Abstract

Cells respond to accumulation of misfolded proteins in the endoplasmic reticulum (ER) by activating the unfolded protein response (UPR) signaling pathway. The UPR restores ER homeostasis by degrading misfolded proteins, inhibiting translation, and increasing expression of chaperones that enhance ER protein folding capacity. Although ER stress and protein aggregation have been implicated in aging, the role of UPR signaling in regulating lifespan remains unknown. Here we show that deletion of several UPR target genes significantly increases replicative lifespan in yeast. This extended lifespan depends on a functional ER stress sensor protein, Ire1p, and is associated with constitutive activation of upstream UPR signaling. We applied ribosome profiling coupled with next generation sequencing to quantitatively examine translational changes associated with increased UPR activity and identified a set of stress response factors up-regulated in the long-lived mutants. Besides known UPR targets, we uncovered up-regulation of components of the cell wall and genes involved in cell wall biogenesis that confer resistance to multiple stresses. These findings demonstrate that the UPR is an important determinant of lifespan that governs ER stress and identify a signaling network that couples stress resistance to longevity.

Introduction

Membrane and secretory proteins fold into their native conformations in the endoplasmic reticulum (ER) assisted by chaperones, thiol-disulfide oxidoreductases and other systems supporting protein post-translational control. Impairments in this complex process cause unfolded proteins to accumulate, provoking ER stress. Adaptation to ER stress is dependent on the unfolded protein response (UPR) signaling pathway that senses accumulation of unfolded proteins in the ER and restores ER homeostasis by (i) temporarily inhibiting protein synthesis, (ii) degrading misfolded or unassembled proteins, and (iii) increasing expression of chaperones and oxidative folding components that facilitate protein folding [1]. However, depending on the severity and timing of ER stress, it may also lead to cell death when adaptive mechanisms fail.

In mammalian cells, the UPR consists of multiple signaling cascades that are activated by three known ER stress sensor proteins, inositol-requiring protein 1 (IRE1), activating transcription factor 6 (ATF6), and double-stranded RNA-activated protein kinase-like ER kinase (PERK) [2–4]. Among these signal transducers, only IRE1 is conserved in budding yeast and is solely responsible for the UPR activation in Saccharomyces cerevisiae [5,6]. IRE1p is an ER-localized transmembrane protein, containing kinase and endoribonuclease (endo-RNase) enzyme activities. Upon activation by ER stress, IRE1p undergoes oligomerization and autophosphorylation [7,8]. In turn, IRE1p autophosphorylation activates its endo-RNAse domain, which facilitates the excision of an intron and unconventional splicing of HAC1 mRNA in yeast [9]. Spliced HAC1 mRNA codes for a functional transcription factor capable of inducing transcription of genes that enhance ER protein folding capacity and alleviating ER stress [10]. However, IRE1p may have other, Hac1p transcription factor-independent functions. In addition to up-regulation of the UPR target genes, metazoan IRE1 has been implicated in degradation of ER-localized mRNAs through its endonuclease activity [11–13]. Such ER-localized mRNA decay occurs during prolonged irredeemable ER stress due to higher-order oligomerization and hyperactivation of IRE1 [12]. Thus, IRE1 may play a dual role in cell fate, by both allowing cellular adaptation to increased protein folding load and promoting apoptosis depending on the severity of ER stress.

ER stress and protein misfolding are increasingly recognized as contributing factors to the pathophysiology of age-related diseases and aging [14]. Moreover, studies involving model organisms demonstrate that improved ER stress resistance is often associated...
Author Summary

Impaired protein function caused by protein misfolding and aggregation has been implicated in the development of age-related diseases and regulation of lifespan. Accumulation of misfolded proteins in the endoplasmic reticulum, a cellular organelle responsible for protein folding and trafficking, activates protective signaling pathways that restore protein homeostasis. One such conserved signalling pathway is mediated by the protein misfolding sensor Ire1p and the transcription factor Hac1p, which up-regulate endoplasmic reticulum chaperones, oxidative folding components and factors that facilitate degradation of misfolded proteins to alleviate increased protein folding demand. Here, we describe the role of the Ire1p pathway and its downstream targets in regulation of lifespan in yeast. While the loss of Ire1p itself had little effect on lifespan, we found that selective inactivation of the individual protein folding and maturation factors led to increased longevity. We also provide evidence that this increased longevity depends on functional Ire1p and induction of multiple cytoprotective pathways that confer resistance to stress.

with increased lifespan and healthy aging [15–18]. However, the role of UPR signaling and individual components of ER stress response in regulating lifespan is not known. In this study, we investigated the contribution of the UPR and its downstream targets, including chaperones, oxidative folding components and components of the ER-associated degradation (ERAD), to aging and examined the mechanism of such regulation in a simple model organism, S. cerevisiae. We demonstrate that modulation of the UPR by genetic means can extend yeast lifespan, and that induction of UPR signaling is required for activation of multiple stress response pathways that drive lifespan extension.

