BACKGROUND: Evidence suggests that air pollution is associated with atherosclerosis and that traffic-related particles are a particularly important contributor to the association.

OBJECTIVES: We investigated the association between long-term exposure to black carbon, a correlate of traffic particles, and intima-media thickness of the common carotid artery (CIMT) in elderly men residing in the greater Boston, Massachusetts, area.

METHODS: We estimated 1-year average exposures to black carbon at the home addresses of Normative Aging Study participants before their first CIMT measurement. The association between estimated black carbon levels and CIMT was estimated using mixed effects models to account for repeated outcome measures. In secondary analyses, we examined whether living close to a major road or average daily traffic within 100 m of residence was associated with CIMT.

RESULTS: There were 380 participants (97% self-reported white race) with an initial visit between 2004 and 2008. Two or three follow-up CIMT measurements 1.5 years apart were available for 340 (89%) and 260 (68%) men, respectively. At first examination, the average ± SD age was 76 ± 6.4 years and the mean ± SD CIMT was 0.99 ± 0.18 mm. A one-interquartile range increase in 1-year average black carbon (0.26 µg/m³) was associated with a 1.1% higher CIMT (95% CI: 0.4, 1.7%) based on a fully adjusted model.

CONCLUSIONS: Annual mean black carbon concentration based on spatially resolved exposure estimates was associated with CIMT in a population of elderly men. These findings support an association between long-term air pollution exposure and atherosclerosis.

Introduction

Exposure to particulate air pollution has been associated with cardiovascular morbidity and mortality in numerous epidemiologic studies (Brook 2004; Brook et al. 2010; Dockery et al. 1993; Pope and Dockery 2006). Evidence suggests that local traffic is a major source of within-city heterogeneity in air pollution exposures (Brueggé et al. 2007; Clougherty et al. 2008) and that mobile sources of pollution may be an important contributor to adverse health effects (Künzli et al. 2000; Laden 2000; Peters et al. 2004). Several studies focusing specifically on the traffic-related constituents of pollution have reported short-term associations with indicators of cardiovascular health (Delfino et al. 2010a, 2010b; Madrigano et al. 2010; Mordukhovich et al. 2009). Evidence for long-term effects of chronic exposure to traffic-related air pollution has come largely from animal studies, which have demonstrated proatherosclerotic effects of diesel exhaust particles and concentrated ambient urban particles (Chen and Nadziejko 2005; Quan et al. 2010; Sun 2005). Recently, a growing number of epidemiologic studies have also observed associations between subclinical atherosclerosis and estimated fine particulate matter (particulate matter ≤ 2.5 µm in aerodynamic diameter; PM2.5) or distance to major roadway (Bauer et al. 2010; Diez Roux et al. 2008; Hoffmann et al. 2007; Künzli et al. 2005).

Black carbon is a correlate of traffic-related combustion products, and a common surrogate for traffic particles in general, weighted toward diesel particles. We have developed a nonlinear land use regression model to estimate black carbon exposures and have applied it within the greater Boston, Massachusetts, metropolitan area (Gryparis et al. 2007). In the present study making use of up to three repeated carotid intima-media thickness (CIMT) measures in a cohort of elderly men, we hypothesized that the estimated annual average concentration of black carbon at participants’ homes in the year before the first study visit would be associated with CIMT, a reliable measure of subclinical atherosclerosis (Kanters et al. 1997; O’Leary and Bots 2010) that predicts cardiovascular outcomes (Namiki et al. 2012; O’Leary et al. 1999). In secondary descriptive analyses, we also estimated associations with residential proximity to a major roadway [defined as U.S. Census feature Class Code A1 (Primary Highway with Limited Access) or A2 (Primary Highway Without Limited Access)] and with average daily traffic within 100 m of residence.

Methods

Study population. The Normative Aging Study is a cohort of community-dwelling men from the greater Boston area recruited in the early 1960s. CIMT was measured in a subsample of participants beginning in 2004, after participants had been followed for four decades. Participants in the CIMT substudy were followed for up to three time points scheduled 1.5 years apart. Our analysis included 380 participants with complete information regarding black carbon concentrations and all covariates at baseline (i.e., the time of the first CIMT measurement). Baseline visits occurred between 2004 and

of land use (e.g., cumulative traffic density within 100 m, population density, distance to nearest major roadway, percent urbanization) at a given location. Weather data were obtained from the Boston airport weather station, and planetary boundary layer data from the National Oceanic and Atmospheric Administration’s national reanalysis data set (http://www.esrl.noaa.gov/psd/data/gridded/data.narr.html).

