUP153\textsubscript{C} mediated restriction; parental Trim-NUP153\textsubscript{C} yielded an HIV-1 to EIAV infectivity ratio of \( \sim 0.41 \) (Figure 3-5B). Deletion of residues 896 to 1045 at the N-terminus of NUP153\textsubscript{C} resulted in a construct that potently inhibited HIV-1 infection to a level \( \sim 8 \) fold greater than the full-length construct, yet lost the ability to inhibit EIAV, yielding an HIV-1 to EIAV infectivity ratio of \( \sim 0.01 \) (Figure 3-5B). Contrasting, deletion of C-terminal residues 1350 to 1475 resulted in a protein still capable of inhibiting EIAV infection to a level comparable to the full-length construct, yet incapable of inhibiting HIV-1 infection beyond the level of the control viruses, resulting in an infectivity ratio of \( \sim 4.70 \). These effects were specific to sequences deleted in the preceding constructs, as neither internal deletion noticeably perturbed the original Trim-NUP153\textsubscript{C} restriction pattern; both
Figure 3-5. Different NUP153C sub-regions mediate Trim-NUP153C restriction of EIAV versus HIV-1 infection. (A) To-scale schematic of NUP153C sequences encoded in various Trim-NUP153C constructs. Red lines represent boundaries of quarter-sized NUP153C sub-regions, while black lines denote the locations of FG motifs. (B) Infectivity of retroviral GFP reporter viruses on HOS cells stably expressing full-length or quarter-deleted Trim-NUP153C constructs, normalized to infection in mock transduced cells. Data represent the geometric mean of 5 experiments, with error bars denoting 95% confidence intervals. HIV-1 to EIAV ratios of infectivity are shown, with associated standard error. (C) Western blot of HOS cells stably transduced with Trim-NUP153C fusion constructs detected with antibody 16b12. Asterisks denote bands corresponding to the expected mobilities of full length or mutated Trim-NUP153C constructs.
constructs displayed the same slight advantage to inhibit HIV-1 infection over EIAV, with HIV-1 to EIAV infectivity ratios similar to the full-length construct. Western blotting confirmed that each deletion construct was expressed at roughly similar levels (Figure 3-5C). The mapping of the HIV-1 binding determinant on NUP153C to residues 1350-1475 by Trim-mediated restriction notably coincides with our preliminary identification of the region C-terminal to residue 1198 using CA-NC tubes and HA-tagged NUP153 deletion constructs (Figure 3-1B).

We next focused on the initial quarter of NUP153C for its importance in mediating restriction of EIAV infection. Stable cell lines expressing only the first quarter of NUP153C fused to the Trim RBCC, as well as smaller derivatives of the NUP153C sequence, were generated (Figure 3-6A). Residues 896-949, which yielded the smallest construct capable of restricting EIAV infection (Figure 3-6B), harbored only two of the 29 FG motifs present within NUP153C. The importance of these FG motifs in mediating EIAV restriction was tested by substituting four consecutive alanine residues for each corresponding FKFG sequence. The combination octa-alanine 903A/924A Trim-NUP153C mutant construct lost its ability to inhibit EIAV infection despite being expressed at a level equal to or greater than unmodified Trim-NUP153C (Figure 3-6B and 3-6C). The 903A/924A mutant moreover retained potent HIV-1 restriction. Separate mutation of each motif revealed 924-FKFG-927 as the dominant FG sequence for mediating EIAV restriction.

Sequence components of NUP153C that mediated restriction of HIV-1 infection were investigated next. Attempts to recover cells expressing the responsible C-terminal quarter of NUP153C (residues 1350-1475) fused to Trim RBCC were unsuccessful. We
Figure 3-6. The importance of FG motifs for Trim-NUP153C mediated inhibition of HIV-1 and EIAV infection. To-scale schematics (A and D), normalized infection data (B and E), and western blotting (C and F) as described for Figure 3-5. Infection data are the geometric mean of at least 4 experiments, with error bars denoting 95% confidence intervals. Inverted grey triangle (panels A and D) denotes area of missense mutation.
instead undertook the alternative strategy to internally delete segments of residues 1350-1475 from the full-length Trim-NUP153C construct (Figure 3-6D). Deletion of residues 1410-1447 selectively diminished inhibition of HIV-1 without affecting EIAV, yielding an increased HIV-to-EIAV infectivity ratio of 2.7, while deletion of residues 1350-1410 did not drastically alter the ratio from that observed with the full length construct (Figure 3-6E and 306F). As residues 1410-1447 contained only one FxFG and one FxF motif, these were mutated to alanine residues, initially in the context of the Δ1350-1410 construct. Combinatorial alteration of both tetra- and tri-peptides reduced restriction of HIV-1 without significantly affecting EIAV restriction (HIV-1/EIAV infectivity ratio = 2.29). Separate mutation showed this effect was largely, if not entirely due to 1415-FTFG-1418, and the 1415A mutation largely prevented restriction of HIV-1 in the full-length construct as well (infectivity ratio = 2.17). Combined, these results highlight the importance of FG motifs for Trim-NUP153C mediated restriction of HIV-1 and EIAV infection. Moreover, different FG motifs appear to selectively recognize HIV-1 versus EIAV CA proteins.

We subsequently tested for Trim-NUP153C FG motif recognition of EIAV and HIV-1 CA proteins in vitro. HA-tagged NUP153C or analogous quarter deleted fragments expressed in 293T cells were used as bait for pull-down by various his-tagged retroviral CA\textsubscript{N} proteins (Figure 3-7A). The construct lacking residues 1045-1198 was expressed far less than the other constructs, and was not interpreted. As expected (Figure 3-4B), none of the constructs bound MLV CA\textsubscript{N} to levels greater than those observed with beads alone. Consistent with the results from Trim-NUP153C restriction, the protein lacking residues 1350-1475 was selectively bound less well by HIV-1 CA\textsubscript{N}. Contrastingly, EIAV
Figure 3-7. FG motifs determine NUP153\textsubscript{C} binding to HIV-1 CA\textsubscript{N}. (A) Pull-down of full-length or quarter deleted HA-NUP153\textsubscript{C} by HIV-1, EIAV, or MLV CA\textsubscript{N} proteins, detected with antibody 3F10. (B) Pull-down of WT NUP153\textsubscript{C}, FG-motif tetra-alanine mutant 1415A, or combinatorial 7xFG/A mutant by beads alone (none, grey), HIV-1 (red), MLV (blue), or EIAV (green) CA\textsubscript{N} proteins, as detected by western blot with antibody 3F10. Results are an average of at least 4 experiments, with error bars denoting standard error. (C) Purified NUP153\textsubscript{C} (black circles, solid line), NUP153\textsubscript{C}\textDelta 1350-1475 (purple triangles, fine dotted line), and NUP153\textsubscript{C}7xFG/A (brown diamonds, coarse dotted line) were incubated with various concentrations of HIV-1 CA\textsubscript{N} and a constant amount of Ni-NTA beads. Data points represent the mean and standard error of at least three experiments, fit with non-linear regression curves. The dissociation constant of NUP153\textsubscript{C} binding was calculated by averaging concentrations of half-maximal binding for 5 individual experiments, with associated standard error. (D) Sedimentation of WT NUP153\textsubscript{C}, FG-motif tetra-alanine mutant 1415A, combinatorial 7xFG/A mutant, or NUP153\textsubscript{C}\textDelta 1350-1475 after incubation with buffer alone or assembled CA-NC. Results are an average of 6 experiments, with error bars denoting 95% confidence intervals. Representative western blotting results are shown.
Figure 3-7, continued

(D) Western blot analysis of CA-NC with different constructs.
CAF bound all of the fragments tested, including the fragment that lacked residues 896-1045.

We further tested whether HIV-1 CA bound was traceable to specific FG motifs. HA-NUP153C containing the 1415-FTFG-1418 tetra-alanine replacement bound HIV-1 CA essentially as well as the unmutated fragment (Figure 3-7B). Since we observed strongly diminished binding when the last quarter of HA-NUP153C was deleted (Figure 3-7A), we next mutated all 7 of the FG motifs within this segment to alanines (HA-NUP153C7xFG/A). The combination of these mutations selectively abrogated binding of HA-NUP153C to HIV-1 CA; importantly, effective binding of the mutant protein to EIAV CA was retained (Figure 3-7B). Decreased Δ1350-1475 and 7xFG/A mutant binding to HIV-1 CA was also observed with purified NUP153C proteins. HIV-1 CA bound purified NUP153C (0.5 µM) in a dose-dependent manner, revealing a corresponding $K_d$ of ~28.3 µM at half-maximal saturation (Figure 3-7C). Although CA displayed some affinity for NUP153CΔ1350-1475 and NUP153C-7xFG/A, the shapes of these linear response curves were notably different from the unmutated protein, and half-maximal saturation was not reached under these assay conditions.

We hypothesized that differing states of CA multimerization might contribute to the partially overlapping specificities observed in the CA pull-down (Figure 3-7A and 3-7B) versus Trim-NUP153C restriction (Figure 3-6E) assays. To test this, assembled CA-NC tubes were substituted for monomeric CA protein. Under these conditions, both the NUP153C-7xFG/A and 1415A mutant proteins displayed significantly diminished binding, similar to the effect observed for the Δ1350-1475 deletion ($P < 0.01$) (Figure 3-
These findings seemingly agree with the results of the Trim-NUP153C mediated restriction assays (Figure 3-5B and 3-6E).