Results

Components of the ER stress response pathway differentially modulate replicative lifespan in S. cerevisiae

Analysis of replicative lifespan, which is defined as the number of times each yeast cell divides before it undergoes senescence, is based on the ability of budding yeast to divide asymmetrically producing distinct mother and daughter cells and is often used as a model of aging in mitotically active cells [19]. To examine the relationship between ER stress response genes and aging, we measured replicative lifespan of mutant S. cerevisiae strains lacking individual components of the UPR and its transcriptional targets. In addition to Ire1p and Hac1p, several downstream effector genes were analyzed including chaperones (Kar2p), oxidative folding (Ero1p, Euc1p, Mop1p, Pdi1p) and ER-associated degradation (ERAD) components (Der1p, Sel1p, Hrd1p), as well as genes involved in N-linked glycosylation (Alg12p, Alg12p, Die2p, Ost3p, Ost6p) and protein trafficking (Bst1p) [10,20]. We found that deletion of either Ire1p or Hac1p, two genes that are involved in sensing accumulation of unfolded proteins in the ER, did not affect yeast lifespan [Figure 1A, B]. Unexpectedly, many of the downstream UPR target mutants, 9 out of 14, were found to be significantly long-lived compared to experimentally matched control wild-type cells [Figure 1C, D and Table 1]. Hereafter, we refer to these mutants as “long-lived ER secretory pathway mutants” or “long-lived UPR target gene deletion mutants”. These data demonstrate that components of the ER stress response pathway may differentially modulate replicative lifespan and are important determinants of longevity in S. cerevisiae.

Lifespan extension in mutants lacking downstream components of the UPR is associated with elevated basal UPR activity

The observation that UPR target gene deletions extend lifespan was counterintuitive, as genes activated by UPR are perceived as protective factors required to restore ER homeostasis, and their deletion might be expected to decrease lifespan. The unexpected and consistent lifespan extension by UPR target gene inactivation may be attributable to hormesis, a phenomenon by which limited stress elicits response mechanisms that protect against similar but higher level stresses associated with aging. To study the molecular mechanisms by which reduced levels of UPR target genes lead to lifespan extension, we focused on two well-characterized genes Alg12p and Bst1p. Alg12p is an enzyme that catalyzes one of the steps in the synthesis of N-linked glycans [21], whereas Bst1p performs removal of the inositol acyl group required for the quality control of ER to Golgi transport of glycosylphosphatidylinositol-anchored proteins [22].

We hypothesized that deletion of genes downstream of the UPR may lead to constitutive activation of Ire1p and induction of UPR dependent cytoprotective pathways. To test this hypothesis, we analyzed whether the level of UPR activity may correlate with the lifespan in alg12A and bst1A. Analysis of Hac1p mRNA splicing was used to monitor the level of UPR activity in wild-type cells and corresponding mutants that were grown in the absence or presence of pharmacological ER stressor tunicamycin for 12 h (Figure 2A). In wild-type cells the basal level of UPR activity was very low, as evidenced by the fact that most of the detected Hac1p mRNA (99%) represented the unspliced form and only 1% corresponded to the spliced form. Treatment of wild-type cells with tunicamycin increased the fraction of spliced HAC1 mRNA to 31%. In contrast, deficiency of the UPR transcriptional targets, Alg12p and Bst1p, was associated with increased basal HAC1 mRNA splicing (7% and 21% of HAC1 mRNA was spliced for alg12A and bst1A, respectively). These data were also in good agreement with ribosome profiling data (see below), which showed different level of HAC1 translational activation in alg12A and bst1A mutants. In addition, we confirmed the level of UPR activation by analyzing the expression of Kar2p, an ER chaperone that is induced by UPR, and found increased Kar2p levels in the long-lived mutants, compared to the mutants that do not affect lifespan (Figure S1A). Taken together, our data indicate that lifespan extension conferred by deficiency of UPR components downstream of Ire1p, including Alg12p and Bst1p, is associated with increased basal UPR activity.