Measurements from continuous ambient monitors and specific monitoring campaigns were used as to develop model predictions. We obtained hourly outdoor black carbon concentrations from a total of 15 ambient monitors from 1999 to 2004: 12 of these monitors were included in a study of spatial variability in traffic-related pollutant concentrations conducted by the Northeast States for Coordinated Air Use Management (NESCAUM), two sites were operated by the Massachusetts Department of Environmental Protection, and one site was located on the roof of Harvard School of Public Health (HSPH) and operated by the HSPH Department of Environmental Health. Measurements from specific monitoring campaigns came from two sources. First, beginning in 1999, hourly outdoor and indoor black carbon concentrations were measured inside and outside of 30 residential homes, using aethelometers over 48-hr intervals as part of a National Institute of Environmental Health Sciences (NIEHS)–funded study of air pollution and heart rate variability (APAHRV) conducted at HSPH (Zanobetti et al. 2010). Second, 24-hr average outdoor elemental carbon concentrations measured over 7-day periods in 23 locations during the winter and summer of 2000 were obtained from a U.S. Environmental Protection Agency (EPA)–funded multi-pollutant exposures study of sensitive individuals (Brown et al. 2008). We have also incorporated interactions between temporal predictors, such as mixing height and wind speed, and source-based geographic variables, such as traffic density. We used regression

Figure 1. Number of participants according to baseline residence locations within 3-digit ZIP codes in Massachusetts. Most participants lived in the greater Boston area.
splines to allow nonlinear relations between predictors and exposure levels and thin-plate splines (a two-dimensional extension of regression splines) to model spatial variability that was not accounted for by the spatial predictors in the model. Separate models were fit for warm and cold seasons. The prediction equation also used central monitor concentrations as an independent variable to reflect average concentration levels for a given day. In essence, the central monitor concentrations serve as direct estimates of the daily time effect. Latent variable models were used to integrate measures of outdoor black carbon, indoor black carbon, and elemental carbon from the monitoring campaigns. The resulting multipollutant model is fit using a Bayesian Markov Chain Monte Carlo approach. The adjusted $R^2$ for the model was 0.83 and the average correlation between predicted and measured BC concentrations in four out-of-sample validation samples was 0.59. This model has been previously used to examine the associations between black carbon and a variety of health outcomes including mortality (Maynard et al. 2007), cognitive function in children (Suglia et al. 2008) and adults (Power et al. 2011), birth weight (Gryparis et al. 2009), lung function (Franco Suglia et al. 2008), and biomarkers of endothelial function (Alexeeff et al. 2011).

GIS (geographic information system) analyses were performed using ArcMap, version 10.1 (ESRI, Redlands CA, USA). All addresses of Normative Aging Study participants have been geocoded and assigned daily predicted black carbon concentrations. For this analysis, we calculated annual average concentrations during the year before the first CIMT measurement for participants for ≥ 9 months of contiguous daily black carbon data during that year. Available data were used as a proxy for a 1-year average for participants who were missing 1–3 months of data. The primary reasons that individuals did not have complete black carbon data was moving to a new home or having a second home outside the study region. If an individual had multiple addresses during the year before their first CIMT measurement and black carbon data were available for all addresses, a composite individual-level annual mean measure of black carbon was calculated using data from the time the individual spent at each address.

**Distance to roadway measures and average daily traffic within 100 m.** We also examined associations with distance to a major roadway and traffic density within a 100-m buffer of residence during the year before the first CIMT measurement in descriptive analyses. Major roadway classifications were provided by Census TIGER Files (U.S. Census Bureau 2013). Distance to the nearest major roadway (Class Code A1 or A2) was computed using the near tool in ArcGIS. We classified residential distance to major roadways as 0 to ≤ 100 m, 100 to ≤ 200 m, 200 to ≤ 1,000 m, and > 1,000 m based on prior studies showing that living within 100 m of a major road is associated with cardiovascular events (Tonne et al. 2007), all-cause mortality among myocardial infarction survivors (Rosenbloom et al. 2012), and atherosclerotic progression (Künzli et al. 2010). In addition, living ≤ 200 m of a major road has been associated with coronary artery calcification, another measure of atherosclerotic burden (Hoffmann et al. 2007). Average daily traffic was determined by summing the product of road segment length and estimated annual average daily traffic within a 100-m buffer of the subject’s residence using the MassHighway 2002 Road Inventory database (Massachusetts Department of Transportation 2013). The measures of annual average daily traffic are based on actual traffic counts for major roadways and estimated according to regional traffic patterns for more local roads.