**Side-chains proximal to a common hydrophobic pocket in HIV-1 CA<sub>N</sub> mediate NUP153<sub>C</sub> binding**

We and others previously observed that various CA mutant viruses exhibit altered sensitivity to NUP153 knockdown [177,231]. We next characterized an expanded set of CA mutant viruses for altered sensitivity to Trim-NUP153<sub>C</sub> restriction. Mutants were selected based on prior descriptions of pre-integrative defects during HIV-1 infection. Alteration of CA residue(s) Pro38, Glu45, Thr54/Asn57, or Gln63/Gln67 can effect core stability [45,57,119,120], whereas Thr54, Asn57, Lys70, Asn74, Gly89, Pro90, Ala92, Gly94, and Thr107 mutants can alter dependencies on various host proteins, including CPSF6, TNPO3, NUP358, CypA, or NUP153 [177,187,191,231,233,234,242,243]. As a number of these mutants exhibit drastically diminished overall levels of infectivity (Figure 3-8A), an unrelated IN mutant virus (D167K), which infects cells at ~ 8% of the level of wild-type (WT) HIV-1 [244], was included to control for our ability to reproducibly measure restriction at reduced viral titers. While the IN mutant virus was as sensitive as the WT virus to Trim-NUP153<sub>C</sub> restriction, a number of CA mutant viruses exhibited significantly reduced susceptibility ($P < 0.001$) (Figure 3-8B). Included among these were CypA and NUP358 CHD binding mutants G89V and P90A [187,233], as well as mutants E45A, T54A/N57A, N57A, N57D, Q63A/Q67A, Q67A, K70R, and N74A.

As these CA mutant viruses could resist Trim-NUP153<sub>C</sub> restriction for any number of reasons, we tested for direct binding defects by pulling down NUP153<sub>C</sub> with
Figure 3-8. HIV-1 CA mutant-NUP153<sub>C</sub> binding and sensitivity to Trim-NUP153<sub>C</sub> restriction. (A) Equal RTcpm of WT and HIV-1 mutant viruses plated on HOS cells, with resulting infectivities normalized to WT virus. (B) Percent infectivity of viruses in Trim-NUP153<sub>C</sub> expressing HOS cells, normalized to mock transduced control cells. Graphs show the mean of at least 5 experiments, with error bars denoting 95% confidence intervals. (C) Purified NUP153<sub>C</sub> pull-down by WT or the indicated mutant his-tagged HIV-1 CA<sub>N</sub> protein, with recovered proteins resolved by SDS-PAGE and detected by SYPRO Ruby stain. Results are an average of 5 experiments, with error bars denoting 95% confidence intervals. A representative staining result is shown. The dotted line highlights the level of NUP153<sub>C</sub> binding to WT CA<sub>N</sub> protein. (D) HA-NUP153<sub>C</sub> in 293T cell lysates pulled-down by WT or various mutant his-tagged HIV-1 CA<sub>N</sub> proteins, with recovered protein resolved by SDS-PAGE and detected by 3F10 and anti-his antibodies. Results are an average of 4 experiments, with error bars denoting standard error. A representative western blot result is shown. The dotted line highlights the level of HA-NUP153<sub>C</sub> binding to WT CA<sub>N</sub> protein.
correspondingly purified CA\textsubscript{N} mutant proteins. Residue Asn57 was critical for binding, as mutant proteins T54A/N57A, N57A, and N57D were strongly diminished in their abilities to pull down NUP153\textsubscript{C} (Figure 3-8C). Although not critical for binding, both Lys70 and Asn74 appeared to participate: mutation of Lys70 to arginine diminished binding while mutation to alanine enhanced binding; contrastingly, mutation of Asn74 to alanine diminished binding, while mutation to aspartic acid enhanced binding to NUP153\textsubscript{C}. The Q63A/Q67A mutation marginally diminished binding by \( \sim 1.3 \) fold. This binding hierarchy was also observed for HA-NUP153\textsubscript{C} protein expressed in mammalian cells, with Asn57 again proving key for the interaction, and mutants K70A and N74D yielding hyper-binding activity (Figure 3-8D). Overall, CA mutant viral sensitivities to Trim-NUP153\textsubscript{C} restriction correlated well with CA\textsubscript{N} mutant binding to NUP153\textsubscript{C} protein in vitro (Figure 3-9A).

As we predict that mutant viruses that require NUP153 for infection also bind NUP153\textsubscript{C}, we compared the sensitivities of CA mutant viruses to NUP153 knockdown with their susceptibility to Trim-NUP153\textsubscript{C} mediated restriction. We observed that CA mutant viruses that require endogenous NUP153 for infection were also sensitive to Trim-NUP153\textsubscript{C} mediated restriction. A strong correlation supported this relationship across the entire panel of CA mutant viruses (Figure 3-9B). This included NUP153\textsubscript{C} loss-of-binding mutants T54A/N57A, N57A and N57D, which retained approximately 85\%, 102\% and 58\% of their infectivity, respectively, upon NUP153 knockdown.
Figure 3-9. Comparison of HIV-1 CA mutant-NUP153<sub>c</sub> sensitivity to Trim-NUP153<sub>c</sub> restriction with binding to NUP153<sub>c</sub>, or sensitivity to NUP153 depletion. (A) Scatter plot of NUP153<sub>c</sub> recovery in pull-down assays (Figure 3-8C) compared to percent infectivity in Trim-NUP153<sub>c</sub> expressing cells (Figure 3-8B). Points are color-coded based on NUP153<sub>c</sub> binding phenotype: grey, not significantly different from WT; white, significantly decreased from WT; black, significantly increased from WT. (B) Scatter plot of normalized infectivity of CA mutant viruses in Trim-NUP153<sub>c</sub> expressing cells compared to the average infectivity of three experiments when endogenous NUP153 was knocked down. The comparison exhibited a significant Spearman rank correlation ($P < 0.0001$). Points are color-coded as in panel C, except for CA mutants not tested for binding, which are denoted with “x” symbols.
The NUP153<sub>C</sub> binding site overlaps with those for PF74 and CPSF6

Residues Asn57, Lys70, and Asn74, highlighted in our binding assays, surround a hydrophobic pocket within CA<sub>N</sub> formed by α helices 3 and 4, and this pocket has been shown to be the binding site of the small molecule inhibitor PF74 [235] (Figure 3-10A). To probe potentially similar binding modes, we tested whether PF74 could compete for HA-NUP153<sub>C</sub> binding to CA<sub>N</sub> (Figure 3-10B). PF74 indeed competed for binding to CA<sub>N</sub> in a dose-dependent manner, with an IC<sub>50</sub> of ~ 13.6 µM. While PF74 binds WT and N74D CA<sub>N</sub> proteins similarly [234], the small molecule was less effective at competing for HA-NUP153<sub>C</sub> binding to N74D CA<sub>N</sub>, yielding an IC<sub>50</sub> of 145.3 µM, perhaps due to the increased binding observed between NUP153<sub>C</sub> and N74D CA<sub>N</sub> (Figure 3-8C and 3-8D). PF74 does not bind K70A mutant CA<sub>N</sub>[234], and accordingly did not compete for HA-NUP153<sub>C</sub> binding to this mutant protein (Figure 3-10B).

This same pocket also engages the mRNA splicing cofactor CPSF6 [177,234,240], which was first implicated in HIV-1 biology by the ability for an exogenously expressed C-terminal truncation mutant CPSF6<sub>358</sub> to restrict PIC nuclear import [177]. Though vastly differing molecules, co-crystal structures of PF74-CA<sub>N</sub> and CPSF6 (residues 313-327)-CA<sub>N</sub> complexes revealed that each exhibit nearly identical insertions of methyl benzyl residues (Phe321 in the case of CPSF6) within the helix 3/4 pocket, in both cases forming two hydrogen bonds with the carboxamide side-chain of CA residue Asn57 (Figure 3-10A and 3-10C). Based on these observations, we tested whether purified NUP153<sub>C</sub> could compete with full-length CPSF6 protein for binding to CA. HA-tagged CPSF6 expressed in 239T cells was incubated with HIV-1 CA-NC tubes prior to centrifugation through a 20% sucrose cushion. CPSF6 pelleted only in the
Figure 3-10. NUP153C competes with molecules that bind the HIV-1 CA hydrophobic pocket. (A) X-ray crystal structure (pdb: 2xde) of compound PF74 (yellow) bound to HIV-1 CA (green). Critical CA side-chains (labeled) are shown as sticks, with oxygen and nitrogen atoms colored red and blue, respectively. Hydrogen bonds are shown as black dashes, with distances labeled. The phenylalanine moiety in PF74 is indicated by the black arrow. (B) PF74 competition of HA-NUP153C binding to WT or mutant his-tagged HIV-1 CA. Recovered HA-NUP153C was detected with antibody 3F10 and quantitated alongside a standard curve of serially diluted HA-NUP153C-containing lysate. Baseline background signal observed with T54A/N57A CA pulldown was subtracted, and all values were normalized to that of the DMSO control (2% DMSO final concentration in each sample). Results are an average of at least 2 experiments, with error bars denoting standard error. Representative western blotting results are shown. (C) X-ray crystal structure (pdb: 4b4n) of a peptide from CPSF6 (backbone carbon atoms shown as sticks in grey) bound to CA (green) in the same orientation as in panel A. Side-chains and hydrogen bonds are represented as in panel A. The CPSF6 Phe321 side chain is indicated by the black arrow. (D) Binding of HA-tagged, full-length CPSF6 protein in 293T cell extract to HIV-1 CA-NC protein, and competition with purified NUP153C or mutants thereof. Results of 5 experiments were normalized to the level of CPSF6 binding observed in the absence of competing factors, with error bars denoting standard error.

