Abstract

Infection of glial cells by the human polyomavirus JC (JCV) causes progressive multifocal leukoencephalopathy (PML). JCV Encephalopathy (JCVE) is a newly identified disease characterized by JCV infection of cortical pyramidal neurons. The virus JCVCPN associated with JCVE contains a unique 143 base pair deletion in the agnogene. Contrary to most JCV brain isolates, JCVCPN has an archetype-like regulatory region (RR) usually found in kidney strains. This provided us with the unique opportunity to determine for the first time how each of these regions contributed to the phenotype of JCVCPN. We characterized the replication of JCVCPN compared to the prototype virus JCVMad-1 in kidney, glial and neuronal cell lines. We found that JCVCPN is capable of replicating viral DNA in all cell lines tested, but is unable to establish persistent infection seen with JCVMad-1. JCVCPN does not have an increased ability to replicate in the neuronal cell line tested. To determine whether this phenotype results from the archetype-like RR or the agnogene deletion, we generated chimeric viruses between JCVCPN of JCVMad-1. We found that the deletion in the agnogene is the predominant cause of the inability of the virus to maintain a persistent infection, with the introduction of a full length agnogene, either with or without agnoprotein expression, rescues the replication of JCVCPN. Studying this naturally occurring pathogenic variant of JCV provides a valuable tool for understanding the functions of the agnogene and RR form in JCV replication.

Introduction

The human polyomavirus JC (JCV) has a circular double stranded DNA genome which can be divided into 3 regions. The early coding region encodes the regulatory proteins small t antigen and large T antigen (T Ag). The late coding region encodes the VP1, VP2 and VP3 structural proteins, and the agnoprotein [1]. The regulatory region (RR) contains the origin of replication, as well as the early and late promoters [2,3]. While the coding regions are well conserved, the RR is hypervariable, with different sequences being isolated from individuals [1]. Archetype RR, which has one 98-bp element and contains a 23-bp and a 66-bp insert, is generally found in the kidneys or urine of healthy and immunosuppressed individuals [4]. RRs from the brain or CSF of PML patients are generally of the rearranged type, containing two 98-bp tandem repeats with additional mutations, insertions and deletions [1,2].

JCV is the etiological agent of Progressive Multifocal Leukoencephalopathy (PML), an often fatal demyelinating disease caused by lytic infection of oligodendrocytes by the virus [5]. Infection with JCV is widespread in the population, but remains asymptomatic in healthy people [6,7]. Development of PML is associated with immune suppression, such as in patients with AIDS [8], organ transplants [9] or hematological malignancies [10]. We have identified two additional syndromes caused by JCV infection in the brain, JCV Granule Cell Neuronopathy [JCV GCN] [11,12,13] and JCV Encephalopathy (JCVE) [14]. The viruses isolated from patients with these syndromes contain previously unreported unique mutations. JCV GCN is associated with deletions in the C-terminus of the VP1 protein [15,16] and JCVE with a deletion in the agnogene [17]. These naturally occurring pathogenic variants provide a unique tool for studying the basic biology of JCV replication and pathogenesis.

JCVE was described in an HIV-negative patient with a history of lung cancer treated with chemotherapy, who presented with cortical lesions, aphasia and progressive cognitive decline. Post-mortem analysis of the brain showed cortical lesions with productive infection of cortical pyramidal neurons [14]. Isolation and sequencing of the JCV DNA present in the brain of this patient identified a virus with an archetype-like RR and a 143 base pair deletion in the agnogene [17]. This virus was named JCV Cortical Pyramidal Neuron 1 (JCVCPN). The deleted agnogene encodes a 10 amino acid truncated peptide. Further analysis found that multiple forms of JCVCPN were present, and that these strains co-existed with a virus containing a full length agnogene. Immunostaining analysis indicated that the majority of the cortical cells infected with JCV contained the truncated form of the agnoprotein [17].
JCV agnoprotein is a highly basic, 71 amino acid, non-essential protein that is expressed late in infection, but not incorporated into virions [18]. It is primarily expressed in the cytoplasm, particularly in the perinuclear region, with a small amount found in the nucleus [19]. Agnoprotein has been shown to form homodimers and oligomers [20]. Agnoprotein contains 3 phosphorylation sites, which can be phosphorylated by protein kinase C [21] and dephosphorylated by protein phosphatase 2A [22]. The phosphorylation state may impact agnoprotein localization [19]. Agnoprotein has been shown to bind to T Ag, down regulating DNA replication [23] and enhancing T Ag origin binding [24]. Agnoprotein may also influence viral gene expression and splicing of viral transcripts [25]. Loss of agnoprotein expression has been associated with loss of early and late mRNA expression [19]. Agnoprotein has also been shown to suppress activity of the late promoter [23], and to interact with the transcription factor YB-1, inhibiting its ability to activate the early and late promoters [26]. Prevention of agnoprotein expression also has been shown to result in decreased levels of T Ag and VP1 protein expression [27]. Viruses lacking agnoprotein are less efficient at packaging DNA and virion formation, with infected cells releasing empty particles [27,28]. The agnoprotein may also function as a viroporin, aiding in the release of virions from infected cells [29]. These studies have added to our knowledge of agnoprotein function in recent years, but the exact mechanisms by which this protein influences the viral life cycle remain unclear.