**Statistical methods.** CIMT was natural log (ln) transformed to improve the normality of the dependent variable distribution. We fit general additive models based on penalized splines using both ln-transformed and untransformed annual average black carbon concentrations to assess the functional form of the outcome–exposure association. These models strongly supported a linear association between CIMT and ln-transformed black carbon exposure, whereas the spline on the natural scale is reported in the Supplemental Material, Figure S1, and showed a nonlinear association. Specifically, there was a positive association between black carbon and CIMT at lower levels of black carbon, while most of the observations occurred, and a negative association with wide confidence intervals (CIs) at high levels, where there were few observations. Therefore, our primary analyses were based on ln-transformed black carbon exposures. We estimated the association between ln-transformed CIMT and annual average ln-transformed daily black carbon concentrations at each participant’s home address during the year before their first CIMT measurement using linear mixed effects with subject-specific random intercepts in SAS PROC MIXED (SAS, version 9.1; SAS Institute Inc., Cary, NC, USA) to account for repeated measures of the outcome in a subset of participants.

We fit our models in stages, first adjusting for a limited set of covariates including age at baseline, BMI, smoking status, and time since beginning of the study to capture long-term time trends. In the second stage, we added information on health status, medication use, and socioeconomic position, any of which could be potential confounders or mediators of the association between black carbon exposure and atherosclerosis. Covariates included in the second stage model were pack-years smoked, years of education (<12, 12–16, and >16 years), alcohol intake (≥ 2 servings/day), categories of physical activity (0 to <12, 12 to <30, ≥ 30 METs/week), median income of the 2000 U.S. Census tract of residence, total cholesterol, lipid-lowering medication (statins), systolic blood pressure, blood pressure medications, and diabetes diagnosis. Time-varying covariates (all but education, baseline exposure, and median income at the U.S. Census tract at baseline) were updated at each visit. We also examined effect modification by using cross-product terms to estimate associations between black carbon and CIMT stratified on age (<75, ≥ 75 years of age), education (<12, ≥ 12 years of education), statin use (yes or no), diabetes (yes or no), and obesity (BMI <30, ≥ 30) at baseline.

We conducted a separate analysis of CIMT progression (specifically, the change in CIMT from baseline to 3 years after baseline) in association with ln-transformed black carbon at baseline among the 260 participants with a measure of CIMT after 3 years of follow up, adjusting for the baseline values of covariates included in the fully adjusted model.

We also conducted several sensitivity analyses. We examined whether removal of potential confounders and mediators (i.e., statin medication use, total cholesterol, blood pressure medication use, diabetes diagnosis) altered the findings, and we also removed age at baseline from our model because some studies have observed that age is an important confounder and potential effect modifier (Rivera et al. 2013). Next, we explored the exposure–response relationship in fully adjusted models using generalized additive models with penalized splines in R (version 2.13; R Foundation for Statistical Computing, Vienna, Austria). We also estimated the cross-sectional association between black carbon during the year before the first CIMT measurement, and CIMT at the first measurement, with model covariates as defined at baseline. We then restricted analyses to participants whose location of residence did not change during the study and examined associations with a 1-year average exposure to black carbon in 2003 as a surrogate for long-term exposure among this population. The year 2003 was chosen because it is the year before the earliest possible baseline visits. In addition, we estimated the association between black carbon and CIMT after excluding participants who resided outside of the eastern Massachusetts region approximately within the boundaries of Interstate 495 (I-495); Figure 1 where the original exposure model was developed and tested.

A statistically significant interaction (p > 0.05) for BMI only (Table 3). Specifically, the association between an IQR increase in average black carbon during the year before baseline was associated with a 1.1% (95% CI: 0.4%, 1.7%) higher CIMT, consistent with a 0.01-mm increase from the mean CIMT of 0.99 mm at baseline (Table 2), which was similar to the mean rate of progression per year in this population (i.e., 0.01 mm). This association was stronger than estimated by the parsimonious model (0.9% higher; 95% CI: 0.2, 1.5%) adjusted for age, BMI, smoking, and time since baseline only.

p-Values for cross-product terms indicated a statistically significant interaction (p < 0.05) for BMI only (Table 3). Specifically, the association between an IQR increase in average black carbon at baseline (–0.0002 mm decrease from baseline on average; 95% CI: –0.002, 0.001 mm; p = 0.79).