(Figure 3-10, continued)
presence of CA-NC (**Figure 3-10D**). This interaction indeed required binding to the CA\textsubscript{N} hydrophobic pocket, as excess PF74 counteracted it. We additionally observed that co-incubation with purified NUP153\textsubscript{C} significantly diminished CPSF6 binding ($P < 0.0001$) by \(\sim 7\) fold as compared to the level observed in the absence of competing factors. This competition was specific, as NUP153\textsubscript{C} mutants \(\Delta 1350-1475\) and 7xFG/A, both of which exhibit greatly diminished binding to CA-NC (**Figure 3-7**), were significantly less effective at competing for CPSF6 binding ($P < 0.05$) (**Figure 3-10D**).

CA residues that mediate binding to NUP153\textsubscript{C} and CPSF6 were further analyzed by assessing CA mutant sensitivities to restriction by the artificial restriction factor Trim-CPSF6\textsubscript{358} (**Figure 3-11A**), a larger derivation of the Trim-CPSF6 fusion proteins previously tested [240]. Though conferring similar levels of restriction, far fewer of the CA mutant viruses were able to resist Trim-CPSF6\textsubscript{358} inhibition (**Figure 3-11B**, red data points) compared to Trim-NUP153\textsubscript{C} (black points). CypA binding mutants G89V and P90A were partially resistant to Trim-CPSF6\textsubscript{358} restriction, whereas N57A, N74A, and N74D in large part conveyed full resistance. The N57A and N74D changes were notably previously shown to prevent binding of CA\textsubscript{N} to the CPSF6 peptide [234]. Interestingly, changes at Asn57 and Asn74 conferred distinguishable resistance profiles to Trim-NUP153\textsubscript{C} versus Trim-CPSF6\textsubscript{358}: both conservative N74D and non-conservative N74A changes rendered HIV-1 resistant to Trim-CPSF6\textsubscript{358}, while only N74A rendered the virus partially resistant to Trim-NUP153\textsubscript{C} (**Figure 3-11B**). Contrastingly, both conservative and non-conservative Asn57 changes prevented Trim-NUP153\textsubscript{C} recognition, while the conservative N57D mutant remained as sensitive to Trim-CPSF6\textsubscript{358} restriction as the WT virus.
Figure 3-11. HIV-1 CA mutant sensitivities to Trim-NUP153 as compared with sensitivities to CPSF6 and Trim-CPSF6. (A) Western blot of HOS cells stably expressing Trim-CPSF6 or CPSF6, detected with antibody 3F10. (B) CA mutant virus sensitivities to Trim-NUP153 (black) and Trim-CPSF6 (red), as compared to cells transduced with an empty vector. Results are an average of at least 3 experiments, with error bars denoting 95% confidence intervals. (C) Scatter plot of CA mutant sensitivities to NUP153 knockdown compared with sensitivities to inhibition by CPSF6. (D) Percent infectivity of CA mutant viruses on CPSF6 expressing HOS cells compared to mock transduced cells. Results are the average of 3 experiments, with error bars denoting standard error.
The breadth of CA mutants restricted by Trim-CPSF6\textsubscript{358} in HOS cells appeared to contrast with prior results of CPSF6\textsubscript{358}-mediated restriction of HIV-1 in Hela cells, where many of the same CA mutations conferred resistance to inhibition [66]. We confirmed these phenotypes in HOS cells, where we observed that many additional CA mutant viruses resist CPSF6\textsubscript{358}-mediated restriction (Figure 3-11C). Many of the CA mutant viruses selectively resistant to CPSF6\textsubscript{358} over Trim-CPSF6\textsubscript{358} restriction were also insensitive to endogenous NUP153 knockdown, resulting in a moderate correlation between CA mutant sensitivities to CPSF6\textsubscript{358} restriction and NUP153 knockdown (Figure 3-11D).

PF74 destabilizes the structure of purified CA cores and can inhibit reverse transcription, which likely accounts for at least part of its antiviral activity [245]. We assessed whether PF74 could additionally antagonize NUP153\textsubscript{C} engagement by CA in the context of HIV-1 infection, given the caveat that we could not unambiguously correlate data from protein binding assays (Figure 3-10B) with effects from PF74-induced capsid destabilization in cells. PF74 exhibited dose-dependent inhibition of WT HIV-1 and N74D CA mutant viral infection, but had no effect on CA mutant T54A/N57A, which lacks the critical Asn57 side-chain necessary for PF74 binding [234] (Figure 3-12A, upper panel; results replotted below to reveal EC\textsubscript{90} values under conditions of Trim-NUP153\textsubscript{C} restriction). WT virus was noticeably less sensitive to PF74 in Trim-NUP153\textsubscript{C} expressing cells, with an EC\textsubscript{90} of 5.65 µM as opposed to 0.65 µM in control cells (Figure 3-12A). The competing effect of PF74 on Trim-NUP153\textsubscript{C} inhibition seemingly occurred between the concentrations of 0.1 and 1 µM (light green shading in Figure 3-12A), as the inhibition curves within the two cell lines were nearly
Figure 3-12. PF74 similarly counteracts HIV-1 in the face of Trim-NUP153C restriction and NUP153 knockdown. Mock transduced and Trim-NUP153C expressing (A) or non-targeting control and NUP153 knockdown (B) HOS cells were infected with equal RT-cpm of denoted viruses in the presence of various PF74 concentrations. Results are shown as infectivity normalized to vehicle only control cells (top), or vehicle only infection for each cell type (bottom) to calculate EC$_{90}$ values. Dashed lines represent Trim-NUP153C or NUP153 knockdown results in panels A and B, respectively. Results are an average of at least 3 experiments, with error bars denoting standard error. Calculated EC$_{90}$ values are displayed with standard error.
superimposable outside of these concentrations. N74D CA mutant virus also exhibited a shift in the PF74 EC\textsubscript{90} concentration in Trim-NUP153\textsubscript{C} cells, though this occurred at higher PF74 concentrations than with the WT virus. Interestingly, an almost identical effect was observed with WT virus when PF74 was titrated onto NUP153 knockdown cells; the EC\textsubscript{90} shifted from 0.54 µM to 5.41 µM, with the same window of concentrations likely accounting for the discrepancy in inhibition curves (Figure 3-12B). While the exact mechanism of NUP153 antagonism – direct, or indirect through the alteration of the state of CA multimerization – is difficult to discriminate, the nearly superimposable interference profiles of PF74 in Trim-NUP153\textsubscript{C} expressing and NUP153 knockdown cells support the relevance of the Trim-NUP153\textsubscript{C} restriction assay as a surrogate readout for the engagement of endogenous NUP153 protein.

**An analogous pocket in EIAV CA mediates binding to NUP153\textsubscript{C}**

Retroviral CA\textsubscript{N} proteins exhibit remarkable similarity in secondary and tertiary structure despite marked differences in primary sequence [246,247]. With the exception of HIV-1 residue Gln67, the previously described polar residues flanking the helix 3/4 hydrophobic pocket (Asn57, Lys70, and Asn74 in HIV-1) exhibit variability across divergent retroviruses (Figure 3-13A, yellow boxes). While HIV-2 and SIVmac only differ at these positions with Arg69 in place of HIV-1 Lys70, EIAV exhibits greater difference: Leu71 corresponds to HIV-1 Lys70, and EIAV Asp58 and Asp75 correspond to HIV-1 Asn57 and Asn74, respectively (Figure 3-13B). These differences may account for the resistance of EIAV to inhibition by PF74 (Figure 3-13C) and CPSF6\textsubscript{358} [240], which we confirmed using HOS cells expressing Trim-CPSF6\textsubscript{358} (Figure 3-13D). As

Asp58 exhibits similar physiochemical properties as its HIV-1 Asn57 counterpart, we mutated this as well as residue Asp75 to test their contributions to NUP153\textsubscript{C} binding. Similar to HIV-1 mutant N57A, EIAV CA mutant D58A was poorly infectious (Figure 3-13E), and the corresponding CA\textsubscript{N} protein was unable to pull down appreciable levels of NUP153\textsubscript{C} protein (Figure 3-13F). Contrastingly, EIAV CA mutant D75A behaved similar to WT EIAV (Figure 3-13E and 3-13F). The Trim-NUP153\textsubscript{C} sensitivities of these viruses corresponded with the binding profiles of their CA\textsubscript{N} proteins: D58A was completely insensitive to Trim-NUP153\textsubscript{C} mediated restriction, while D75A remained as sensitive as WT EIAV (Figure 3-13G).