In addition to agnoprotein function, the DNA of the agnogene has been shown to contain 3 host cell factor binding sites. Deletion of the agnogene DNA has a greater effect on replication than prevention of agnoprotein expression by mutation of the start codon [30]. In the agnoprotein deletion present in JCVCPN, 1 of the 3 sites is completely deleted, and a second is shortened by 1 nucleotide. We hypothesized that the agnoprotein deletion of JCVCPN allowed the virus to infect cortical pyramidal neurons. We used cell culture models to study the replication of JCVCPN compared to the prototype strain JCVMad-1 [31] in different cell types. We generated chimeric viruses of JCVCPN and JCVMad-1, swapping both the agnogene and RR, to determine the specific effects of the agnoprotein deletion and the archetype-like RR on viral replication in cell culture. In these experiments we characterized the replication of JCVCPN in different cell types, and determined the relative contributions of the agnoprotein and archetype-like RR to the JCVCPN replication phenotype. Studying these novel naturally occurring changes in JCVCPN provided unique insights into our understanding of the function of the agnogene and RR form in JCV replication.

**Materials and Methods**

**Cell Culture**

Cos-7 [32], SVG [33] and IMR-32 [34] cells were purchased from the ATCC. Cos-7 cells were maintained in Dulbecco’s Modified Eagle Medium (DMEM) supplemented with 10% fetal bovine serum (FBS), Penicillin (500 units/mL) and Streptomycin (500 μg/mL). SVG cells were maintained in Minimum Essential Medium (MEM) supplemented with Sodium Bicarbonate (1.5 g/L), 10% FBS, Penicillin (500 units/mL) and Streptomycin (500 μg/mL). IMR-32 cells were maintained in MEM supplemented with Sodium Bicarbonate (1.5 g/L), Sodium Pyruvate (1 mM), Non-Essential Amino Acids (NEAA) (Invitrogen), 10% FBS, Penicillin (500 units/mL) and Streptomycin (500 μg/mL).

**Plasmids**

Construction of the JCVCPN and JCVMad-1 plasmids was previously described by Dang et al. [17]. To generate the agnoprotein chimeric viruses Mad-1 C-Agnovo and CPN M-Agno, the agnogene region was excised using the restriction enzymes ApaI and PciI (New England Biolabs), and the digested DNA was run on an agarose gel. The agnoprotein DNA and the virus minus the agnogene DNA bands were excised and purified using the QIAquick Gel Extraction Kit (QIAGEN). Agnoprotein DNA segments were ligated into the viral backbone using T4 ligase (New England Biolabs). The resulting plasmids were transformed into TOP10 (Invitrogen) or XL1-Blue cells (Agilent). Plasmid DNA was maxi prepped (QIAGEN), and plasmids were fully sequenced. The RR chimeras were generated with the same protocol, using the restriction enzymes BamHI and PciI (NEB) to excise the RR. Mad-1 Pt and Mad-1 Del plasmids were previously described [30], and obtained as a generous gift from Dr. Safak. The agnoprotein from these viruses was introduced into our JCVMad-1 or JCVCPN plasmid using the ApaI and PciI restriction sites as previously described.

**Transfection**

Full-length JCV genomes were digested out of the plasmid backbone using EcoRI (NEB) and run on a 0.6% agarose gel. The 5 kb virus band was purified using the QIAquick Gel Extraction Kit (QIAGEN). Cells were transfected with 1 μg (for IMR-32 and SVG cells) or 2 μg (for Cos-7 cells) of purified JCV DNA using FuGENE6 transfection reagent (Roche or Promega) in 6 well plates. 3 days post-transfection, cells were passaged 1:3 to T25 flasks, and subsequently every 3–4 days 1:4 in T25 flasks. At each passage, supernatant was collected and cells were collected, pelleted and stored at −80°C until further analysis.

**DNA Extraction and Quantitative PCR (QPCR)**

DNA was extracted from cell pellets and supernatant samples using the QIAamp DNA Blood Mini Kit (QIAGEN). QPCR was performed as previously described [15]. An RNAase P primer/probe set (Applied Biosystems) was used in a multiplex assay with the JCV primer/probe set on cell lysate samples. Copies RNAse P per reaction was determined and divided by 2 to determine the number of input cells for each reaction. Copies JCV/cell was calculated by dividing the copies JCV per reaction by the number of cells per reaction. All samples were run in triplicate.