We also considered clustering by socioeconomic status by including an additional random effect for ZIP code. In secondary descriptive analyses, we estimated associations between CIMT and residential proximity to a major roadway (0 to ≤ 100 m, > 100 to ≤ 200 m, > 200 to ≤ 1,000 m, or > 1,000 m) and between CIMT and average daily traffic within 100 m of the participant’s residence (categorized according to quartiles).

Results

A total of 380 participants completed a baseline visit between 2004 and 2008, including 340 (89%) who completed at least two follow-up visits and 260 (68%) who completed three follow-up visits through 2010 (Table 1). At baseline (the time of first CIMT measurement), the mean (± SD) age and BMI of participants were 75.9 ± 6.4 years and 28.1 ± 4.1 kg/m² respectively, and 355 (93%) were retired or semiretired. The mean CIMT at baseline was 0.99 ± 0.18 mm, which was higher than levels observed in younger, population-based cohorts. Participants were 61 to 96 years of age at baseline and CIMT ranged from 0.63 to 2.10. Median predicted black carbon concentrations at baseline for each subject was 0.29 µg/m³, with the interquartile range (IQR) equivalent to 0.26 µg/m³ (25th to 75th quartile, 0.16–0.42 µg/m³).

Based on our fully adjusted model, an IQR increase in average annual black carbon during the year before baseline was associated with a 1.1% (95% CI: 0.4%, 1.7%) higher CIMT, consistent with a 0.01-mm increase from the mean CIMT of 0.99 mm at baseline (Table 2), which was similar to the mean rate of progression per year in this population (i.e., ± 0.01 mm). This association was stronger than estimated by the parsimonious model (0.9% higher; 95% CI: 0.2, 1.5%) adjusted for age, BMI, smoking, and time since baseline only.

p-Values for cross-product terms indicated a statistically significant interaction (p < 0.05) for BMI only (Table 3). Specifically, the association between an IQR increase in average black carbon and CIMT was stronger among men who were not obese at baseline (1.4%; 95% CI: 0.7, 2.2%; n = 284) than among men who were obese (0.6%; 95% CI: –0.6, 1.8%; n = 96, pinteraction = 0.04). No other significant interactions were observed. CIMT progression among the 260 men with CIMT measured 3 years apart was not significantly associated with an IQR increase in annual average black carbon at baseline (–0.0002 mm decrease from baseline on average; 95% CI: –0.002, 0.001 mm; p = 0.79).

In our sensitivity analyses (Table 2), point estimates did not change when we removed additional potential mediators associated with health status. Results from our cross-sectional

BMI and CIMT in this study, such that

location was associated with a slightly smaller

difference on the log scale. In analyses in which

in our final model. We did not observe any
deviation from linearity on the log scale. In

and 1-year averaged modeled exposure from

Heinz-Nixdorf recall study in Germany

Bauer et al. 2010) in addition to a recent

study that reported associations with NO2

(nitrogen dioxide), which is also a marker of

traffic particles (Rivera et al. 2013).

Previous studies have reported that CIMT

is a strong predictor of future vascular events.

A meta-analysis reported that age- and sex-

adjusted relative risks of myocardial infarction

and stroke per 0.10 mm CIMT difference were

1.15% (95% CI: 1.12, 1.17%) and

1.18% (95% CI: 1.16, 1.21%), respectively; and

although the relationship between CIMT and

risk was not linear, linear models fit well

for moderate-to-high CIMT levels. The levels

of CIMT at baseline observed for men who

participated in our study were higher than

those reported in populations that included

younger, healthier populations of both men

and women (Chambless et al. 1997; Lim

et al. 2008) and were more similar to those

reported in a study of patients with arterial

disease and cardiovascular risk factors (Dijk

et al. 2006). In the Atherosclerosis Risk in

Communities (ARIC) study, a cutoff of 1 mm

was used to evaluate risk of coronary heart
disease, and the hazard ratio for coronary heart
disease comparing men with CIMT measures

> 1 mm versus < 1 mm was 1.85 (95% CI:

1.28, 2.69), which would suggest that the

levels of CIMT observed in our study popula-
tion might be associated with elevated risk of

cardiovascular disease.

A few recent studies have begun to exam-
inations between ambient air pollu-
tion exposure and atherosclerotic progression

as measured by CIMT. In one recent study,

both PM2.5 and residential distance from

highway were examined in a population of

participants pooled from five double-blind

randomized trials that estimated the effects

of interventions on the progression of CIMT

in the Los Angeles area (Künzli et al. 2010).