**Comparison of NUP153 requirement and cell cycle dependence**

Changes at Asn57 in HIV-1 CA have previously been associated with cell cycle dependence: T54A/N57A infection was attenuated in both chemically arrested cell lines and non-dividing primary macrophages [57,117], and the N57A mutant virus was recently shown to lose infectivity upon chemical arrest of Hela cells [233]. We confirmed the importance of Asn57, as well as other previously observed cell cycle dependent phenotypes, with our panel of CA mutant viruses; alanine substitution of residue Glu45, Thr54, Asn57, or Gln67 rendered the virus significantly sensitive to growth arrest (Figure 3-14A and 3-14B). Notably, we found even the conservative N57D substitution rendered the virus as, if not more sensitive, than these mutants to growth arrest. A handful of CA mutant viruses have been described to be sensitive to cell cycle arrest in Hela cells in a CypA-dependent manner [117,118]. We found N57A and N57D CA mutant viruses to remain highly cell cycle dependent when the interaction with CypA

Data points for CA mutant viruses P38A, T54A, A92E, and G94D clustered with the WT virus within these panels, so their labels were omitted to aid legibility.
was blocked by the addition of cyclosporine during infection (Figure 3-14C).

Based on the coincident NUP153-insensitive and cell cycle dependent phenotypes of Asn57 mutant viruses, we tested the association between NUP153 requirement and cell cycle dependency in the context of our expanded panel of mutant viruses. We observed a moderately strong inverse correlation between requirement for NUP153 and cell cycle dependence during infection (Figure 3-14D). Notably, of the viruses tested in our panel, all of the ones that were cell cycle dependent were NUP153 independent. The correlation however was not absolute, as N74D, G89V, P90A, and T107N mutant viruses did not require NUP153 for infection yet remained cell cycle independent. There was a moderate correlation between cell cycle dependence and Trim-NUP153C resistance (Figure 3-14E). We observed a moderate to low correlation between cell cycle dependence and CPSF6358 mediated restriction, and no correlation with Trim-CPSF6358 mediated restriction (Figure 3-14F and 3-14G). These results reveal that cell cycle dependence is associated with NUP153 independence, and that this relationship likely depends on CA-NUP153 binding.
Discussion

NUP153 FG motif binding within the CA helix 3/4 cavity

GFP-tagged NUP153 expressed in animal cell lysate was recently shown to co-sediment with HIV-1 CA-NC tubes in vitro [248]. We confirmed this observation for HA-tagged protein, and extended it by using purified recombinant protein to demonstrate direct binding between the FG-enriched NUP153\textsubscript{C} and the HIV-1 CA NTD. Mutation of CA residue Asn57, Lys70, or Asn74, which each flank the hydrophobic pocket between CA \(\alpha\) helices 3 and 4, perturb binding of NUP153\textsubscript{C} protein to HIV-1 CA\(_N\). Furthermore, NUP153\textsubscript{C} competes with PF74 and CPSF6 for binding, both of which engage the same pocket. Notably, co-crystal structures between HIV-1 CA\(_N\) and the latter two molecules exhibit an almost identically situated benzyl ring within the hydrophobic cavity, with the amide nitrogen and carbonyl oxygens of this phenylalanine moiety each forming a hydrogen bond with the side chain of Asn57 [234] (Figure 3-10). This observation, in conjunction with our finding that FG motifs within NUP153\textsubscript{C} strongly contribute to binding with CA\(_N\), suggest that the phenylalanine moieties of specific FG motifs found in NUP153\textsubscript{C} likely take on a similar conformation during binding. We accordingly speculate that hydrogen bonding with Asn57 underlies the FG motif interaction, as both N57A and N57D mutations abrogated binding. While originally described to support CPSF6 binding [234], the high degree of amino acid conservation within this region of CA amongst primate lentiviruses likely also reflects the requirement for binding to NUP153 during virus infection [231].
Relevance of FG motif binding for NUP153 dependency during HIV-1 infection

Supporting the relevance of the NUP153-CA interaction, both a divergent set of retroviruses and a targeted set of CA missense mutants exhibited significant correlations between CA binding to NUP153C – either tested in vitro or inferred through Trim-NUP153C recognition – and requirement for endogenous NUP153 protein during infection (Figures 3-4 and 3-9). Notably, loss-of-binding CA mutant viruses T54A/N57A, N57A, and N57D infected cells independent of endogenous NUP153 expression. The relationship between NUP153 binding and host factor requirement was consistent with PF74 sensitivity as well; while potentially mediated through an indirect effect on uncoating, PF74 interfered with Trim-NUP153C restriction at the same concentrations that it antagonized the inhibition of infection caused by NUP153 knockdown (Figure 3-12).

Woodward and colleagues reported that ectopically-expressed NUP153C protein imparted an approximate twofold defect on HIV-1 infection [98], a result we did not reproduce despite efficient NUP153C expression (Figure 3-2). By contrast, appending NUP153C to the RBCC domains of rhTrim5α resulted in potent HIV-1 restriction, allowing us to infer the results of NUP153C binding to the CA shell during virus infection. NUP153 has been shown to bind HIV-1 IN [98], and though we observed minimal binding (≤1% of input IN recovered by GST-NUP153C pull-down; Figure 3-15), it was comparably weaker than our findings with HIV-1 CA (30-40% of input NUP153C recovered), and was less correlative with lentiviral requirement for endogenous NUP153 (Figure 3-4D) as FIV IN bound more robustly than HIV-1 IN to NUP153C in our hands (Figure 3-15). Thus, while NUP153 may bind more than one HIV-1
Figure 3-15. GST-NUP153\textsubscript{C} pull-down of HIV-1 and FIV IN. GST-NUP153\textsubscript{C} pulled-down an average of \(~0.85\%\) of input his-tagged HIV-1 IN and \(~5.55\%\) of input his-tagged FIV IN over 3 experiments. A representative experiment is shown. Note preferential western blot detection of the FIV IN N-terminal his-tag over that of the HIV-1 tag.
determinant, our results are consistent with a direct interaction between NUP153<sub>C</sub> and viral CA<sub>N</sub> underlying the requirement for NUP153 during HIV-1 infection.

**Potentially degenerate binding of NUP153 FG motifs**

Different FG motifs within Trim-NUP153<sub>C</sub> mediated restriction of EIAV versus HIV-1 infection (Figure 3-6). Contrastingly, correspondence to protein binding in vitro was less strict: NUP153<sub>C</sub>Δ896-1045 effectively bound EIAV CA<sub>N</sub>, though this deletion variant could not inhibit EIAV as a Trim-fusion. The 1415-FTFG-1418 tetra-alanine mutant, which lost the ability to inhibit HIV-1 as a Trim-fusion, was little if at all reduced for pull-down by HIV-1 CA<sub>N</sub>, though alteration of all seven FG motifs in the last quarter of NUP153<sub>C</sub> yielded a protein greatly deficient for binding to HIV-1 CA<sub>N</sub> (Figure 3-7). Because the tetra-alanine 1415-FTFG-1418 NUP153<sub>C</sub> mutant protein was significantly defective for binding assembled CA-NC tubes, we infer that this specific FG motif is important for NUP153<sub>C</sub> binding to multimerized CA.

We believe our results reflect the nature of the NUP153<sub>C</sub>-CA interaction during HIV-1 infection. Unlike a bimolecular interaction between two well-folded domains, each with a single binding site, NUP153<sub>C</sub> exhibits no appreciable secondary structure and is highly repetitive in its primary sequence, particularly for phenylalanine-based FG motifs. As FG sequences appear to dictate NUP153<sub>C</sub> binding to CA<sub>N</sub>, each of the 29 motifs may possess some affinity for CA<sub>N</sub>. Residues adjacent to the phenylalanine, such as glycine, may allow proper flexibility to fit into the helix 3/4 pocket for Asn57 engagement. We envision that residues peripheral to the motif may also contribute intra- and inter-molecular interactions. This interpretation is consistent with the mode of CPSF6
binding: the CPSF6 FG dipeptide (residues Phe321 and Gly322) is critical for CPSF6\textsubscript{358} mediated restriction [240], while upstream residues Val314 and Leu315 fulfill important secondary roles through engaging additional hydrophobic patches located between CA\textsubscript{N} \( \alpha \) helices 4 and 5. CPSF6 backbone functional groups also interact to varying degrees with the side-chains of CA residues Asn74, Thr107, Lys70, and Gln67 [234] (Figure 3-10C).

Given this model, we hypothesize that differential accessibility of the CA\textsubscript{N} helix 3/4 pocket might factor into the contrasting binding specificities observed between monomeric and oligomerized CA: while the pocket is likely exposed as a soluble NTD fragment in the pull-down assay, it may be less available within the context of a multimeric CA array. The CTD of the adjacent CA subunit covers the bottom edge of the cavity (Figure 3-16A), and the interacting NUP153\textsubscript{C} peptide would need to reach into the crevice between CA subunits, past the cyclophilin-binding loop, and under helix 5 to reach the pocket (Figure 3-16B). These steric requirements likely limit the number of NUP153\textsubscript{C} FG motifs capable of forming energetically favorable interactions with the oligomerized CA array present on the viral core.

