**Abstract**

**Background:** Protective immunity against cholera is serogroup specific. Serogroup specificity in *Vibrio cholerae* is determined by the O-specific polysaccharide (OSP) of lipopolysaccharide (LPS). Generally, polysaccharides are poorly immunogenic, especially in young children.

**Methodology:** Here we report the evaluation in mice of a conjugate vaccine for cholera (OSP:TThc) made from *V. cholerae* O1 Ogawa O-Specific Polysaccharide–core (OSP) and recombinant tetanus toxoid heavy chain fragment (TThc). We immunized mice intramuscularly on days 0, 21, and 42 with OSP:TThc or OSP only, with or without dmLT, a non-toxigenic immunoadjuvant derived from heat labile toxin of *Escherichia coli*.

**Principal Findings:** We detected significant serum IgG antibody responses targeting OSP following a single immunization in mice receiving OSP:TThc with or without adjuvant. Anti-LPS IgG responses were detected following a second immunization in these cohorts. No anti-OSP or anti-LPS IgG responses were detected at any time in animals receiving un-conjugated OSP with or without immunoadjuvant, and in animals receiving immunoadjuvant alone. Responses were highest following immunization with adjuvant. Serum anti-OSP IgM responses were detected in mice receiving OSP:TThc with or without immunoadjuvant, and in mice receiving unconjugated OSP. Serum anti-LPS IgM and vibriocidal responses were detected in all vaccine cohorts except in mice receiving immunoadjuvant alone. No significant IgA anti-OSP or anti-LPS responses developed in any group. Administration of OSP:TThc and adjuvant also induced memory B cell responses targeting OSP and resulted in 95% protective efficacy in a mouse lethality cholera challenge model.

**Conclusion:** We describe a protectively immunogenic cholera conjugate in mice. Development of a cholera conjugate vaccine could assist in inducing long-term protective immunity, especially in young children who respond poorly to polysaccharide antigens.
**Author Summary**

Cholera is a severe dehydrating diarrheal illness of humans caused by organisms *Vibrio cholerae* serogroups O1 or O139 serogroup organisms. Protective immunity against cholera is serogroup specific. Serogroup specificity in *V. cholerae* is determined by the O-specific polysaccharide (OSP) of lipopolysaccharide (LPS). Generally, polysaccharides are poorly immunogenic, especially in young children. Unfortunately, children bear a large burden of cholera globally. Here we describe a novel cholera conjugate vaccine and show that it induces immune responses in mice, including memory responses, to OSP, the T cell-independent antigen that probably is the target of protective immunity to cholera. These responses were highest following immunization of the vaccine with a novel immunoadjuvant, dmLT. We also show that immunization of mice with this conjugate vaccine protects against challenge with wild-type *V. cholerae*. A protectively immunogenic cholera conjugate vaccine that induces long-term memory responses could have particular utility in young children who are most at risk of cholera.

**Introduction**

Cholera is a severe dehydrating diarrheal illness of humans caused by organisms *Vibrio cholerae* O1 or O139 serogroup organisms. *V. cholerae* O139 has largely disappeared and is reported from just a few Asian countries [1]. Cholera affects 3–5 million people each year, killing ∼100,000 annually, and cholera is endemic in over 50 countries [2]. *V. cholerae* O1 can be distinguished genotypically and phenotypically into classical and El Tor biotypes [2] and Ogawa and Inaba serotypes. Ogawa differs from Inaba only by the presence of a 2-O-methyl group in the non-reducing terminal sugar of O-specific polysaccharide (OSP) [3–5]. Currently, the global cholera pandemic is caused by organisms *V. cholerae* O1, El Tor, organisms, with the prevalent O139 serogroup organisms. Protective immunity against pure water (centrifugation at 4°C, 7,500 × g, 8 times, 8 min each time) against 10 mM aqueous ammonium carbonate. After lyophilization, 3.6 mg and Use of Laboratory Animals, and the “ILAR Guide for the Care and Use of Laboratory Animals”.