**RNA Extraction and qRT-PCR**

RNA was extracted using the RNEasy Mini Kit (QIAGEN). RNA samples were digested with DNase I (Ambion) to remove any contaminating DNA. Reverse transcription was done using the High Capacity RNA-to-cDNA Kit (Applied Biosystems). QPCR was performed on a 7300 Real-time PCR System using Gene Expression Master Mix (Applied Biosystems). For amplification of the early transcript mRNA, a primer probe set spanning the Large T Ag splice site was used. The primers were JCT208F (5’-CATCAGGCTGATTTTGGTACATG-3’), reverse complement of position 4784–4806 and JCT 279R (5’-CGAGGATTCCCCATTACGTGTT-3’), position 4392–4412. The probe used was JCT-232p (6FAM-5’-CATCAGGCTGATTTTGGTACATG-3’), reverse complement of position 4784–4806 and JCT-232p (6FAM-5’-CATCAGGCTGATTTTGGTACATG-3’), reverse complement of position 4392–4412. For detection of late transcript mRNA we used the primers JCVP1-745F (5’-GGTGAACACTTA-TACTTTGACCTGTT-3’), position 2213–2239 and JCVP1-812R (5’-TGCTGGAGAACCAGGACGCTGTGTT-3’), reverse complement of position 2261–2280 and the probe JCVP1-773p (6FAM-
5′-ATG TCT GTG GCA TGT TTA-3′-MGB, position 2241–2248). A TATA-box binding protein (TBP) primer/probe set (Invitrogen) was used as the endogenous control for determination of relative quantity by the comparative Ct method [35]. All samples were run in triplicate wells.

Western Blotting

Cells were lysed in TNN lysis buffer (50 mM Tris-HCl pH 7.5, 150 mM NaCl, 0.1% NP40) with 0.2 mM Na-Orthovanadate and 1% protease inhibitor cocktail for 30 minutes on ice. Samples were centrifuged at 8000 rpm for 4 min to remove cell debris. Laemmli Buffer (Bio-Rad) was added to whole cell lysate. Samples were boiled for 10 min and run on a 10% SDS-PAGE gel in Tris/ Glycine/SDS running buffer (Bio-Rad). Samples were transferred for 2 hours at 150 mamps to a nitrocellulose membrane in Transfer Buffer (Tris/Glycine with 20% methanol) or to a nitrocellulose membrane using the iBlot system (Invitrogen). Membranes were blocked using 5% milk in PBST and incubated overnight at 4°C with VP1 antibody pAB597 (1 mg/mL) diluted 1:1000 or loading control anti-alpha tubulin [DM1A] (abcam) in 2% milk in PBST. An HRP conjugated goat-anti mouse IgG secondary antibody (Bio-Rad) was used and detection was done with ECL Plus reagent (Thermo Scientific). Signal was detected on film.

Flow Cytometry Analysis of JCV-Positive Cells

Cells were trypsinized, collected and washed with 2% FBS in PBS. Cells were passed through a 30 μm filter (Miltenyi Biotec) and incubated for 20 minutes at 4°C in AquA Amine to stain dead cells, and then washed with PBS. Cells were fixed with Cytofix/Cytoperm (BD Biosciences) for 20 minutes at 4°C then washed with PBS. Staining with the primary antibody PAB597 (mouse monoclonal anti-VP1) in Perm/Wash Buffer (BD Biosciences) was done for 2 hours at 4°C. Cells were washed with Perm/Wash Buffer, then PBS and then stained with Alexa 488 conjugated goat-anti mouse IgG secondary antibody (Bio-Rad) was used and detection was done with BD LSR II Flow Cytometer (BD Biosciences).

JCV Infectivity Test

Cos-7 cells were plated in 6 well plates at low density and allowed to adhere overnight. Cell free supernatant collected from transfected cells was put on the Cos-7 cells, and incubated 2 hours at room temperature with rocking. Supernatant was not digested with DNase to remove free JCV DNA, as previous experiments have shown that digesting with DNase does not affect the levels of JCV DNA detected in the supernatant by qPCR, or the percentage of cells subsequently infected from the supernatant (data not shown). The infection was allowed to proceed for 7 days. Cells were then collected and analyzed for either VP1 expression by flow cytometry or JCV DNA by QPCR as previously described.

Statistical Analyses

Analyses were done using SAS Software version 9.3. Data was tested for normality before statistical analysis. P-values for DNA levels were determined using the non-parametric Wilcoxon Rank Test. P-values for mRNA levels were done using univariate analysis, and taking the student’s t p value. Flow cytometry p-values were determined using Student’s t test.