Deletion of Ire1p and Hac1p prevents lifespan extension in UPR target gene deletion mutants

To address whether lifespan extension in strains lacking UPR target genes is dependent on functional Ire1p (an ER stress sensor) and Hac1p (an ER stress-responsive transcription factor), we generated double mutant strains combining the long-lived alg12A and bst1A deletions with either ire1A or hac1A. If high basal UPR activity is required for increased longevity in the ER secretory pathway mutants, one would predict that deletion of either Ire1p or Hac1p should attenuate lifespan extension in these mutants. Consistent with this hypothesis, we observed decreased lifespan in alg12Aire1A and alg12Ahac1A double mutants compared to alg12A (p<0.0001) (Figure 2B and Table S2). Moreover, both double mutants were significantly shorter-lived than the wild-type strain.
Since a single deletion of either IRE1 or HAC1 did not affect yeast replicative lifespan under unstressed conditions (Figure 1), these data suggest an adverse genetic interaction of ALG12 deletion with that of IRE1 or HAC1. We also found that lifespan extension conferred by bst1Δ deletion was significantly reduced in bst1Δire1Δ and bst1Δhac1Δ cells (p < 0.0001), and that the corresponding double mutants had lifespan similar to that of wild-type cells (Figure 2C). In contrast, deletion of IRE1 and HAC1 did not significantly change the lifespan of the long-lived strain overexpressing Sir2 (SIR2OE) as well as fob1Δ and tor1Δ deletion mutants [Figure S1B, C, and Table S2]. Therefore, these genetic epistasis experiments demonstrate that lifespan extension in the long-lived UPR target gene mutants is dependent on functional Ire1p and the ability to activate ER stress response. Moreover, deletion of UPR target genes extends lifespan by mechanisms distinct from those responsible for the lifespan extension observed under conditions of increased Sir2 activity or reduced mTOR signaling, a genetic mimic of dietary restriction [23].

Elevated basal UPR activity in mutants lacking downstream components of the UPR does not confer resistance to pharmacologically induced ER stress

It is possible that constitutive activation of UPR signaling in the long-lived ER secretory pathway mutants may lead to increased resistance to pharmacologically induced ER stress. To test whether elevated basal UPR signaling may pre-condition cells against stress and increase cellular stress resistance, alg12Δ and bst1Δ strains were analyzed for growth in the presence of tunicamycin. However, both alg12Δ and bst1Δ had decreased resistance to this pharmacological ER stressor (Figure 2D) suggesting that ALG12 and BST1 deficiency puts cells at a disadvantage in the presence of ER stress. Moreover, the double mutant strains combining the long-lived deletions with either ire1Δ or hac1Δ completely abolished the growth of cells in the presence of tunicamycin, similar to ire1Δ and hac1Δ single mutants (Figure S1D). Together, these data indicate that Ire1p and Hac1p are required for lifespan extension in alg12Δ and bst1Δ, but the long lifespan in these mutants cannot be explained solely by increased ER stress resistance, at least as measured by tunicamycin resistance.

Ribosome profiling detects translational control by UPR signaling

To characterize the mechanisms of lifespan extension in the long-lived ER secretory pathway mutants, we examined genome-wide translational changes in response to Ire1p hyperactivation in alg12Δ and bst1Δ mutants using ribosome profiling. Ribosome profiling is based on deep sequencing of ribosome-protected mRNA fragments and provides quantitative data on the translation
regulation by monitoring translation efficiency (TE). Ribosome profiling data can also be used to measure translational synthesis. When coupled with mRNA-sequencing (RNA-seq), mRNA abundance is not always a good predictor of protein level of thousands of genes [24]. A key advantage of this method is the much greater sensitivity than that obtained with microarrays as mRNA abundance, there were significantly fewer down-regulated genes (out of 241 genes that changed expression, 220 genes were induced and 21 were repressed) than genes repressed at the translational level (63 genes). The fact that there were more genes whose expression was reduced at the translational level indicates that UPR largely induces genes at the level of transcription, whereas UPR repressed genes are mostly regulated at the level of protein translation.

Deletion of ALG12 and BST1 leads to transcriptional and translational induction of multiple stress response genes