**Materials and Methods**

**Ethics statement**

The use of animals complied fully with relevant governmental and institutional requirements, guidelines, and policies. This work was approved by the Massachusetts General Hospital Subcommittee on Research Animal Care (SRAC) – OLAW Assurance # A5596-01; Protocol #2004N000192. The work adheres to the USDA Animal Welfare Act, PHS Policy on Humane Care and Use of Laboratory Animals, and the “ILAR Guide for the Care and Use of Laboratory Animals”.

**Bacterial strains and media**

*V. cholerae* O1 El Tor Ogawa strain X25049 [13] was used to prepare LPS for use in vaccine preparation and immunological assays, in addition to vibriocidal assays, and wild-type classical *V. cholerae* O1 classical Ogawa strain O395 [10] was used in vibriocidal assays and the neonatal challenge. Strains were grown in Luria-Bertani broth.

**Vaccine antigen**

LPS was recovered from X25049, and OSP-core (OSPc) was derived from LPS as previously described [9,14]. As a carrier protein, recombinant tetanus toxoid heavy chain fragment (TThc) was used [15,16]. TThc was prepared as a 52,108 Da recombinant protein in E. coli BL21 (DE3) Star with a self-cleaving intein tag using affinity and size exclusion chromatography, as previously described [17].

Conjugation was carried out as previously described [14]. Briefly, 3,4-dimethoxy-3-cyclobutene-1,2-dione (4.0 mg) was added to a solution of Ogawa O-SP-core antigen (8.0 mg) in pH 7 phosphate buffer (0.05 M) contained in a 2 mL V-shaped reaction vessel, and the mixture was gently stirred at room temperature for 48 h. The solution was transferred into an Amicon Ultra (4 mL, 3K cutoff) centrifuge tube and dialyzed against pure water (centrifugation at 4°C, 7,500 × g, 8 times, 35 min each time). The retentate was lyophilized to afford the OSP-core square monomethyl ester as white solid (7.4 mg, 91%).

TThc (3.2 mg) and the methyl square derivative of the Ogawa O-SP-core antigen described above (7.4 mg) were weighed into a 1 mL V-shaped reaction vessel and 240 mL of 0.5 M pH 9 borate buffer was added (to form ~5 mM solution with respect to the antigen; antigen/carrying 2:1). A clear solution was formed. The mixture was stirred at room temperature and the progress of the reaction was monitored by SELDI-TOF MS at 24, 48, 72, 96, and 168 h, when no more increase of antigen/carrying ratio could be observed. The mixture was transferred into an Amicon Ultra (4 mL, 30 K cutoff) centrifuge tube and dialyzed (centrifugation at 4°C, 7,500×g, 8 times, 8 min each time) against 10 mM aqueous ammonium carbonate. After lyophilization, 4.6 mg (83%, based on TThc) of conjugate was obtained as a white solid. On the basis of the molecular mass of the carrier (52,108 Da), conjugate (90,000 Da, determined by SELDI-TOF MS) and average MW of the OSP antigen of 3,900 Da [14], the antigen/TThc ratio was 6.4:1 (conjugation efficiency, 32%) (figure 1). A corresponding conjugate was made of OSP: bovine serum albumin (BSA, Sigma #A-4503) using the same approach as described above for use in immunologic assays. The OSP:BSA product contained 4.8 moles OSP per BSA.

For these experiments, we used dmLT, a double mutant derivative of *Escherichia coli* heat labile toxin (LT), as an immunoadjuvant. dmLT (R192G/L211A) retains immunoadjuvants with markedly reduced enterotoxicity [18]. dmLT was prepared as previously described [18,19].