**Association with core uncoating and sensitivity to cell cycle arrest**

Accordingly, alterations in the rate or extent of CA core uncoating may alter engagement of NUP153 during infection. Though both Trim-NUP153\textsubscript{C} and Trim-CPSF6\textsubscript{358} presumably encounter CA cores shortly after entry (Figure 3-3) [240], Trim-CPSF6\textsubscript{358} restricted the hyperstable CA mutant viruses E45A and Q63A/Q67A [45,57,119,120,249] as efficiently as WT cores, while Trim-NUP153\textsubscript{C} was less effective at restricting either of these mutants. Both mutant CA\textsubscript{N} proteins in large part retained
Figure 3-16. Location of NUP153\textsubscript{C} binding site within multimerized CA. (A) Model of the HIV-1 CA hexamer (pdb: 3j34) [43], with surface representations of two adjacent CA units shown. Side chains involved in NUP153\textsubscript{C} binding are shown as sticks and labeled, with the binding pocket highlighted by a dashed white circle. (B) Model of the HIV-1 inter-hexameric CA interface (pdb: 3j34). The two molecules in panel A were rotated 90° around the y-axis, -10° around the x-axis, and juxtaposed with two CA molecules from the adjacent hexamer. The z-plane was clipped to expose the NUP153\textsubscript{C} binding site within the interface.
NUP153C binding in vitro, suggesting that some CA disassembly may be needed for interaction with NUP153C within cells.

These hyperstable CA mutant viruses acutely depend on the cycling state of the cell. Comparison between cell cycle dependence and NUP153 reliance resulted in a strong negative correlation within the panel of CA mutant viruses (Figure 3-14D). This correlation was stronger than the relationship between CPSF6358 sensitivity and cell cycle dependence (Figure 3-14F), suggesting a more direct association with NUP153 engagement. Consistent with this, CPSF6 binding mutant virus N74D was cell cycle independent, while N57A and N57D mutant viruses, both of which are also defective for NUP153 binding, were sensitive. While the direct cause of cell cycle dependence is not clear, we suspect that defective NUP153 binding is a key contributor, and that hyper-stable CA cores may phenotypically mimic this effect.

**Competitors of NUP153-CA binding**

The HIV-1 CA side-chains involved in NUP153C binding overlap those identified to interact with CPSF6. Accordingly, we found recombinant NUP153C able to compete with CPSF6 for binding to HIV-1 CAx in vitro (Figure 3-10D). The overlapping binding sites suggest these proteins may take interdependent or even antagonistic roles during infection. While the role of endogenous CPSF6 protein in HIV-1 infection is unknown, the cytoplasmic CPSF6358 truncation variant potently restricts HIV-1 [66, 177, 234, 240, 250]. Like Trim-NUP153C, CPSF6358 likely interacts with the viral core shortly after entry; both a Trim-fusion protein containing the CPSF6 binding domain [240], and the cytoplasmically expressed CPSF6375 isoform [251], yield proteins capable
of preventing the completion of reverse transcription. Interestingly, CPSF6_{358} does not inhibit reverse transcription, but instead blocks HIV-1 nuclear import. Additionally, CPSF6_{358} appears to inhibit only a subset of CA mutant cores that it is able to bind [66] (Figure 3-11B and 3-11C). This may reflect an incomplete understanding of the mechanism of CPSF6_{358} restriction, which could involve antagonism of the CA-NUP153 interaction (Figure 3-11D). While CPSF6_{358}-mediated stabilization of the CA core [66,250] may contribute to the nuclear import defect, it seems possible that direct competition for NUP153 binding may also be at play.

Small molecules that bind the helix 3/4 pocket in CA may also preclude NUP153 binding during HIV-1 infection. At least part of the PF74 antiviral mechanism occurs before nuclear entry, as it can inhibit HIV-1 reverse transcription [245]. Yet, its altered dose-response curve in NUP153 depleted cells suggests that it antagonizes CA engagement with NUP153 as well (Figure 3-12). Notably, recently identified pyrrolopyrazolone small molecules BI-1 and BI-2 bind the same pocket, yet inhibit HIV-1 nuclear import [252]. As both PF74 and the pyrrolopyrazolone compounds bind CA_{N} with similar affinity [234,252], we speculate that the contrasting phenotypes observed with these small molecules is due to their similar abilities to directly compete with host factors that bind the helix 3/4 pocket juxtaposed with their differential affects on CA core stability: PF74 destabilizes incoming capsids [235], whereas BI-1 and BI-2 can stabilize capsid structures in vitro [252]. TNPO3 depletion is proposed to mis-localize endogenous CPSF6 into the cytoplasm, recreating the phenotypes conferred by CPSF6_{358} expression [66]. Resembling our observations with NUP153 knockdown cells, infection of TNPO3 depleted cells exhibited a similar profile of reduced sensitivity to PF74 [253].
Materials and Methods

Plasmid constructs

Infection assays utilized single-round viruses carrying either GFP or luciferase reporter genes. GFP-based constructs included HIV-1, EIAV, BIV, RSV, FIV, MLV, HIV-2 strain ROD, simian immunodeficiency viruses SIVmac, SIVagmSab, and SIVagmTan, all described previously [96,231]. HIV-1 CA mutations were generated through site-directed mutagenesis of the HIV-1\textsubscript{NL4-3}-based pHp-dl-N/A packaging plasmid [217] (AIDS Research and Reference Reagent Program [ARRRP]), which were co-transfected with either pHI-vec2.GFP or pHI-Luc transfer vectors [231].

Human NUP153 (accession number NM_005124.3), or deletion mutants thereof, fused to N-terminal HA tags were expressed from the pIRES-dsRed Express HA-NUP153 expression vector [231]. Trim-fusion constructs, which were built within pLPCX-rhTrim5\textalpha-HA [121], were created by engineering a BamHI site at nucleotides corresponding to residues 301 and 302 of rhesus Trim5\textalpha, and ligating the digested vector with sequences encoding HA-NUP153\textsubscript{C}, NUP153\textsubscript{C}-HA, or CPSF6\textsubscript{358}-HA [177]. Truncated Trim-HA was engineered by modifying the Trim-HA-NUP153\textsubscript{C} vector to encode two stop codons at the nucleotides corresponding to the first two residues of NUP153\textsubscript{C}. All deletion and missense mutations within animal-cell expressed NUP153\textsubscript{C} were engineered by site-directed-mutagenesis of plasmids pLPCX-Trim-HA-NUP153\textsubscript{C} or pLPCX-HA-NUP153\textsubscript{C}.

HIV-1\textsubscript{NL4-3} CA carrying C-terminal his and FLAG tags was expressed from the pET11a-HIV1-CA-his-flag bacterial expression vector. The vector encoding tagged HIV-
1 CA NTD (pET11a-HIV1-CA_N-his-flag) was constructed by removing nucleotides corresponding to CA residues 147-231 from the full-length expression vector. Bacterial expression vectors for FIV CA were generated by amplifying DNA encoding full-length FIV CA (residues 1-223; pET11a-FIV-CA-his) or NTD only (residues 1-140; pET11a-FIV-CA_N-his) from pFP93 [254] with a primer encoding a C-terminal his-tag, and ligating with digested pET11a DNA. pET22b-based bacterial expression vectors encoding C-terminally his-tagged N-tropic MLV (pET22b-NMLV-CA-his) and EIAV (pET22b-EIAV-CA-his) were obtained from the laboratory of Dr. Joseph Sodroski, and CA NTDs were engineered from full-length his-tagged constructs by removing nucleotides corresponding to residues 133-263 of N-MLV, and residues 149-231 of EIAV, by site-directed mutagenesis.

A construct encoding an N-terminal GST protein fused to NUP153C (pGEX2T-GST-NUP153C) was created by deleting sequences encoding residues 1-895 from a bacterial expression construct (pGEX2T-hNUP153) encoding the full-length human protein [180]. Plasmid pGEX2T-his-GST-pp-NUP153C, which was utilized to obtain tag-free NUP153C protein, was derived from pGEX2T-GST-NUP153C by sequentially engineering a PreScission protease site between GST and NUP153C and then appending a his-tag N-terminal to GST. A stop codon was introduced at the nucleotides corresponding to residue 1350 to generate the Δ1350-1475 truncation mutant. The 7xFG/A mutant NUP153C was engineered for bacterial expression by swapping the WT sequence present in pGEX2T-his-GST-pp-NUP153C with a fragment encoding NUP153 residues 1178-1475 amplified from pLPCX-HA-NUP153C-7xFG/A. All coding sequences were verified through DNA sequencing.
Cells

293T and HOS cells were cultured in DMEM (Invitrogen) supplemented with 10% FBS, 100 U/ml penicillin, and 0.1 mg/ml streptomycin. HOS cells stably transduced with MLV-derived LPCX transfer vectors were subsequently selected and maintained with 2 μg/ml puromycin. Approximately 25,000 HOS cells seeded per well of a 24-well plate were transfected the next day with a final concentration of 40 nM siNUP153#1 (GGACTTGTTAGATCTAGTT) or a mismatch control of siNUP153#1, referred to as siControl (GGTCTTATTGGAGCTAATT) (Dharmacon) [231], using RNAiMax (Invitrogen) according to the manufacturer’s instructions. Dividing or cell cycle arrested cells were collected at the time of infection, fixed in 70% ethanol, and incubated for 30 min at room temperature in staining solution [0.1% Triton X-100, 0.2 mg/ml RNAse A (Invitrogen), and 20 μg/ml propidium iodide in phosphate-buffered saline (PBS)]. The cells were washed, and cellular DNA content was assessed with a FACSCanto flow cytometer (Becton, Dickenson and Company) equipped with FACSDIVA software.