We next used ribosome profiling to detect translational changes in the long-lived alg12Δ and bst1Δ mutants and found enhanced expression of UPR target genes, which correlated with increased HAC1 mRNA splicing and production of Hac1p. We observed ∼3 and 12-fold increase in Hac1p production in alg12Δ and bst1Δ, respectively (Figure 3A, B). In the case of the alg12Δ mutant, more than 1.5-fold increase in protein production was observed for 34 genes, whereas 16 genes were down-regulated (Table S5). Compared to alg12Δ, BST1 deficiency resulted in a much stronger translational regulation. In the bst1Δ mutant, translational changes were observed for 373 genes (52 genes were repressed and 321 genes were induced) (Table S6). As expected, there was a significant overlap with the genes that were up-regulated by tunicamycin treatment (Figure S3). Known UPR targets,
including chaperones (KAR2, LHS1, JEM1, SCJ1), oxidoreductases (ERO1, MPD1, EUG1, PDI1) and genes involved in glycosylation (PMT3) and ERAD (ADD37 and HRD1) were among the top hits (Figure 3C and Table S5 and S6). In addition, genes involved in many other ER secretory pathway processes were induced including glycophsphatidylinositol anchor synthesis (ERI1, MCD4, GWT1), lipid biogenesis (INO4, SCS3), and vesicular trafficking (MVB12, ERV29). Although many more of the UPR target genes were induced in the bst1Δ mutant compared to alg12Δ, the lower extent of induction in alg12Δ mutant cells can be explained by the lower level of ER stress and reduced HAC1 splicing.

In addition to genes associated with secretory pathway function, both of the long-lived mutants showed enrichment in genes with functions in mRNA splicing and degradation (CWC21, CWC25, DCS1), iron homeostasis (ARN2, FIT1, FIT3, FTH1, HMX1, TIS11/CTH2), mitochondrial protein quality control and sorting (MGR1, MSP1), as well as multiple stress response pathways (DDR2, HOP1, HLR1, LOT6, TSL1, DOG2, ICT1, SED1, CRG1) [25–33].

Similar to the tunicamycin treated cells, the number of genes whose translation was increased in alg12Δ and bst1Δ mutants exceeded the number of down-regulated genes (Figure 4A). To analyze if any of the observed differences can be explained by translational control, we calculated TE for each mRNA, which represents the relative number of footprints normalized to mRNA abundance. A significantly larger fraction of genes whose TE changed more than 1.5-fold had a decreased TE rather than increased (Figure 4B). These data are consistent with the overall down-regulation of protein synthesis during ER stress. However, several genes showed translational activation in alg12Δ and bst1Δ mutants as well as in tunicamycin treated cells. Among these genes, HAC1 and ERI1 were strongly regulated at the level of translation, but were not up-regulated transcriptionally.

Induction of the cell wall integrity signaling in alg12Δ and bst1Δ

Gene ontology analyses (DAVID) [34] of footprint data revealed that a number of genes up-regulated in the long-lived mutants are involved in cellular response to stress (Figure 5A). A second cluster of genes that were expressed at higher level in alg12Δ and bst1Δ mutants comprises of cell wall components and genes involved in cell wall biogenesis. The induction of cell wall components in the long-lived strains was particularly appealing, as it suggested a link between the UPR, stress resistance and increased longevity. Many of the genes that code for proteins of...
the cell wall have been implicated in resistance to multiple stressors, and are known to be regulated by the cell wall integrity (CWI) pathway. The CWI pathway responds to cell wall stress through several cell-surface sensors (Wsc1p, Wsc2p, Wsc3p, Mid2p and Mid1p) [33] that activate a small G protein, Rho1p. Activation of Rho1p triggers a MAPK signaling cascade leading to transcriptional up-regulation of CWI target genes through several cell-surface sensors (Wsc1p, Wsc2p, Wsc3p, Mid2p and Mid1p) [33] that activate a small G protein, Rho1p. Among other targets, CWI regulates synthesis of β-glucan and biogenesis of cell wall components. Strikingly, among genes that were up-regulated in the long-lived mutants were MID2 stress sensor, SLT2/MPK1 MAPK kinase, and RIM1 transcription factor. We also observed increased expression of Rim1p transcription factor targets in bst1Δ mutant including genes involved in cell wall biogenesis (β-glucan synthases GSC2/FKS2 and FKS1, chitin synthase CHS3) and multiple cell wall components (BGL2, CIS3, CWP1, CWP2, CRH1, SED1, YLR194C) [36]. To test if the CWI pathway is important for the lifespan extension in alg12Δ and bst1Δ mutants, we tested sensitivity of these strains to calcofluor white and congo red, which are known pharmacological inducers of the cell wall stress. Consistent with activation of the CWI signaling, we observed increased resistance of both alg12Δ and bst1Δ to cell wall stress compared to wild-type strain (Figure 5B). Moreover, induction of the CWI signaling in the long-lived ER secretory pathway mutants was associated with increased resistance to other stresses including heat shock and oxidative stress (Figure S4), providing additional evidence that deletion of ALG12 and BST1 confers multiple stress resistance.