**Immunization of mice and sampling**

We immunized cohorts of 10–15, three to five week old Swiss Webster female mice intramuscularly with OSP:TThc or OSP (10 µg sugar per mouse; total 3 doses) with or without dmLT (3 µg). Mice were immunized on days 0, 21, and 42. We collected blood samples via tail bleeds on days 0, 21, 28, 42, 49 and 56. Samples were collected, processed, aliquoted, and stored as previously described [10,11]. For the memory B cell assay, splenocytes were isolated after day 56 and processed for ELISPOT as previously described [20].
Detection of specific antibody responses in serum

We quantified anti-LPS and OSP IgG, IgM and IgA responses in serum using standard enzyme-linked immunosorbent assay (ELISA) protocols [10,11]. To assess anti-LPS antibody responses, we coated ELISA plates with *V. cholerae* O1 Ogawa LPS (2.5 μg/mL) in PBS [10,11]. To assess anti-OSP antibody responses, we coated ELISA plates with OSP:BSA (1 μg/mL) in PBS. To each well, we added 100 μL of serum (diluted 1:25 in 0.1% BSA in phosphate buffered saline-Tween) and detected the presence of antigen-specific antibodies using horseradish peroxidase-conjugated anti-mouse IgG, IgM or IgA antibody (diluted 1:1000 in 0.1% BSA in phosphate buffered saline-Tween) (Southern Biotech, Birmingham, AL). After 1.5 h incubation at 37°C, we developed the plates with a 0.55 mg/mL solution of 2,2′-azinobis (3-ethylbenzothiazoline-6-sulfonic acid) (ABTS; Sigma) with 0.03% H2O2 (Sigma), and determined the optical density at 405 nm with a Vmax microplate kinetic reader (Molecular Devices Corp., Sunnyvale, CA). Plates were read for 5 min at 30 s intervals, and the maximum slope for an optical density change of 0.2 U was reported as millioptical density units per minute (mOD/min). We normalized ELISA units (EU) by calculating the ratio of the optical density of the test sample to that of a standard of pooled sera from mice vaccinated with cholera vaccine from a previous study run on the same plate. We characterized a responder as a ≥2-fold increase in anti-LPS and OSP EU kinetic responses.

Memory B cell responses

We assessed memory B-cell assays after the third round of immunization based on previously described methods [20]. Briefly, we treated splenocytes from mice with 1 ml erythrocyte lysis buffer (Sigma) and resuspended them in RPMI supplemented with 10% fetal bovine serum (FBS) (Hyclone, Logan, UT), betamercaptoethanol (Sigma, St. Louis, MO), R595 LPS (Alexis), ConA stimulated supernatant and antibiotics (penicillin, streptomycin). The ConA stimulated supernatant was made from naïve mice splenocytes cultured with 2.5 μg/ml ConA and 20 ng/ml PMA for 48 hours at 37°C in a humid atmosphere with 5% CO2. We then cultured spleen cells in 96 well round-bottom plates containing 1×10^5 cells/mL irradiated syngeneic spleen cell feeders (1200 rad) from naïve mice, and 1×10^5 cells/well from immunized mice in a total volume of 200 μL. Plates were then incubated at 37°C in a humid atmosphere with 5% CO2. After 6 days in culture, cells were harvested and antigen-specific memory B cell responses were measured by conventional ELISPOT method. We assessed antigen-specific OSP and total IgG ELISPOT assays on these cultured cells. Specifically, nitrocellulose bottom plates (MAHAS4510, Millipore, Bedford, MA) were coated with OSP:BSA (100 ng/well) or with goat anti-mouse IgG (Southern Biotech, Birmingham, AL) or with keyhole limpet hemocyanin (KLH; Pierce Biotechnology, Rockford, IL) (2.5 μg/mL, negative control). After we blocked the plates with RPMI supplemented with 10% FBS, we added the cultured cells to the wells and incubated the plates for 5 h at 37°C in a humid atmosphere with 5% CO2. We then added biotinylated anti-mouse IgG antibody (Southern Biotech, Birmingham, AL) at 1:1000, detected IgG antibody expressing cells using horseradish peroxidase-conjugated avidin-D (5 mg/mL, Vector Labs), and developed plates with AEC (3 amino-9-ethyl-carbozole; Sigma). We used unstimulated
samples as negative controls and assessed responses to KLH. We characterized a responder as having >2 times total IgG cells with stimulation versus no stimulation and >3 anti-OSP spots.