Results

**JCVCPN has a 143 base pair deletion in the agnogene and an archetype-like RR**

The JCVCPN1.2 RR is archetype-like, lacking a duplication of the TATA-box and containing a 66 bp and 80 bp insert, which contain portions of the 23 bp and 66 bp inserts present in archetype RR [Fig 1A] [17]. A 143 bp deletion in the agnogene is also present in JCVCPN1 [Fig 1B] [17]. This deletion creates a premature stop codon, and is predicted to code for a truncated 10 amino acid agnoprotein. Multiple forms of JCVCPN were identified, including JCVCPN1.1 and JCVCPN1.2 which both contain the same regulatory region and agnogene deletion. In addition, JCVCPN1.2 contains a 75 bp duplication between the agnogene and the VP2 gene, encompassing the start of the VP2 gene (Fig 1B). This form is predicted to encode for both a truncated and a full length VP2. Our studies determined that JCVCPN1.1 and JCVCPN1.2 are phenotypically equivalent in our cell cultures model (data not shown). Therefore, we chose to conduct the experiments in this study using the JCVCPN1.2 strain, because it was the predominant strain in the JCVE patient’s brain. JCVCPN1.2 is referred to as JCVCPN for the remainder of this work.

**JCVCPN can replicate DNA in cell culture, but at a lower level than JCVMad-1**

To determine the cellular tropism of JCVCPN, we studied its replication in cell culture. We used multiple cell lines to model the replication of the virus in three different types of cells, kidney cells, glial cells, and neuronal cells. Cos-7 cells are African Green Monkey kidney cells which express SV40 T Ag, and are known to replicate JCV well [32]. SVG cells are human fetal glial cells, also transformed with SV40 T Ag [33]. IMR-32 cells are a human neuroblastoma cell line, derived from a tumor isolated from the abdominal cavity of a child, which do not express any polyomavirus T Ag [34]. We first wanted to determine if JCVCPN is capable of genome replication. To do so, linearized genomes of JCVCPN and JCVMad-1 were transfected into Cos-7, SVG and IMR-32 cells. DNA from cell lysate, representing JCV DNA replicated in the transfected cells, and supernatant, representing DNA released from the transfected cells, was extracted and digested with DpnI to remove any remaining input plasmid DNA. JCV genome copy number was determined by QPCR. We found that JCVCPN replicated DNA after transfection in all 3 cell lines tested (Fig. 1C–H). However, the levels of DNA were not equivalent to those seen with the prototype strain JCVMad-1.

In Cos-7 kidney cells, JCVMad-1 establishes a high level infection that persists over 3 weeks, as measured by copies JCV DNA in the cell lysate and supernatant (Fig. 1C and 1D). JCVCPN has equivalently high levels of JCV genomes present in the cell lysate and supernatant during the first week post-transfection, but does not maintain such a high viral load, with the copy number decreasing with time. In SVG glial cells, both JCVMad-1 and JCVCPN establish persistent infections (Fig 1E and 1F). Levels of JCV genome copies in cell lysate and supernatant at later time points post-transfection are significantly lower than those of JCVMad-1, but with a smaller magnitude of difference than observed in Cos-7 cells. In IMR-32 neuronal cells, JCVMad-1 DNA decreased over the first 2 weeks after transfection, and then leveled off, remaining detectable over 3 weeks (Fig. 1G and 1H). In contrast, JCVCPN decreased and dropped below the limit of detection at 14 days post-transfection in cell lysate and 17 days post-transfection in the supernatant. These results indicate that JCVCPN is able to replicate its genome after transfection into Cos-7, SVG and IMR-32 cells, but may have a decreased capacity to
persist and spread within the culture compared to prototype JCV_{Mad-1}. Additionally, JCV_{CPN} does not display a replication advantage in the neuronal cell culture line tested.

JCV_{CPN} expresses both early and late transcripts, but at decreased levels compared to JCV_{Mad-1}

Knowing that JCV_{CPN} is able to replicate viral DNA, but not establish a persistent high level infection, we wanted to determine if JCV_{CPN} is able initiate transcription of mRNAs from the early and late promoters. To do so, we used qRT-PCR on RNA from transfected cells using primer and probe sets located in TAg to detect early transcripts, and in VP1 to detect late transcripts. In Cos-7, SVG and IMR-32 cells, JCV_{CPN} expresses detectable levels of both the early and late transcripts (Fig. 2). In Cos-7 cells, the level of early transcripts is significantly lower than those seen with JCV_{Mad-1} 3 and 10 days post-transfection (Fig. 2A). In SVG cells,
the level of early transcripts is similar between JCV\textsubscript{CPN} and JCV\textsubscript{Mad-1} 3 and 7 days post-transfection, and significantly lower 10 days post-transfection (Fig. 2B). In IMR-32 cells, level of early transcripts produced by JCV\textsubscript{CPN} is significantly lower than those of JCV\textsubscript{Mad-1} at 3, 7 and 10 days post-transfection (Fig. 2C). In all three cell lines, the level of late transcripts is markedly lower in JCV\textsubscript{CPN} transfected cells compared to JCV\textsubscript{Mad-1} transfected cells (Fig. 2D–F). These results indicate that, although both the early and late promoter of JCV\textsubscript{CPN} are transcriptionally active, they function at a level lower than JCV\textsubscript{Mad-1}. The decrease in transcript levels is larger for the late than the early promoter.