We also found strong induction of genes involved in trehalose (TSL1, TPS1, TPS2, NTH1) and chitin (CHS1, CHS7, CRH1, GFA1) synthesis. Increased trehalose and chitin accumulation is a common cell defense strategy that protects cells against a variety of stressful conditions, including heat, acid and cold shock. Another potential target up-regulated in bst1Δ that may mediate lifespan extension is glycerol-3-phosphate dehydrogenase GPD1. Gpd1 catalyzes the production and accumulation of glycerol in response to hyperosmotic stress and acts as an osmoregulator by preventing loss of water and turgor of the cells. Induction of the osmotic stress response and increased glycerol production have been shown to extend yeast replicative lifespan, whereas deletion of GPD1 shortens lifespan even in the absence of osmotic stress [37]. In addition, up-regulation of glycerol biosynthesis genes has been linked to extension of chronological lifespan in Tor1- and Sch9-deficient mutants [38].

Decreased protein translation has been shown to extend lifespan in a wide range of species, including S. cerevisiae, Caenorhabditis elegans, and Drosophila melanogaster [39,40]. For example, increased longevity caused by Tor1p inhibition or knockout of Tor1-regulated SCH9 kinase is achieved, at least in part, by reduction in mRNA translation. In addition, decreased protein synthesis caused by deficiency of ribosomal protein subunits often leads to ER stress resistance and increased lifespan [15]. However, overall protein translation was not affected in alg12Δ and bst1Δ mutants (Figure 4C). We also did not observe changes in the expression of antioxidant genes or components of proteasome suggesting that elevated proteasomal capacity and oxidative stress response do not contribute to longevity in alg12Δ and bst1Δ mutants. In addition, we did not observe induction of other stress response transcription factors, including IAP1, SKN7, MSN2 and MSN4.

Taken together, our data demonstrate that lifespan extension conferred by the ER secretory pathway mutants is dependent on functional UPR, and that increased basal UPR signaling may promote longevity in S. cerevisiae through increased expression of multiple stress response genes and activation of the CWI-MAPK pathway.
Discussion

It is commonly accepted that aging is associated with a decline in homeostatic mechanisms that protect organisms from accumulation of senescence factors including aggregated proteins, oxidatively damaged cellular components and toxic metabolites [41–43]. Recent studies suggest that cellular capacity to adapt to ER stress may also decline with age [44]. Cells respond to accumulation of misfolded proteins in the ER by activating the UPR signaling pathway that restores ER homeostasis by degrading misfolded proteins, inhibiting translation, and increasing expression of chaperones and oxidative folding components [1]. Although the mechanisms by which cells sense ER stress and activate stress response genes are well studied [45,46], the role of UPR signaling in aging remains unknown. We have begun to characterize the role of UPR in regulating lifespan in S. cerevisiae.

To our surprise, we determined that inactivation of IRE1 and HAC1 that are involved in sensing ER stress in yeast does not affect lifespan under physiological conditions. We have begun to characterize the role of UPR in regulating lifespan in S. cerevisiae. To our surprise, we determined that inactivation of IRE1 and HAC1 that are involved in sensing ER stress in yeast does not affect lifespan under physiological conditions. However, from the analysis of 14 different UPR target gene deletions, at least 9 were found to be significantly long-lived. In addition, we found that extended lifespan in the UPR target gene deletion mutants is associated with increased basal UPR activity. These observations prompted us to hypothesize that deletion of genes downstream of UPR may lead to constitutive activation of Ire1p and increased ER stress resistance. Our data provide evidence that functional Ire1p and transcriptional factor Hac1p are required for lifespan extension by deletion of UPR target genes.

Despite elevated basal UPR activity in alg12Δ and bst1Δ, these strains were not resistant to pharmacologically induced ER stress conferred by tunicamycin. This provides an interesting contrast to another recent study whereby it was found that many ribosomal deletion mutants were resistant to tunicamycin through a HAC1-independent mechanism [15]. In that case, however, tunicamycin resistance did not correlate with lifespan extension. From comparing these studies, it is clear that the long lifespan of alg12Δ and bst1Δ does not come from mitigating ER stress, at least phenocopied by tunicamycin exposure, and that induction of the UPR and associated stress response pathways is more likely to modulate aging through separate mechanisms.