Neonatal challenge experiments
To assess protection afforded by immunization, we used a cholera neonatal mouse challenge assay, as previously described [10,11], using wild-type O1 Ogawa V. cholerae O395. In brief, we removed three to five days old un-immunized CD-1 suckling mice (n = 20 mice/cohort) from dams two hours prior to inoculation. We then administered to pups a 50 μl inoculum comprised of 2.5 × 10^6 CFU of V. cholerae O395 mixed with a 1:250 dilution of pooled day 56 serum from mice intramuscularly immunized with the conjugate vaccine OSP:TThc with dmLT, or immunized with dmLT alone. Following oral challenge, we kept neonates separate from dams at 30°C and monitored animals every 3 hr for 36 hr, after which surviving animals were euthanized.

Statistics and graphs
We compared data from different groups using Mann-Whitney U tests. Within each group, comparisons of data from different time points to baseline data (day 0) were carried out using Wilcoxon Signed-Rank tests. Kaplan-Meier and log rank analysis were carried out to compare survival curves in the neonatal challenge study. All reported P values were two-tailed, with a cutoff of P<0.05 considered a threshold for statistical significance. We performed statistical analyses using GraphPad Prism 4 (GraphPad Software, Inc., La Jolla, CA).

Results
Analysis of OSP:TThc
We determined progress of conjugation and average carbohydrate content/carbohydrate–protein ratio of OSP:TThc by Surface-Enhanced Laser Desorption–Ionization Mass Spectrometry (SELDI) [25]. Similar to the matrix assisted variant (MALDI) [26], this technique determines average degree of incorporation of carbohydrate onto protein, as well as molecular weight distribution in glycoconjugates. The SELDI analysis showed that the average molecular mass of the conjugate was 90,150 Da. Subtracting from that value the molecular mass of the recombinant protein TThc carrier, 52,108 Da [17][27] the conjugate product molecular mass increased by 38,042 Da. Based on the difference between m/z values of subpeaks within the SELDI peak [14] ; also [28] the molecular mass of the polymolecular OSP–core was determined to average ≈5,900 Da, representing attachment of various lengths of OSP to core. The molecular mass of the conjugate determined by SELDI, 91,150 Da, then indicated the molar ratio of OSP–core:TThc to be 6.4:1.

OSP-specific antibody responses
Following the first injection, we detected significant anti-OSP serum IgG antibody responses in mice receiving OSP:TThc with or without adjuvant (figure 2). Higher magnitude and response rates (P<0.01) were observed in the cohort of animals receiving conjugate vaccine with dmLT (response rate after two doses: 100%). No anti-OSP IgG responses were detected at any time in animals receiving un-conjugated OSP only, with or without immunoadjuvant, or in animals receiving immunoadjuvant alone. Mice receiving OSP:TThc with or without immunoadjuvant and mice receiving OSP alone developed anti-OSP IgM responses (figure 3). IgM responses were only detected following a minimum of two immunizations, and response frequency and magnitude were highest in animals receiving OSP:TThc with adjuvant. No significant IgA anti-OSP antibody was detected in any group (not shown).

LPS-specific antibody responses
Significant serum anti-LPS IgG responses developed following a second immunization in mice receiving conjugate with or without adjuvant (figure 2). Anti-LPS IgM responses were detected in all vaccine cohorts except in mice receiving immunoadjuvant alone (figure 3). No significant anti-LPS IgA responses developed in any group (not shown).

Vibriocidal responses
Low-level vibriocidal responses (magnitude and response frequency) were detected in animals receiving unconjugated OSP with or without adjuvant (figure 4). Administration of the immunoadjuvant alone did not elicit any vibriocidal response in animals.

Antigen-specific memory B cell responses
Antigen-specific IgG memory B-cell responses are shown in table 1. OSP IgG specific memory B cell responses were detected in 65% of mice immunized with conjugate vaccine and adjuvant. 18% and 22% of mice immunized with OSP in the presence of
dmLT or OSP:TThc alone developed detectable OSP specific memory B cell responses, respectively. No OSP memory response was detected in mice receiving dmLT alone.