JCV\textsubscript{CPN} fails to produce detectable levels of VP1 protein in Cos-7 cells

We then wanted to determine if JCV\textsubscript{CPN} produces VP1 protein from the late mRNA. JCV\textsubscript{Mad-1} transfected cells produce VP1 protein, with the amount of VP1 present increasing with later times post-transfection (Fig. 2G). JCV\textsubscript{CPN} does not produce detectable levels of VP1 protein, even with long exposure times (Fig. 2G).

JCV\textsubscript{CPN} produces low levels of infectious virions

Although we could not detect VP1 expression by Western Blot or flow cytometry in transfected cells, there may be a very low level of expression below our limit of detection. We therefore wanted to determine if JCV\textsubscript{CPN} transfected cells are producing virions capable of infecting a new round of cells. To do so, supernatant
was collected from transfected Cos-7, SVG and IMR-32 cells 7, 14 and 21 days post-transfection and was used to infect Cos-7 cells. Infection was allowed to proceed for 7 days. Cells were collected, and analyzed for JCV DNA by QPCR or stained for VP1 and analyzed by flow cytometry.

JCVMad-1 containing supernatant from Cos-7 cells was able to establish an infection in the new cells, with the viral load and the percentage of cells infected increasing with supernatant collected at later time points post-transfection (Fig. 3A and B). The percentage of VP1 positive cells was significantly higher than in the samples treated with supernatant from mock transfected cells (Fig. 3B). In contrast, cells infected with JCVCPN containing supernatant had significantly lower levels of viral DNA detected, which decreased over time, becoming undetectable in samples infected with supernatant collected 21 days post transfection (Fig. 3A). The percentage of JCVCPN VP1 positive cells was not significantly higher than observed with Mock supernatant (Fig. 3B), which is most likely due to the lack of detectable expression of VP1 protein in JCVCPN transfected cells.

Similar results were seen using supernatant from transfected SVG and IMR-32 cells, with low levels JCV DNA detected in cells infected with JCVCPN containing supernatant collected 7 days post-transfection, and then decreasing (Fig. 3C and D). Using supernatant from SVG cells, JCVCPN DNA remains detectable with supernatant collected 14, but not 21, days post-transfection and JCVMad-1 infected cells had DNA levels that were significantly higher than those observed with JCVCPN at all time points (Fig. 3C). In contrast to the results observed using Cos-7 supernatant, the viral loads in JCVMad-1 infected cells decreased with later collection points using SVG supernatant (Fig. 3C). Cells infected with supernatant collected 14 and 21 days post-transfection from IMR-32 cells had undetectable JCVCPN DNA levels (Fig. 3D). JCVCPN DNA was detected in cells infected with supernatant collected from IMR-32 cells at 7 and 21 days, but not 14 days, post-transfection (Fig. 3D). This is most likely due to the levels of JCV DNA being below the limit of detection of our assay.

**Generation of chimeras and agnogene mutants**

The results of the above experiments comparing JCVCPN and JCVMad-1 suggest that JCVCPN has a block preventing late gene expression and protein production, as well as in the production and release of infectious virions. The two major regions of difference between JCVCPN and JCVMad-1 are the RR and the agnogene. To determine which area of the virus is the major contributor to the phenotype of JCVCPN, we generated chimeric viruses of JCVCPN and JCVMad-1 (Fig. 4). We swapped the agnogene genes of the two viruses to generate Mad-1 G-Agno and CPN M-Agno. Mad-1 C-RR and CPN M-RR were generated by exchanging the RRs of the two viruses. We obtained two agno deletion mutations, Mad-1 Pt, which has a start codon point mutation which prevents the expression of agnoprotein, and Mad-1 Del, which has the entire agnogene deleted. CPN M-Pt contains the full length agnogene with the start codon point mutation from