We used ribosome profiling to identify specific pathways and protective mechanisms that contribute to lifespan extension in the long-lived ER secretory pathway mutants at the genome-wide level. Using this method, we identified translational changes in the ER stress and Unfolded Protein Response in Aging

![Figure 4. Translational control in the long-lived ER secretory pathway mutants.](doi:10.1371/journal.pgen.1004019.g004)
long-lived mutants \( \text{alg12}\Delta \) and \( \text{bst1}\Delta \) compared to wild-type cells in unstressed conditions. We discovered that \( \text{ALG12} \) and \( \text{BST1} \) deficiency selectively regulates a subset of genes that belong to only a few functional groups. In addition to activation of UPR target genes, we observed induction of other cytoprotective pathways including general stress response proteins and proteins involved in multidrug resistance. The second most prominent change that occurs in the long-lived ER secretory pathway mutants is cell wall remodeling. Although multiple signaling pathways contribute to remodeling of the cell wall, the regulation of this process is controlled primarily by the mitogen-activated protein kinase (MAPK) \( \text{Slt2p/Mpk1p} \) via the CWI pathway. Our analysis revealed extensive up-regulation of components of CWI signaling including \( \text{Slt2p/Mpk1p} \), \( \text{Mid2p} \) cell wall stress sensor and \( \text{Rlm1p} \) transcription factor. Activation of the CWI pathway leads to an increased synthesis of \( \beta \)-glucan and enhanced expression of \( \text{Rlm1p} \) targets that confer resistance to multiple stresses. Genes up-regulated by CWI signaling have been implicated in the tolerance of \( \text{S. cerevisiae} \) to a variety of stressors including oxidative stress, heat shock, hypo-osmotic stress, actin depolymerization, high and low pH stress and DNA damage [35]. In addition to the CWI signaling cascade, two \( \text{Slt2p-independent} \) pathways, which require \( \text{Mpt5p} \) and \( \text{Ssd1p} \), have been shown to regulate integrity of the cell wall and promote longevity in \( \text{S. cerevisiae} \) [47]. Interestingly, \( \text{MPT5} \) and \( \text{SSD1} \) encode RNA-binding proteins that have been proposed to post-transcriptionally up-regulate expression of genes involved in cell wall biogenesis by increasing TE and stability of the target mRNAs. We found significant up-regulation of \( \text{Ssd1} \) in at least one of the long-lived ER secretory pathway mutants analyzed in our study (\( \text{bst1}\Delta \)). Therefore, we conclude that the lifespan extension in the ER secretory pathway mutants does not result solely from improved protein homeostasis caused by UPR activation, but might also require activation of multiple stress response pathways.

Figure 5. Deletion of \( \text{ALG12} \) and \( \text{BST1} \) leads to activation of the CWI signaling pathway. (A) Gene Ontology analysis of differentially regulated genes in \( \text{bst1}\Delta \). X-axis shows the number of genes in each functional category. (B) Sensitivity of \( \text{alg12}\Delta \) and \( \text{bst1}\Delta \) mutant strains to cell wall stress caused by calcofluor white (CFW) and congo red (CR). For each strain, 10 \(^{6} \) serial dilutions of logarithmically growing cells were spotted on agar plates containing indicated concentrations of the drugs. Pictures were taken after 48 h incubation at 30°C. doi:10.1371/journal.pgen.1004019.g005
In support of this mechanism, we identified four components of the chitin biosynthesis (CHSI, CHST, CRH1, GFA1) and four genes involved in the synthesis of trehalose (TSL1, TPS1, TPS2, NTH1). Chitin, β(1,4)-linked N-acetylglucosamin polymer, serves as a structural component of the cell wall and represents about 1–2% of its inner layer polymers. However, during stress, cell wall chitin levels can increase up to 20% [49] making cell tolerant to adverse environmental conditions. In turn, trehalose (α,α-glucose disaccharide) has been implicated in heat shock resistance. In response to thermal stress, accumulation of cytoplasmic trehalose leads to increased osmolarity that protects proteins from denaturation and aggregation [49].

Another possible means by which deletion of UPR transcriptional targets could increase replicative lifespan is by enhancing mitochondrial protein turnover. Two other genes that were upregulated in bst1A mutant include MGR1 and MSL1. MGR1 encodes a component of the mitochondrial inner-membrane iAAA protease complex that functions to degrade misfolded mitochondrial proteins and participates in protein quality control in mitochondria [50], whereas Mslp1 is involved in mitochondrial protein sorting [51]. Thus, activation of mitochondrial protein turnover upon ER stress caused by deletion of UPR components may increase longevity in part by influencing mitochondrial function.

Activation of the UPR signaling in the UPR target gene deletion mutants is consistent with previous reports showing hyperactivation of UPR in cells lacking genes involved in the ER secretory pathway function. In yeast, deletion of several components of the ERAD system (DER1, SEL1, HRD1, UBC1 and UBC7) [10,52] as well as inactivation of the ER chaperone Kar2p [53] have been shown to dramatically induce UPR. More recently, hundreds of single-gene knockouts have been shown to perturb UPR signaling in yeast representing a number of diverse functional groups [20]. It would be important to determine in future studies if these deletion mutants show significant overlap with those affecting longevity and the requirement for increased UPR function in these settings.