Virus production

Viral vector particles were produced by transfecting 293T cells in 10-cm plates with 10 μg total of various ratios of the aforementioned virus production plasmids using CaPO₄. The cells were washed 16 h after transfection, and supernatants collected from 24 to 72 h thereafter were clarified at 300 x g, filtered through 0.45 μm filters (Nalgene), and either allotted and frozen or concentrated by ultracentrifugation using an SW32Ti rotor at 50,000 x g for 2 h at 4°C before freezing. Concentrations of HIV-1 and EIAV CA mutant
viral stocks were determined alongside concomitantly produced WT viruses using an exogenous $^{32}$P-based assay for RT activity [222].

**Infectivity assays**

HOS cells (10,000 or 2,500) seeded onto 48-well or 96-well plates, respectively, were infected with various reporter viruses. Percentages of GFP-positive cells were determined 48 h post-infection (hpi) using a FACSCanto flow cytometer equipped with FACSDIVA software. GFP reporter experiments comparing retroviral genera were performed with virus inoculates adjusted to yield ~ 40% GFP-positive cells in control samples. HIV-1 or EIAV CA mutant viruses ($2 \times 10^5$ RTcpm) were used to infect 96-well and 48-well plates of cells, respectively. HIV to EIAV infectivity ratios were calculated after initially normalizing to the average of MLV and FIV negative control viruses to account for slight differences in overall infectivities between stable cell lines. Cyclosporine (5 µM, Sigma) was introduced to cells at the time of infection. Cell cycle arrest experiments were performed by plating 2,500 control or 5,000 experimental cells treated with 5 µM Etoposide-phosphate (Calbiochem) the day before infection. Quantitative PCR for the accumulation of viral late reverse transcripts and 2-LTR-containing circles were performed as previously described [231]. The quantitation of early reverse transcripts was performed using primers AE989 and AE990 and Taqman probe AE995 [255].

**Western blot analysis**
Cells stably expressing Trim-fusion proteins were lysed in Buffer A [25 mM Tris-HCl pH 7.5, 200 mM NaCl, 1 mM DTT, 1 mM EDTA, Complete protease inhibitor (Roche)] and sonicated for 30 s total with a misonix sonicator. Protein concentration of the bulk lysate was determined by Bradford assay (Bio-rad), and 75 µg of each sample were electrophoresed through Tris-glycine polyacrylamide gels, and transferred onto polyvinylidene fluoride membranes. Transiently expressed HA-tagged proteins were either extracted with buffer H [10 mM Tris-HCl pH 8.0, 10 mM KCl, 1.5 mM MgCl$_2$] followed by repeated freeze-thaws, or Triton buffer [50 mM Triethanolamine, 250 mM NaCl, 0.5% Triton X-100], and pelleted in a microcentrifuge for 20 min at 21,000 x g at 4°C. Stably expressing cells were also fractionated by initial lysis in Buffer F1 [20 mM Tris-HCl pH 7.5, 10 mM NaCl, 1.5 mM MgCl$_2$, 0.25 % Triton X-100, and Complete Protease Inhibitor], followed by centrifugation at 6,000 x g. The supernatant was removed as Fraction 1, and the process was repeated, with the resulting supernatant combined with the previous fraction. The subsequent pellet was resuspended in Buffer F2 [Buffer F1 lacking Triton X-100, but with 0.5% sodium deoxycholate and 1% Tween-40], and pelleted at 21,000 x g for 15 min. The supernatant was removed as Fraction 2, and pellet was resuspended in 1x Turbo DNase buffer and treated with 40 U/ml Turbo DNase (Ambion) for 10 min at 37° C. Two parts fraction 1, one part fraction 2, and one part of the remaining fraction (Fraction 3) were each mixed with sample loading buffer and separated on Tris-glycine polyacrylamide gels. Exogenously expressed HA-tagged proteins were detected using a 1:4,000 dilution of HRP-conjugated 3F10 antibody (Roche) or 1:4,000 dilution of mouse 16b12 antibody (Covance) and developed with ECL prime (GE Healthcare) or Femto (Thermo Scientific) detection reagents. NUP153,
NUP62, and NUP358 were detected with a 1:4,000 dilution of mouse monoclonal antibody mab414 (Abcam). HRP-conjugated mouse anti-β-actin antibody or mouse anti-α-tubulin antibody (Abcam) were used at 1:10,000 dilutions to confirm equal lysate loading across samples. His-tagged HIV-1 CA was detected with 1:15,000 α-his HRP (Clontech). CA-NC protein was detected with 1:5,000 mouse anti-p24 antibody ab9071 (Abcam). Histone H3 was detected with 1:2,000 rabbit histone H3 antibody #9715 (Cell Signaling Technology). All mouse and rabbit primary antibodies were detected using 1:10,000 dilutions of anti-mouse or anti-rabbit HRP secondary antibodies (Dako).

**Immunofluorescence confocal microscopy**

Cells transduced with empty LPCX vector or stably expressing HA-epitope tagged rhTrim5α, NUP153C, or fusion proteins thereof, were cultured on eight-well chamber slides. After 24 h, the cells were fixed with 4% paraformaldehyde for 10 min, washed, and permeabilized with PBS containing 0.5% Triton X-100. The permeabilized cells were blocked with PBS containing 10% FBS for 1 h, and stained with a 1:100 dilution of anti-HA antibody 16b12. After a 30 min wash with PBS, the cells were incubated for 1 h with a 1:1,000 dilution of an Alexa Fluor 555 conjugated goat anti-mouse IgG antibody (Invitrogen), as well as Hoechst 33342 (Invitrogen) diluted to a concentration of 0.2 µg/ml. After an additional 30 min wash with PBS, the samples were covered with mounting medium [150 mM NaCl, 25 mM Tris pH 8.0, 0.5% N-propyl gallate, and 90% glycerol]. The processed samples were analyzed on a Nikon Eclipse spinning disk confocal microscope.
NUP153 protein purification

GST-NUP153C was expressed in BL21-CodonPlus (DE3)-RILP *E. coli* (Agilent) grown in 2X YT media and induced at an optical density of 0.8 at 600 nm (OD$_{600}$) with 1 mM isopropyl β-D-1-thiogalactopyranoside (IPTG) for 1 h at 18°C. Cells were pelleted at 6,000 x g, and sonicated for 5 min in buffer A. The lysate was centrifuged for 30 min at 35,000 x g, and the pellet was resuspended in buffer B [1 M NaCl, 25 mM Tris-HCl pH 7.5, 1 mM DTT, 1 mM EDTA, Complete protease inhibitor] with a dounce homogenizer. The lysate was again spun at 35,000 x g, and the pellet was resuspended in Buffer C [2 M Urea, 200 mM NaCl, 25 mM Tris-HCl pH 7.5, 1 mM DTT, 1 mM EDTA, Complete protease inhibitor] with a dounce homogenizer. After a last centrifugation at 35,000 x g, the supernatant was collected and incubated with glutathione-sepharose beads (GE Healthcare) overnight at 4°C. The beads were washed with buffer D [200 mM NaCl, 25 mM Tris-HCl pH 8.0, 1 mM DTT, 1 mM EDTA, Complete protease inhibitor], and the protein was eluted with buffer D containing 20 mM glutathione. Eluted protein was dialyzed against buffer D to remove excess glutathione, spin concentrated by ultrafiltration through a 10,000 nominal molecular weight limit (NMWL) Amicon filter (Millipore), and flash frozen in liquid nitrogen for storage at -80°C.

BL21-CodonPlus (DE3)-RILP *E. coli* transformed with pGEX2T-his-GST-pp-NUP153C was grown to an OD$_{600}$ of 0.8, followed by induction with 1 mM IPTG for 1 h at 18°C. Cells were pelleted at 6,000 x g, and sonicated for 5 min in buffer A. The lysate was then centrifuged for 30 min at 35,000 x g, and the pellet was resuspended in buffer E [6 M Urea, 200 mM NaCl, 25 mM Tris-HCl pH 7.5, 1 mM DTT, 1 mM EDTA, Complete protease inhibitor] with a dounce homogenizer. The lysate was then
centrifuged at 40,000 x g for 1 h, and the resulting supernatant was incubated with Ni-NTA conjugated agarose beads (Qiagen) overnight. The beads were then initially washed with buffer E, and then progressive dilutions of buffer E into cleavage buffer [150 mM NaCl, 50 mM Tris-HCl pH 7, 1 mM DTT, 1 mM EDTA] (3:1, 1:1, 1:3), with a final wash in cleavage buffer only, each supplemented with 7.5 mM imidazole. The beads were incubated with 5 U of PreScission protease (GE Healthcare) for 48 h. The supernatant, which was cleared with 0.1 volumes of Ni-NTA beads and glutathione-sepharose beads each at 4°C to remove uncleaved protein and residual PreScission protease, was centrifuged at 21,000 x g for 15 min at 4°C. The resulting supernatants were quantitated following fractionation by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and staining with SYPRO Ruby (Invitrogen) or Coomassie blue, as compared to a standard curve of bovine serum albumin (BSA), using ChemiDoc MP imager (Bio-Rad) with Image Lab software. Cleaved full length NUP153 was recovered at ~ 50% purity, with the predominant contaminants degradation products of the full-length protein, as inferred through comparison with western blots using mab414 antibody.