---

**Figure 3.** JCVCPN transfected IMR-32, SVG and Cos-7 cells produce low levels of infectious virions. Supernatant from transfected Cos-7, SVG and IMR-32 cells was collected 7, 14 and 21 days post-transfection, and used to infect naive Cos-7 cells. At 7 days post-infection, cells were collected and either analyzed for JCV DNA using QPCR (A, C and D) or stained for VP1 and analyzed using flow cytometry (B). Supernatant collected 7 days post-transfection from JCVCPN transfected Cos-7 (A), SVG (C) or IMR-32 (D) cells can establish an infection in naive Cos-7 cells, as measured by the presence of JCV DNA 7 days post-infection. Levels of DNA detected with JCVCPN infection are significantly lower than with JCVMad-1 infection (A, C and D). (B) VP1 positive cells are detected after infection with JCVMad-1, but not JCVCPN containing supernatant. Data is the average of 3–4 independent experiments. Error bars represent standard deviation. P values were calculated using Wilcoxon rank test for QPCR data, comparing JCVCPN to JCVMad-1. P-values for flow cytometry data were calculated using students t test, comparing JCVMad-1 and JCVCPN to mock at each time point. ND is not detected.

doi:10.1371/journal.pone.0080840.g003
Mad-1 Pt. We studied these additional mutants in Cos-7 cells, because these cells displayed the greatest difference in phenotype between JCVMad-1 and JCVCPN.

The agnogene deletion is the major contributor to the phenotype of JCVCPN

To begin characterizing the phenotypes of the viruses shown in Figure 4, linearized DNA was transfected into Cos-7 cells, and JCV DNA levels in cell lysate and supernatant were monitored for 3 weeks using QPCR (Fig. 5). Mad-1 C-Agno has significantly lower levels of DNA from 10–21 days post-transfection compared to Mad-1, while Mad-1 C-RR has DNA levels similar to Mad-1 (Fig. 5A and 5C). This indicates that introducing the agnogene deletion of JCVCPN into Mad-1 results in a decrease in DNA replication. In contrast, the introduction of the agnoprotein and Mad-1 Del is JCVMad-1 with the entire agnogene deleted. CPN M-Pt is JCVCPN with the agnoprotein of Mad-1 Pt.

Deletion in the agnogene prevents expression of VP1 protein

We then sought to determine if the levels of VP1 protein expression would correspond with levels of viral DNA in cells transfected with the chimeras and agno deletion mutants. Western blots were done for VP1 expression in JCV transfected Cos-7 cells. At 14 days post-transfection, only JCVCPN, Mad-1 Pt, Mad-1 C-RR and CPN M-Agno have detectable levels of VP1 (Fig. 6A). At 21 days post-transfection, all of these viruses and CPN M-Pt have detectable VP1 protein expression (Fig. 6B). All of these viruses have full length agnones, but Mad-1 Pt does not have agnoprotein expression. Compared to JCVMad-1, Mad-1 Pt shows some decrease in VP1 expression, while Mad-1 Del has a complete lack of VP1 expression. All of the viruses with the JCVCPN agnogene deletion, JCVCPN, Mad-1 C-Agno and CPN M-RR lack VP1 expression (Fig. 6A and 6B). Taken together, these results indicate that the deletion in the agnogene results in decreased or undetectable levels of VP1 protein expression, and that the levels of DNA replication correspond with the presence of VP1 protein expression.

Deletions in the agnogene reduce the production of infectious virions

Finally, we sought to determine if the ability to produce infectious virions of the chimeric and agno deletion viruses also corresponds with DNA levels and VP1 protein production in these cells. Supernatant collected from Cos-7 cells 21 days post-transfection was used to infect naïve Cos-7 cells, and the DNA levels (Fig. 7A) and percentage of cells expressing VP1 (Fig. 7B) were determined by QPCR and flow cytometry, respectively, at day 7. Compared to JCVMad-1-infected cells, both Mad-1 C-agno and Mad-1 Del-infected cells have significantly lower viral loads, showing a 1.5–2 log decrease (Fig. 7A). Mad-1 Pt and Mad-1 C-RR-infected cells also have significantly lower viral loads than JCVMad-1-infected cells, but tended to have a smaller magnitude of decrease (Fig. 7A). Mad-1 C-agno and Mad-1 Del-infected cells have significantly lower percentages of cells expressing VP1, while Mad-1 Pt and Mad-1 C-RR-infected cells do not (Fig. 7B). CPN M-Agno, CPN M-RR and CPN M-Pt-infected cells all have detectable DNA levels, with significantly higher viral loads compared to JCVCPN (Fig. 7A). Compared with JCVCPN-infected cells, CPN M-Agno-infected cells have a significantly higher percentage cells expressing VP1, and CPN M-Pt-infected cells tended to have more cells expressing VP1. Interestingly, introduction of only the full length gene without protein expression in CPN M-Pt is enough to rescue the DNA levels, and show some increase in percent of cells expressing VP1.