Although stress resistance correlates with increased longevity in a variety of model organisms, including yeast [15,18], worms [54,55] and fruit flies, the link of UPR signaling pathway, ER stress resistance and longevity remains poorly understood. Interestingly, inactivation of Ire1 and Xbp1 results in shortened lifespan in C. elegans, and UPR signaling contributes to the increased longevity of daf-2 mutants and in response to dietary restriction [56,57]. Moreover, overexpression of a constitutively active form of XBP-1 in neurons, but not in other tissues, results in increased ER stress resistance and extends lifespan in worms [58]. However, ubiquitous up-regulation of UPR signaling in the whole animal does not promote longevity despite elevated resistance to ER stressors.

Our data suggest that while increased UPR signaling is an important determinant of lifespan extension, it is not sufficient to confer enhanced ER stress resistance in yeast cells. Instead, we found that the increased longevity in the UPR target gene mutants is associated with induction of multiple stress response programs. Taken together, these data highlight the complexity of organism’s response to various stresses and demonstrate interdependencies among multiple longevity pathways.

Materials and Methods

Yeast strains and media

All yeast strains were derived from the parent strains of the haploid yeast ORF knockout collection [59], BY4741 (MATa his3Δ1 leu2Δ0 met15Δ0 ura3Δ0 and BY4742 (MATa his3Δ1 leu2Δ0 by2Δ0 ura3Δ0), or the DanP library [60] (Table S7). Double mutant strains combining the long-lived deletions with either ire1A or hac1A were prepared by standard PCR-based gene disruption method. The deletion of each ORF was confirmed by PCR with locus-specific primers (Figure S5). All strains were grown at 30°C in complete YPD medium (1.0% yeast extract, 2.0% peptone, and 2.0% glucose).

Replicative lifespan assay

Lifespan assays were carried out as described previously [61]. Analysis of replicative lifespan is based on the ability of budding yeast to divide asymmetrically producing distinct mother and daughter cells. For the replicative lifespan assay, cells were grown on freshly prepared YPD plates for 2 days at 30°C. For each strain, founder cells were plated on agar plates by selecting the newborn daughter cells using micromanipulator. Cells were monitored for cell divisions every 90 min, and subsequent budded daughter cells were separated and removed as they formed. The process continued until cells stopped dividing. Replicative lifespan was calculated as the number of times each mother cell divided before it underwent senescence. Statistical analysis of the lifespan data was performed using a Wilcoxon Rank-Sum test.

HAC1 mRNA splicing

Total RNA was extracted by RiboPure-Yeast Kit (Ambion) according to the manufacturer’s instructions. RNA was treated with DNaseI, and first strand cDNA was synthesized using the SuperScript III reverse transcriptase (Invitrogen) with random hexamer primers. For the analysis of HAC1 mRNA slicing, RT-PCR was performed with the following primers that flank the HAC1 intron: 5’-CGGTAGACACACAAATTTG-3’ and 5’-CATGAAATGGAAGATAACC-3’. PCR fragments were resolved in 2% agarose gels, stained with EtBr, and quantified by densitometry.

Spot assays

Resistance of strains to tunicamycin, calcofluor white, and congo red was determined using spot assays. Cells were initially grown in liquid culture without the drugs until OD600 = 0.6, and 10x serial dilutions for each strain were spotted on agar plates containing indicated concentrations of the drugs. The plates were incubated at 30°C, and images were taken 48 h after plating.

Ribosome profiling and mRNA sequencing

Yeast cultures were grown to OD600 = 0.5 in 500 ml of complete YPD medium, and cells were collected by filtering through 0.45 µm filter (Millipore) with glass holder. Pellets were scraped with spatula, flash frozen in liquid nitrogen and stored at −80°C. To pharmacologically induce ER stress, tunicamycin was added into the medium at a final concentration 1 µg/ml, and cells were incubated at 30°C for an additional 30 min. Yeast extracts were prepared by cryogrinding the cell paste with BioSpec cryomill. Aliquots of cell lysates were used for footprint extraction and isolation of total RNA. Preparation of lysates, ribosome fractionation, and construction of footprint and RNA-seq libraries were performed as in [62] with modifications. A detailed description of protocols can be found in the Text S1. Sequencing of footprint and RNA-seq libraries was performed on the Illumina HiSeq2000 platform. Primers used in library preparation are listed in Table S8.
Bioinformatics analyses
Ribosomal footprints and mRNA reads were aligned to the S. cerevisiae genome from the Saccharomyces Genome Database (SGD), http://www.yeastgenome.org/, release number R64-1-1. Sequence alignment was performed by Bowtie software v.0.12.7 [63] allowing two mismatches per read. Custom Perl scripts were used to count reads over features of interests (genes, UTRs etc.), deal with introns, overlaps and highly homologous sequences.