**CA binding assays**

Recombinant HIV-1 CA-NC was expressed in *E. coli*, purified, and assembled into CA-NC complexes as previously described [40]. Expression constructs encoding full-length HA-NUP153 or fragments thereof were transiently transfected into 293T cells using X-tremeGENE 9 DNA transfection reagent (Roche). Cells were collected after 48 h, lysed with successive freeze thaws in buffer H, and clarified by centrifugation at
21,000 x g at 4°C. CA-NC complexes were incubated with clarified lysates for 1 h at room temperature before ultracentrifugation for 30 min at 100,000 x g through a 50% sucrose cushion prepared in PBS. The resulting pellet was resuspended in 1x sample loading buffer, and fractionated by SDS-PAGE. Experiments with purified proteins were stained with Coomassie blue or SYPRO Ruby, while experiments using a lysate component were developed by western blot. Quantification was performed with a ChemiDoc MP imager using Image Lab software.

His-tagged HIV-1, MLV, EIAV, and FIV capsid proteins, either full length or NTD only, were expressed in BL21-CodonPlus (DE3)-RILP *E. coli*, grown to an OD$_{600}$ of 0.6, and induced for 4 h with 1 mM IPTG. Bacteria pelleted by centrifugation were resuspended in Buffer A, sonicated, and centrifuged at 30,000 x g for 30 min. The supernatants were incubated overnight with Ni-NTA-sepharose beads, eluted with 20 mM Tris-HCl pH 8.0, 200 mM imidazole elution buffer, and dialyzed into Tris Buffer (20 mM Tris-HCl pH 8.0). Dialyzed protein was concentrated by ultrafiltration through a 10,000 NMWL filter, centrifuged at 21,000 x g, and the resulting soluble protein was quantitated by spectrophotometer.

Pull-down assays with full-length CA or CA$_N$ proteins were performed by mixing 20 µl reactions with the following final concentrations: 0.02 µl packed volume Ni-NTA beads per µl (0.4 µl total), 20 µM CA, 25 mM Tris-HCl pH 8.0, and either 0.5 µM purified NUP153$_C$ with 0.1% NP-40 and 150 mM NaCl, or 100 µg 293T lysate overexpressing HA-tagged NUP153 with 0.25% Triton X-100 and 200 mM NaCl. Mixtures were left rocking at room temperature for 1 h after which the samples were washed twice in buffer M [25 mM Tris-HCl pH 8.0, 150 mM NaCl, and 0.1% NP-40],
allowing the beads to settle by gravity, and finally resuspended in 1x sample loading buffer. Saturation curves were achieved by mixing 3 µl packed volume Ni-NTA beads with 0.5 µM purified WT or mutant NUP153C, 150 mM NaCl, 25 mM Tris-HCl pH 8.0, and 0.1% NP-40, with half-log increments of HIV-1 CA\textsubscript{N} from 2 µM to 200 µM. Both bead-bound and supernatant fractions were separated by SDS-PAGE and stained with SYPRO Ruby, with the percent of NUP153\textsubscript{C} protein bound calculated at each concentration. The $K_d$ of NUP153\textsubscript{C} binding was calculated by subtracting nonspecific binding to beads and fitting the resulting data-points with a one-site saturation binding nonlinear regression using Prism6 software (GraphPad).

CPSF6 competition experiments were performed through modification of the CA-NC protocol. Assembled CA-NC was diluted to a final concentration of 0.8 µM in the reaction mixture. WT or mutant NUP153\textsubscript{C} was added to a final concentration of 4 µM, along with 10 µg total 293T extract expressing C-terminally HA-tagged CPSF6, resulting in final concentrations of 170 mM NaCl, 75 mM Tris-HCl pH 8.0, and 0.025% Triton X-100. Mixtures (20 µl) were incubated at room temperature for 20 min, after which they were spun over a 30 µl 20% sucrose cushion in a microcentrifuge at 21,000 x g for 20 min at 4°C. The resulting pellet was resuspended in sample loading buffer and separated by SDS-PAGE. Western blotting with p24 antibody indicated ~ 35% of input CA-NC was recovered in the pellet. CA-NC co-sedimentation assays with WT or FG mutant NUP153\textsubscript{C} were performed similarly, but were instead centrifuged over a 25% sucrose cushion.
IN pull-down assay

His-tagged HIV-1 and FIV IN [96] and GST [256] were expressed and purified as previously described. Pull-down of soluble IN was performed as previously described for GST-LEDGF326-530 [244], with 0.8 μM of his-tagged HIV-1 or FIV IN incubated with 0.47 μM GST-NUP153C or control GST pre-bound to glutathione-sepharose beads in PD buffer [150 mM NaCl, 25 mM Tris-HCl pH 7.4, 5 mM MgCl₂, 5 mM DTT, 0.1% NP-40]. BSA (5 μg) was included as an additional specificity control. The reaction was incubated for 2 h at 4°C, after which the beads were washed 4 times with PD buffer, and settled each time for 20 min in the absence of centrifugation. Recovered samples were resolved by SDS-PAGE, and stained with Coomassie blue and western blotted with anti-his antibody.

Statistical analysis

Dependencies between variables were assessed by Spearman rank correlation using Prism6 software. The significances of pair-wise differences were calculated by Student’s t-test (two-tailed) using Prism6 software.
Chapter 4

General Discussion
Model of NUP153 FG engagement during lentiviral infection

Current data and the known biology of this protein suggest NUP153 is likely important for trafficking the HIV-1 PIC through the nuclear pore and into the nucleus [29,82,231] (Figure 4-1). The viral nucleoprotein complex is likely to initially dock to the NPC by engaging NUP358 [82,233]. While intact HIV-1 cores are too large to enter the central channel, CA cores in various stages of disassembly may enter far enough for remaining CA to be accessed by the FG domains present in NUP153C.

CA binding with NUP153C may serve two distinct roles during infection. Firstly, NUP153 may be responsible for physically translocating the PIC by engaging CA molecules that may associate with it. The relatively short half-life of NUP153 at the NPC may contribute to the release of the PIC into the nucleoplasm [181]. Secondly, as even a partially disassembled core could remain too large to efficiently pass through the NPC channel, CA interaction with NUP153 may be required to fully uncoat the viral core at the NPC and prime the PIC for nuclear import. Indeed, CA cores have been shown to dock to NPCs for several hours before PIC nuclear translocation [80]. CA oligomers may interact with a limited subset of NUP153C FG motifs, while increased CA pocket accessibility from progressive core disassembly may expose monomeric CA to an expanded number of NUP153C FG repeats. While CA mutant viruses such as N74D may uncoat differently and circumvent this mechanism without penalty in various transformed cell lines, they apparently incur steep costs to infectivity in other cell types, such as primary macrophages [233,257].
Figure 4-1. The NUP153-CA interaction during HIV-1 infection. Partially uncoated HIV-1 cores dock at the NPC through engaging NUP358 (light green). Once docked, NUP153 (dark green) FG motifs bind CA through phenylalanine insertion into the hydrophobic pocket of the NTD, forming hydrogen bonds with CA residue Asn57, as well as adjacent polar side-chains (enlarged to the right). CA engagement with NUP153 is required for HIV-1 nuclear import, either directly during PIC translocation, or for completion of a prerequisite uncoating step. Perturbation of NUP153 engagement may affect multiple steps, such as intranuclear trafficking and integration site selection [231,248,258].
**Convergence in NUP153 use amongst viral families**

Divergent viruses have adapted to use NUP153 for their own devices. Our results suggest EIAV, which presents different amino acid residues flanking the CA$_N$ hydrophobic pocket, may have either retained, or convergently evolved NUP153 binding. Hepatitis B virus (HBV) has also been reported to bind NUP153 during its nuclear transport; though the HBV core is sufficiently small to traverse the NPC channel, NUP153 binding is believed to be important for HBV core conformational change and genome release within the nuclear basket [200]. This interaction may also require binding to NUP153 FG motifs, as both of the broadly defined regions mapped for HBV capsid binding overlapped parts of NUP153$_C$. The *S. pombe* homolog of NUP153, Nup124p, is important for Tf1 retrotransposition and binds the Tf1 Gag protein, though binding did not necessarily appear to map to Nup124p FG motifs [197,259]. Perhaps akin to effects caused by differential HIV-1 uncoating, the requirement for Nup124p appears to be related to the state of Tf1 Gag multimerization [199].

It remains to be determined whether FG motifs found on additional nucleoporins may bind HIV-1 and aid its infection. While the effects of NUP98 depletion on HIV-1 infection are relatively modest [175,177,248], this protein can also co-sediment with HIV-1 CA-NC tubes in vitro [248]. Similarly, the GLFG-motif enriched domain of *S. cerevisiae* NUP100, predicted to be orthologous to vertebrate NUP98, binds Ty3 Gag protein [260]. Alternatively, while CA binding with the CHD is proposed to determine the requirement for NUP358 [233], it remains to be seen whether its own FG domains may bind CA and contribute to its function during infection [261]. While numerous FG nucleoporins exist, it is likely that certain characteristics specific to NUP153, including
its length, flexibility, and its relatively high dissociation rate from the NPC, along with its spatial location around the nuclear rim of the NPC, makes this protein particularly important for lentiviral passage through the nuclear pore.