Künzli et al. (2010) observed a rate of pro-

gression of 5.46 µm (95% CI: 0.13, 10.79)

per year associated with living within 100 m

of major road and that a 10-µg/m
increase in PM2.5 was associated with a slightly

smaller change of 2.53 (95% CI: –0.31, 5.38)

µm per year. More recently, similar results have

been reported in MESA, where Adar et al. (2013)

observed that 2.5-µg/m
higher levels of resi-
dential PM2.5 during the follow-up period

were associated with 5.0 µm/year (95% CI:

2.6, 7.4 µm/year) greater IMT progressions

among persons in the same metropolitan

area. We did not observe a significant asso-
ciation with progression over 3 years; given

the relatively short period of follow-up on

only 260 participants, we had limited power
to test this association in the present study.

In addition, men who survived long enough
to participate in the present study may have
had a low likelihood of CIMT progression,

and healthier participants within the cohort

may have been more likely to have completed

follow-up than men with increasing CIMT.

The annual rate of CIMT progression in our

study population (approximately 0.01 mm, or

10 µm/year) was similar to rates reported in

MESA and other cohort studies including the

ARIC study (Ranjit et al. 2006) and in older

men and women in the Whitehall II study

(Halcox et al. 2009).

We observed significant associations with

the measured in-transferred daily predictions

of black carbon at participant residence.

In our secondary, exploratory analyses, we exa-
mined associations with measures of residen-
tial proximity to major roadways as well as

traffic density. In the present study, contrary
to our expectation, mean CIMT was greatest

in men living farthest from a major road at

baseline, although associations were not

statistically significant and only a small num-

ber of participants (n = 32) lived ≤ 200 m

from a major road at baseline. A study by

Allen et al. (2009) reported no association

between roadway proximity and abdominal

aortic artery calcification, another measure

of atherosclerotic burden. As these authors

have pointed out, the roadway classification

system describes a type of road and not the

traffic volume and traffic pollution, more
directly, which may in part explain these dif-

fering results. In the present study, CIMT

was higher in participants exposed to traf-

fic counts higher than the first quartile, but

estimates were relatively imprecise and not

statistically significant.

Of the potential susceptibility factors that

we examined, the only statistically significant

interaction was observed for stratification by

obesity: We observed higher associations

with black carbon among non-obese indi-

viduals. We hypothesized that this finding

was due to the strong association between

BMI and CIMT in this study, such that

obesity and other related factors likely have

a larger effect on a measure of subclinical

atherosclerosis than black carbon and the

association between black carbon and intima-

media thickness is observed only in the non-

obese individuals. In addition, Freedman

et al. (2004) have noted that CIMT may be

more difficult to measure in obese individu-

als and may be assessed with less precision.

The association between black carbon and

CIMT was also somewhat stronger in men

without diabetes than in men with diabe-

tes, although estimates were imprecise. These

results contrast those of other studies that

have reported evidence to suggest that per-

sons with diabetes are particularly suscep-

tible to the effects of traffic pollution (Baja et al.
To address this, we also analyzed associations assigning everyone black carbon exposure based on 2003 data for their addresses and the results were similar to those observed in our final model. Future work will be necessary to elucidate this association.

Because our study participants were elderly male residents of the Boston area, 97% of whom reported their race as white, these results may not be generalizable to other populations of environmentaly exposed men and women. This particular analysis was also limited to a subset of Normative Aging Study participants who continued to be followed during the study period, many of whom consented to return on an additional day for CIMT testing. Our study participants were elderly men ranging in age from 61 to 96 years of age at first visit, who, on average, had already developed a considerable degree of atherosclerotic burden at baseline. Furthermore, the mean CIMT reported at baseline was higher than has been reported in other community-based samples, which generally have younger participants (Adar et al. 2013; Rivera et al. 2013). There may be some degree of measurement error in CIMT, but this would likely be nondifferential with respect to exposure. In addition, we also cannot rule out the role of residual confounding by socioeconomic position or other factors. Although there was some attrition over time, two or more measurements were obtained for 89% of individuals.

Conclusions

We observed that low levels of ambient exposure to estimated black carbon were associated with CIMT in a population of elderly men continuing to participate in a long-term prospective cohort study. Given the growing interest in the relationship between air pollution and atherosclerosis (Künzli et al. 2011) and the limited body of human studies examining repeated measurement of indicators of atherosclerotic burden, future studies are needed to substantiate the association between specific sources of pollution and atherosclerotic progression in order to clarify the underlying mechanisms.