Neonatal mouse challenge assay

We found a significant difference in survival between mice challenged with wild-type *V. cholerae* O1 Ogawa O395 mixed with sera collected from mice immunized with conjugate and adjuvant (95% survival at 36 hours), compared to mice challenged using sera from mice immunized with adjuvant alone (0% survival at 30 hours; 95% protection; \( P < 0.05 \)) (figure 5).

Discussion

In this study, we demonstrate that a cholera conjugate vaccine containing OSP recovered from *V. cholerae* is protectively immunogenic and induces anti-OSP memory B cell responses in mice. There is a growing body of evidence that anti-OSP responses may be a prime mediator of protective immunity against cholera. Protective immunity to cholera is serogroup specific. Previous infection with *V. cholerae* O1 provides no protection against O139 and vice versa. This is despite the fact that O1 and O139 express essentially identical cholera toxins (CT) and that O139 is thought to be a derivative of an O1 El Tor strain with high-level homology of most genes in O1 El Tor and O139 [29,30]. O139 differs from O1 in its genes encoding OSP and in the presence of capsule. The capsule of O139 is comprised of a polysaccharide whose repeating unit is identical to the O139 OSP [15]. The core moieties of O139 and O1 are identical [31]. These data suggest that protection from cholera may be mediated by the serogroup OSP of LPS.

Analysis of anti-OSP responses in cholera patients and their potential role in protection has only recently been initiated [9,32]. There is however significant evidence that anti-LPS responses correlate with protection from cholera [33,34]. The vibriocidal response correlates with protection [35] and is largely comprised of anti-LPS IgM responses [36]. We have recently shown that the vibriocidal response can be largely adsorbed away by OSP [9]. Anti-LPS IgA responses in serum and stool have also been associated with protection against cholera among household contacts of cholera patients in Bangladesh [34]. Anti-LPS memory B cell responses similarly correlate with protection against cholera [33].

Currently, two oral killed cholera vaccines are WHO-prequalified and commercially available [37]. One contains approximately \( 10^{11} \) killed *V. cholerae* O1 Ogawa and Inaba strain organisms (Ogawa and Inaba) and is supplemented with

doi:10.1371/journal.pntd.0002683.g005

1 mg of recombinant non toxic B subunit of cholera toxin
(WC-rBS; Dakoral, Crucell, Sweden). The other is bivalent,
containing killed classical and El Tor O1 organisms as well as
an O139 strain, and it does not contain supplemental cholera toxin
subunit (Shanchol, Shantabiotechnic-Sanoﬁ, India). Following two
times, these vaccines are 40–85% effective for 6–60 months
[13,37–39]. The level of response and duration of protection
is particularly decreased in children younger than 5 years of age,
compared to older children and adults [38,40,41], with booster
doses of Dakoral being recommended every 6 months for children
under 5 years of age [42]. In comparison, wild-type cholera is
associated with high level (90–100%) of protective immunity for
at least 3 years in volunteer challenge studies [43] and 3–10 year
protection in population-based studies [44]. The level and
duration of protection afforded by previous wild-type cholera
appeared to be the same in young children and in older individuals
[45,46].

We have previously shown that wild-type cholera is associated
with a pro-inﬂammatory response even in young children in
Bangladesh, but that vaccination of Bangladeshi children with
WC-rBS induces a T-regulatory response [47]. We have also shown
that wild-type cholera induces anti-LPS memory B cell
responses, even in young children [45], but that children and adult
recipients of WC-rBS do not develop such responses [13,41]. In
addition, induction of memory B cell responses correlates with the
magnitude of early T cell responses in older recipients of WC-rBS
[47], but younger child recipients do not develop T cell responses
[47]. These observations may in part explain the lower level and
shorter duration of protection afforded by WC-rBS in young
children compared to that induced by wild-type disease.
Unfortunately, children bear a very large burden of cholera, especially
in endemic areas [48,49]. For instance, 40–80% of children in
Bangladesh develop serologic evidence of previous exposure to V. cholerae
by the age of 15 years [35,50], and in areas of India, there
is an estimated cholera incidence of 7 per 1000 for children less
than 5 years of age, compared to 2.19 in older children and 0.93 in
adults (>14 years age) [51]. There is thus a need for improved
cholera vaccines or immunization strategies capable of inducing
high-level and long-term immunity, especially in young children.