The results of these infection experiments suggest that the deletion in the agnogene is the primary cause of the phenotype observed with JCVCPN. However, CPN M-RR, with the JCVMad-1 RR does show some increase in DNA replication and production of infectious virions compared to JCVCPN, which may indicate that the RR composition is also affecting replication of the virus, but to a lesser degree than the agnoprotein deletion. It is likely that the combination of the agnoprotein deletion together with archetype-like RR is the cause of the overall phenotype of JCVCPN. Overall, these experiments have used the unique naturally occurring JCVCPN agnogene deletion and archetype-like RR to clarify the
role of the agnogene and RR forms in JCV replication in cell culture.

**Discussion**

JCV_{CPN} was isolated from the brain of the first patient to be diagnosed with JCVE, a novel syndrome characterized by infection of cortical pyramidal neurons. JCV_{CPN} was the first naturally occurring isolate with a large deletion in the agnogene, which was originally called agno due to the unknown nature of its function. While studies have begun to shed light on the function of the agnoprotein and agnogene, there is still much to be learned. JCV_{CPN} presents the opportunity to study the function of the agnogene and agnoprotein in a naturally occurring pathogenic variant of JCV, isolated in association with infection of a new cell type.

In this study, we compared the replication of JCV_{CPN} to that of the prototype virus JCV_{Mad-1}. We used Cos-7 cells to model infection in kidney cells and SVG cells as a glial cell model. Both of these cell lines are widely used to study the replication of JCV in kidney and glial cells, and it is commonly thought that the results obtained in them are applicable to what would occur in these cell types during JCV infection in humans. Studying the replication of JCV in cortical pyramidal neurons is challenging, as there are no cortical pyramidal neuron cell lines available. We therefore used IMR-32 neuroblastoma cells to model neuronal infection. Using these cell lines allowed us to study the replication of JCV_{CPN} in

---

**Figure 5.** The agnogene deletion of JCV_{CPN} is the primary cause of its replication defect. Linearized JCV DNA of JCV_{Mad-1}, Mad-1 C-Agno, Mad-1 C-RR, Mad-1 Pt, Mad-1 Del, JCV_{CPN}, CPN M-Agno, CPN M-RR, and CPN M-Pt were transfected into Cos-7 cells and DNA levels were quantified over 3 weeks, as described in Figure 1. (A and C) Levels of DNA with JCV_{Mad-1} and the chimeras and agno deletion viruses on the JCV_{Mad-1} backbone were measured in the cell lysate (A) and supernatant (C). Mad-1 C-Agno and Mad-1 Del show significantly lower levels of DNA late in infection. (B and D) Levels of DNA with JCV_{CPN} and the chimeras and agno deletion viruses on the JCV_{CPN} backbone were measured in the cell lysate (B) and supernatant (D). Introduction of a full length agnogene causes the greatest increase in DNA levels. Data represents the average of 4–10 independent experiments. Error bars represent standard deviation. P-values were calculated with the Wilcoxon Rank Test. ND is not detected.

different cell types in cell culture. We found that JCV CPN was capable of replicating its genome in cell culture. However, it could not establish an infection at the same level observed with JCVMad-1 over time and did not display any replication advantage over JCVMad-1 in any cell line. Levels of JCV CPN DNA replication in Cos-7 and IMR-32 cells were similar to JCVMad-1 at early time points, and then decreased at later time points, indicating that the virus is able to replicate viral DNA after transfection but the infection could not spread and persist in the cell culture at the same level as JCVMad-1. In addition, mRNA and VP1 protein analyses showed some decrease in early transcription and a marked decrease in late transcription, with no detectable VP1 protein production. In all three cell lines, low levels of infection were observed using supernatant from JCV CPN transfected cells, but only using supernatant collected at early times post-transfection, and at levels significantly lower than seen with JCVMad-1. These data indicate that the virus has a block in late gene expression and protein production, which results in low levels of infectious virions being released, and an inability to sustain a persistent high level infection in cell culture. Furthermore, since agnoprotein has been implicated in late stages of viral maturation, there may be an additional block at the level of virion formation and/or release independent of the lack of VP1 production.

JCV CPN and JCVMad-1 are different in two regions, the RR and the agnogene. This provided us with the unique opportunity to determine for the first time how each of these regions contributed to the phenotype of JCV CPN. We therefore studied a series of chimeric viruses of the RR and agnogene. Interestingly, the agnogene deletion in JCV CPN was the predominant cause of its phenotype, not the archetype-like RR. Moreover, the loss of the agnogene DNA had a larger effect on the replication of the virus than the loss of agnoprotein expression. Finally, the archetype-like RR also showed a detrimental effect on the replication of the virus but of a smaller magnitude than that of the agnogene deletion. For these experiments we used Cos-7 cells, because they displayed the largest difference in phenotype between JCV CPN and JCVMad-1 and allowed us to use the greatest number of techniques to study these viruses. We believe that the results obtained in these experiments are representative of what would be observed with the other cell lines used in this study.