Analyses of differential gene translation and translation efficiency
To analyze differential gene expression and translation we disregarded 100 nt from the 5'-end of each gene therefore avoiding bias caused by the region with elevated footprint density in the vicinity of the ATG start codon. Rpkms (reads per kilobase per million mapped reads) values, which represent the number of reads normalized to gene length and total number of reads, were used as a measure of gene expression. An average Rpkms value for two biological replicates was calculated for each gene, and the genes with fewer than 10 Rpkms were excluded from further analysis (Figure S6). The gene was considered regulated if its Rpkms value changed more than 1.5-fold (0.6 in log2 scale). To calculate TE, footprint Rpkms values were divided by mRNA Rpkms. Clustering was performed using Cluster 3.0 software [64] and the data were visualized using Java Treeview [65].

Polysome analyses
Polysome profile analysis of an aliquot of cell extracts was performed using sucrose gradients (10-50% wt/wt) in polysome gradient buffer [20 mM TrisHCl (pH 8.0), 140 mM KCl, 5 mM MgCl2, 0.2 g/l cycloheximide, 0.5 mM DTT]. 1 ml of cell lysate containing 50 units (OD600) were loaded on top of the gradients, and sedimented at 35,000 rpm at 4°C in a SW41 Ti rotor (Beckman) for 3 h. Gradients were collected from the top using the Brandel gradient fractionation system and profiles were monitored at 254 nm.

Supporting Information
Figure S1 The ER secretory pathway mutants extend lifespan by mechanisms distinct from those in SIR2OE and fob1A. (A) Analysis of Kar2p expression in the ER secretory pathway mutants. (B, C) SIR2 overexpression (SIR2OE) and deletion of FOB1 (fob1A) extend yeast replicative lifespan by mechanisms independent of Ire1p and Hac1p. Mean lifespans are shown in parentheses. (D) Sensitivity of the ire1A and hac1A mutants to ER stress. For each strain 10× serial dilutions of logarithmically growing cells were spotted on agar plates without the drug (untreated) or plates containing 0.2 μg/ml tunicamycin (TM). Pictures were taken after 48 h incubation at 30°C. (TIF)

Figure S2 Analysis of coordinate changes in translation and transcription in response to ER stress. (A) Comparison of genes up-regulated by tunicamycin from this study with known UPR targets. Treatment of wild-type cells with tunicamycin (TM) induced protein translation more than 1.5-fold for 107 genes. Known transencriptional UPR targets include 381 genes as defined by Travers et al. [10]. These two groups have 43 genes in common. (B) Comparison of genes whose mRNA abundance and protein translation were induced by tunicamycin treatment. (TIF)

Figure S3 Regulation of protein translation in the long-lived ER secretory pathway mutants. (A) Genes whose protein translation was induced more than 1.5-fold in alg12A and bst1A mutants and tunicamycin (TM) treated wild-type cells. (B) Genes whose protein translation was repressed more than 1.5-fold in alg12A and bst1A mutants and tunicamycin (TM) treated wild-type cells. (TIF)

Figure S4 Deletion of ALG12 and BST1 leads to heat and oxidative stress resistance in yeast. (A) Sensitivity of alg12A and bst1A mutant strains to heat stress. Ten-fold serial dilutions of log-phase cultures were plated onto YPD and incubated at either 30°C or 40°C, and images were taken 48 h after plating. (B) Viability of alg12A and bst1A mutant strains following treatment with 1 mM hydrogen peroxide (H2O2) for 30 min. Results are represented as means ± SEM from three independent experiments. (TIF)

Figure S5 Verification of mutant strains prepared in this study. (A, B) Double mutant strains combining alg12A and bst1A deletions with either ire1A or hac1A were verified by PCR analysis with locus-specific primers. (TIF)

Figure S6 Reproducibility of footprint and mRNA-abundance measurements. (A, B) Comparison of footprint and mRNA-abundance measurements between two replicates. Footprint and mRNA rpkm values are shown for wild-type cells treated with tunicamycin. Pearson correlation coefficients are indicated. (TIF)