**Interdependence of CA-determined host factors during infection**

A number of phenotypic similarities suggest the roles of TNPO3, NUP153, NUP358, CPSF6, and CypA during HIV-1 infection are interrelated. CA mutant virus N57A is NUP153 and CPSF6 binding-defective but detectably binds the NUP358 CHD, yet does not require NUP358 expression for infection. Perhaps most starkly, the N74D CA mutant virus is insensitive to knockdown of TNPO3, NUP153, and NUP358, despite possessing a CA protein capable of binding all three proteins with similar affinities to WT CA (Figure 3-8 and [233]). As the N74D mutation clearly counteracts CPSF6 binding [177,234], it seems plausible that CPSF6 engagement licenses HIV-1 to employ NUP358 and NUP153 during infection. CPSF6 is currently believed to be exclusively nuclear at steady state, suggesting that it may not exert its effects on HIV-1 until the virus engages the NPC. Curiously, siRNA depletion of CPSF6 does not affect HIV-1 infection [177].

CypA also appears to alter nuclear transport factor dependence during HIV-1 infection. The CypA and NUP358 CHD binding mutants G89V and P90A are comparably less sensitive to NUP153 depletion and CPSF6\textsubscript{358} restriction than WT virus [66,231,233]. Consistent with this, abrogation of CA binding with CypA, either through CypA depletion or competition with the small molecule cyclosporine, rescued viruses inhibited by NUP153 or NUP358 knockdown [231,233]. While cyclosporine treatment
can partially rescue WT HIV-1 infection in TNPO3 depleted cells [233,253], the lack of complete rescue may reflect its multiple potential roles in promoting HIV-1 infection. CypA binding to HIV-1 CA can alter its disassembly [191], suggesting that its effect on NUP153, NUP358, and TNPO3 may be indirect through modulating the rate and extent of CA core uncoating.

**Effects of nuclear transport proteins on integration site selection**

While HIV-1 appears to predominantly utilize NUP153, NUP358, and TNPO3 to affect its import into the nucleus, these factors can also affect post-nuclear trafficking as evidenced by differences in HIV-1 integration site distributions upon factor knockdown. Numerous different forces can influence integration site distribution. IN favors certain nucleotide patterns at the site of integration [262,263]. Integration also favors the distorted major grooves that occur when DNA is wrapped around the nucleosome core [264,265], as well as certain epigenetic modifications [265]. Lens epithelium-derived growth factor (LEDGF)/p75, which is a lentiviral IN-binding cofactor, in large part dictates integration along active transcriptional units [255,266,267]. Interestingly, TNPO3, NUP358, and NUP153 appear to contribute to an even broader level of integration site preference [68]: depletion of TNPO3, NUP358, and to a lesser extent, NUP153, reduced the extent of integration in gene dense regions of chromatin [233,248,258,268]. This pattern was consistent with the involvement of CA, as the HIV-1 chimeric virus encoding MLV CA, as well as CA missense mutants N57A and N74D, showed a similar shift in integration site distribution [233,258,268]. Notably, CypA binding was also found to affect integration site selection, as disruption of CypA binding
to CA by cyclosporine treatment resulted in an increase in the number of integration 
events in chromosomal regions enriched in transcriptional units [233].

It is possible that these proteins are directly involved in directing the PIC to 
distinct regions of chromatin; NUP153 has been shown to associate with large regions of 
active chromatin in drosophila [205], and TNPO3 may engage the HIV-1 intasome to 
effect integration [94]. On the other hand, NUP358 appears more important for 
integration targeting than NUP153, yet this protein does not appear to be found within the 
nucleus during interphase [150]. Furthermore, depletion of a number of other nuclear host 
proteins including IK, ANAPC2, WDHD1, SNW1, and PRPF38A similarly redirected 
integration away from gene-dense chromosome regions [268]. It remains formally 
possible that the roles of some host factors in dictating integration to these regions may 
be indirect, instilled through alteration of global chromosomal environment as compared 
to specific affects on HIV-1 PIC trafficking. Still, ablation of gene dense region targeting 
by CA mutations such as N74D highlights a specific role for CA in post-nuclear PIC 
trafficking. The mechanism of nuclear import may be linked with integration site 
targeting by affecting the chromosomal environments first encountered by the PIC upon 
nuclear entry.

Model of CA and nuclear transport factors during HIV-1 nuclear entry

We propose the following working model to coalesce recently reported results 
from the rapidly evolving field of HIV-1 PIC nuclear transport (Figure 4-2). While the 
initial steps of uncoating likely occur shortly after entry [45], the final events of 
uncoating may occur at the NPC [80]. The partially uncoated PIC likely docks at the NPC
Figure 4-2. Model of the potential roles of the CA-dependent nuclear transport factors during HIV-1 infection. NUP358, NUP153, and CPSF6 at the nuclear pore likely act on PIC-associated CA to aid HIV-1 infection. TNPO3 is required to localize CPSF6 to the nucleus; premature cytoplasmic CPSF6 binding to CA can prevent nuclear import. TNPO3 may affect integration by interacting with IN within the nucleus. CypA modulates CA uncoating, altering dependencies on NUP358, NUP153, and TNPO3. Perturbation of this pathway by CA mutation or TNPO3, NUP153, or NUP358 knockdown results in altered integration site selection away from gene-dense regions of chromatin.
by engaging the NUP358 CHD with its remaining CA proteins [82,233]. Once docked, CPSF6 and NUP153 then engage the PIC. The combined actions of these proteins are necessary for PIC nuclear import. TNPO3 expression is required for proper nuclear localization of CPSF6; CPSF6 binding to CA cores too early during infection misregulates the upstream steps of uncoating [66,250] and NPC engagement, blocking infection at the step of nuclear import. TNPO3 may also have an additional intra-nuclear role permitting proper nuclear trafficking and integration, perhaps related to its interaction with IN. These concerted steps of uncoating and nuclear import appear to influence the downstream steps of nuclear trafficking and integration. It will be instructive to see if CPSF6 depletion similarly influences HIV-1 integration site distribution.

The precise mechanistic requirements for NUP358, NUP153, and CPSF6 for nuclear import remain unclear: these proteins may be critical for a prerequisite uncoating step prior to nuclear import, or they may be directly involved in the act of PIC nuclear translocation. As these three proteins have each been published to bind CA, the latter model presupposes that CA would need to be concomitantly imported into the nucleus with the PIC. This point remains highly controversial; CA has historically been noticeably absent from the nucleus, with only a couple recent reports observing potential PIC-associated CA signals within the nuclear fraction [81,82]. Notably, TNPO3, NUP358, and NUP153 are not absolutely required for HIV-1 infection of transformed cell lines: while the WT virus is highly dependent on these factors, certain CA mutant viruses such as N74D can bypass CPSF6 binding and infect cells depleted for NUP358, NUP153, or TNPO3 without a concomitant loss of infectivity. While the N74D CA
mutant virus was previously proposed to bypass these requirements by relying on an alternative set of NUPs (including NUP155 and NUP98) [177], it is not clear whether these proteins indeed fulfill critical roles for N74D mutant virus infection [248].

Alternatively, if the main function of these nuclear transport factors is to uncoat the PIC as a prelude for nuclear import, then alterations to viral uncoating may obviate the need for this mechanism during infection. CypA modulates HIV-1 core stability [191], and is accordingly capable of modulating the viral requirement on NUP153 and the other nuclear transport factors [231,233,253]. While a mechanism for active PIC nuclear transport would be required in all cell types, optimal CA uncoating may be particularly important in certain cell types, such as macrophages. Indeed, the N74D CA mutant virus exhibits a significant infectivity defect in monocyte-derived macrophages [233,257], where its reverse transcription is defective [257]. Because Asn74 is highly conserved among primate lentiviruses, HIV-1 may very well rely on these nuclear transport factors in vivo [177].

Curiously, while HIV-1 appears to rely upon NUP358, NUP153, TNPO3, and CPSF6 during infection, other lentiviruses only appear to share certain aspects of this mechanism. SIVmac does not bind NUP358, and accordingly does not rely on this protein for infection. Furthermore, EIAV utilizes NUP153 and TNPO3, though it does so in the apparent absence of CPSF6 binding. FIV likely utilizes an entirely different mechanism, as it does not seem to require any of these factors. Thus, although recent years have witnessed significant advances on the role of CA and particular nuclear transport proteins in HIV-1 PIC nuclear import, there is clearly much left to learn about
how HIV-1 and some of the other lentiviruses circumvent the nuclear envelope to reach their chromosomal targets of integration.

**Concluding remarks**

Despite two decades of research, the identities of the critical molecular interactions between viral and host proteins governing HIV-1 nuclear import has remained elusive. We find the CA proteins of HIV-1 and a subset of other lentiviruses directly bind NUP153, a major functional component of the nuclear pore complex. Determinents of CA interaction with the NUP153 FG motifs correlate well with the viral requirement for this nucleoporin during infection. Specific FG motifs within NUP153 were necessary for the interaction, highlighting a mechanism wherein certain lentiviral capsids have likely evolved to recognize the unique biophysical properties of the nuclear pore. Our findings demonstrate a key facet of lentiviral nuclear entry, and posit comparable mechanisms to occur across viruses and viral elements that require entry into the host nucleus.