Previous studies have implied that agnoprotein had a role in viral DNA replication [23,24]. However, JCV CPN is able to
produce levels of DNA similar to JCV\textsubscript{Mad-1} early after transfection, with DNA levels decreasing with time. These results suggest that an agnogene-deletion mutant can indeed replicate DNA, but levels drop off due to blocks at later steps in infection, thereby preventing spread within the cell culture. Conflicting studies have associated agnoprotein with gene expression, with both the loss of agnoprotein [19,30] or its presence [23,26] suppressing activity of the late promoter of JCV in different experimental systems. Additionally, deletion of the full agnoprotein causes a greater decrease in VP1 expression than prevention of agnoprotein expression without deletion of the agnoprotein DNA [30]. Our data shows that the deletion in the agnogene of JCV\textsubscript{CPN} results in a block in late gene expression, impairing the release of virions capable of infecting new cells and propagating the infection in cell culture. This is consistent with the results of Akan et al [30] and highlights the importance of the agnoprotein DNA in addition to the protein it codes for. Further studies are needed to determine the mechanism of the block in VP1 expression. One possibility is that a host cell factor which binds to one of the sites in the agnoprotein, identified by Akan et al [30], is involved in expression of the late transcript. Further investigations to identify these cellular proteins are warranted to determine the mechanism by which they act during JCV replication. Another potential mechanism is that deletions in the agnogene somehow alter the splicing or translation of VP1 from the late mRNA.

Previous studies of JCV deletion mutants lacking agnoprotein expression have implicated the agnoprotein in genome packaging and/or virion formation and release, with empty capsids being produced by viruses lacking the agnoprotein [27,28]. In our study however, the agnoprotein start codon point mutant was able to replicate its DNA and produce infectious virions at a level similar to JCV\textsubscript{Mad-1} in Cos-7 cells, which suggests that at least in these cells, the agnoprotein is not necessary for formation and release of virions containing viral genomes. Archetype RR is typically found in the urine, but the JCV\textsubscript{CPN} RR isolated from the brain of the JCVE patient is archetype-like. Studies of the replication of different forms of RR have shown that archetype RR form has less active early and late promoters [36]. Surprisingly, our study did not find the archetypal-like RR of JCV\textsubscript{CPN} to be the primary cause of the decreased levels of late transcription and VP1 protein expression. Introducing the archetypal-like RR of JCV\textsubscript{CPN} into JCV\textsubscript{Mad-1} had little effect on the ability of the virus to replicate. JCV\textsubscript{Mad-1} RR introduced into JCV\textsubscript{CPN} partially rescues replication, but had a lesser impact than introduction of a full length agnoprotein and agnoprotein, which may have influenced the replication of JCV\textsubscript{CPN}. Third, it may be that having low levels of replication in the brain was actually advantageous to the virus while faced with a healthy immune system, allowing it to accumulate until the immune system became compromised and JCV\textsubscript{CPN} developed.

After observing the infection of granule cell neurons in JCV GCN and cortical pyramidal neurons in JCVE, we conducted studies to determine if infection of neurons by JCV was limited to these syndromes, or if it is more widespread. Based on staining of PML brain samples, it is predicted that up to 31% of patients have granule cell neurons infected by JCV [57]. Additionally, infection of cortical neurons by JCV in classic PML cases has been observed with infection present in the gray white junction and gray matter [30]. These studies demonstrate that infection of neurons occurs in a large number of PML patients, and is not limited to patients with JCV GCN or JCVE. Further studies of the molecular composition of JCV in neurons of patients with classic PML are needed to determine whether these cells are also infected by JCV-deletion mutants.

The study of unique pathogenic isolates of JCV, such as JCV\textsubscript{CPN} or JCV\textsubscript{GCN} allows us to decipher the basic biology of JCV replication using mutations that have arisen naturally during infection in humans. Our studies of JCV\textsubscript{CPN} have provided valuable insights into both the function of the agnoprotein and agnoprotein, as well as a naturally occurring variation of the regulatory region, on JCV replication. Our results have helped clarify the role of the agnoprotein in DNA replication, transcription and protein expression, demonstrating that a deletion in the agnoprotein has a dramatic effect on the expression of VP1 protein and the production of infectious virions. Further studies of naturally occurring variants of JCV will continue to add clarity to our understanding of the biology of JCV replication and pathogenesis.

Acknowledgments

We would like to thank Dr. Long Ngo for advice in statistical analysis. We would like to thank Dr. Mahmut Safak for the generous gift of Mad-1 Pt and Mad-1 Del plasmids.