Immune responses targeting OSP may be critical in deter-
miming protective immunity from cholera. Since OSP is a T
cell-independent antigen, and because young children do not
develop prominent responses to polysaccharide antigens admin-
istered alone, we are particularly interested in developing a cholera
conjugate vaccine. Here we show that a cholera conjugate vaccine
is protectively immunogenic in mice and induces memory B cell
responses against OSP. Previous prototype cholera conjugates
have been developed [52][53][54]. Our work contains a number of
innovative features. The conjugation process is carried out using
sugaric acid chemistry, linking the glucosamine present in core
oligosaccharide to carrier protein via single point attachment [14].
This takes advantage of the core oligosaccharide, effectively using
it as a linker and resulting in a sun-burst display of OSP in a
manner that may mimic that present on the surface of V. cholerae.
Recent data suggest that the way LPS antigen is presented can
impact subsequent immune responses [55]. The fact that the
resulting conjugate in our analysis is not cross-linked and,
therefore, easier to characterize, together with conjugation
methodology that produces conjugates in a predictable manner
[56], maximizes the likelihood that vaccine generated in this way
and its immunological properties would be reproducible, which is
not the case with a number of conjugate vaccines for cholera
reported to date. Of note, we do not think that core oligosaccha-
ride contributes significantly to the protective immunity that we
observed since previous infection of humans with V. cholerae O1
does not provide protection from V. cholerae O139 and vice versa,
despite the presence of identical core oligosaccharides. We also
employed as carrier a recombinant immunogenic fragment of
tetanus toxoid that could be used as carrier in other vaccines as
well. Individuals at risk of cholera are often the most globally
disenfranchised and impoverished and may not have received all
recommended immunizations, including tetanus vaccine. In
addition, we used a novel immunoadjuvant, dmLT [18]. A
number of derivatives of the ADP-ribosylating LT molecule of E.
coli have been developed and evaluated in humans [18,57,58].
These molecules have in common their retained immunoadju-
vanticity but markedly diminished enterotoxicity [18]. We have
previously shown that transcutaneously applied CT or LT can act
as an immunoadjuvant [10,11]; here we show that low-dose dmLT
can also be safely administered parenterally in mice.

Our study is encouraging, but many questions remain. Would
an Inaba-based vaccine result in comparable results? Would a
response targeting Ogawa OSP cross protect against Inaba?
Previous human suggests it may not [59] Would an Inaba-based
vaccine protect against Ogawa-associated disease? Could a bi/
multi-valent conjugate vaccine be developed? Our vaccine
induced vibrioidal responses. Is this a reflection of the fact that
a signiﬁcant component of the vibrioidal response can be
adsorbed with OSP [9] or are additional puriﬁcation steps
required? How do conjugates using puriﬁed OSP compare to
glycoconjugate vaccines prepared from synthetic carbohydrates,
which are also under development [10,11,60,61]? Could other
immunoadjuvants be used? Is it possible to induce mucosal
responses, or would a parenteral cholera vaccine be sufﬁcient
when most humans at risk of cholera are also at high risk of
tropical or environmental enteropathy with attendant leaking of
serum antibodies into the intestinal lumen?

Despite these questions, it is notable that previously produced
killed LPS-based whole cell parenteral cholera vaccines were
associated with up to 80% protection against disease in humans
[62]. Our data suggest that an improved parenteral cholera
conjugate vaccine can be developed, one that induces immune
responses, including memory B cell responses, to a normally T cell
independent antigen (OPS) that is the major target of protective
immunity to cholera. Furthermore, this conjugate vaccine can
protect against wild-type challenge in animals. Such a conjugate vaccine could have particular utility in young children who are most at risk of cholera.
