ABSTRACT

The galaxy cluster SPT-CL J0205-5829 currently has the highest spectroscopically-confirmed redshift, $z = 1.322$, in the South Pole Telescope Sunyaev-Zel’dovich (SPT-SZ) survey. XMM-Newton observations measure a core-excluded temperature of $T_X = 8.7^{+0.9}_{-0.6}$ keV producing a mass estimate that is consistent with the Sunyaev-Zel’dovich derived mass. The combined SZ and X-ray mass estimate of $M_{500}=4.8 \pm 0.8 \times 10^{14} M_\odot$ makes it the most massive known SZ-selected galaxy cluster at $z > 1.2$ and the second most massive at $z > 1$. Using optical and infrared observations, we find that the brightest galaxies in SPT-CL J0205-5829 are already well evolved by the time the universe was $< 5$ Gyr old, with stellar population ages $\gtrsim 3$ Gyr, and low rates of star formation ($\lesssim 0.5 M_\odot/yr$). We find that, despite the high redshift and mass, the existence of SPT-CL J0205-5829 is not surprising given a flat $\Lambda$CDM cosmology with Gaussian initial perturbations. The a priori chance of finding a cluster of similar rarity (or rarer) in a survey the size of the 2500 deg$^2$ SPT-SZ survey is 69%.

1. INTRODUCTION

The South Pole Telescope (SPT; Carlstrom et al. 2011) has recently completed a survey designed to discover all massive galaxy clusters within a 2500 deg$^2$ region of the southern sky. High redshift galaxy clusters are valuable as probes of the initial conditions of the universe, particularly the distribution of matter at early epochs. Since galaxy clusters are the most massive collapsed systems, their abundance is sensitive to the properties of the early universe including Gaussianity around the peak of the matter density field (e.g., Lucchin & Matarrese 1988; Colafrancesco et al. 1989; Mortonson & Hu 2010) and the nature of inflationary models. In addition to cosmology, the constituent galaxies of these clusters, which have essentially co-evolving star formation histories, are useful for studying galaxy formation and evolution.

The SPT-SZ survey finds clusters via the Sunyaev-Zel’'dovich (SZ; Sunyaev & Zel’dovich 1972) effect. The vast majority of baryonic mass of a galaxy cluster is in the form of diffuse, ionized gas, known as the intracluster medium (ICM), unassociated with any particular galaxy. Photons from the cosmic microwave background (CMB) are Compton scattered by the free electrons in this ionized gas. The scattered photons gain energy on average in a spectral distortion of the observed CMB known as the thermal SZ effect. The surface brightness of the SZ effect is independent of the distance to the cluster because the SZ effect depends solely on the line-of-sight integral of thermal pressure of the ionized gas. Therefore, the total SZ flux is a measure of the total thermal energy in the gas, which is tightly correlated to the cluster mass. This makes SZ surveys an efficient means for finding high mass clusters at all redshifts (e.g., Carlstrom et al. 2002).

Observations of fine scale CMB anisotropy with the SPT, Planck Satellite (Planck Collaboration et al. 2011), and Atacama Cosmology Telescope (ACT; Marriage et al. 2011) have recently been used to detect massive clusters in large surveys of the sky. The progress of the cluster survey by SPT is reported by Staniszewski et al. (2009), Vanderlinde et al. (2010), Williamson et al. (2011), Reichardt et al. (2012) where the details of the survey strategy, data reduction, and cosmological analysis are also presented. The SPT has now completed a survey of 2500 deg$^2$ in the southern hemisphere in three millimeter-wavelength bands. The SPT-SZ survey is essentially complete for clusters with a mass of $M_{500} \gtrsim 5 \times 10^{14} h_{70}^{-1} M_\odot$ at $z > 0.3$ and $M_{500} \gtrsim 3 \times 10^{14} h_{70}^{-1} M_\odot$ at $z > 1$.

The SPT-SZ survey has discovered several galaxy clusters that have been spectroscopically confirmed at $z > 1$ (Brodwin et al. 2010, Foley et al. 2011). Other groups are also discovering high redshift clusters through X-ray (e.g., Rosati et al. 2004; Mullis et al. 2005; Stanford et al. 2006; Rosati et al. 2009; Henry et al. 2010), or infrared imaging (e.g., Stanford et al. 2008; Brodwin et al. 2006; Eisenhardt et al. 2005; Muzzin et al. 2009; Wilson et al. 2009; Papovich et al. 2010; Brodwin et al. 2011; Stanford et al. 2012). However, these techniques do not have the benefit of simultaneously providing the nearly redshift-independent mass selection and wide area coverage of the SZ technique.

The rich and dense environments of galaxy clusters can also be exploited to study galaxy evolution. They provide a simple way of identifying large populations of galaxies that have similar formation histories. As the redshift of the clusters in the sample increases, earlier phases in the process of galaxy evolution are observed. With these observations, scenarios of galaxy formation can be tested with less temporal extrapolation. This also perhaps has ramifications for the hierarchical formation scenario, as the ages of the bright elliptical galaxies may be related to the epoch of the final assembly of the cluster as suggested by semi-analytical simulations such as Dubinski (1998) and Boylan-Kolchin et al. (2009). Recent observations of high redshift dense environments point to a period of prodigious star formation (Papovich et al. 2012; Snyder et al. 2012) at $z > 1.3$, after which the bulk of the stellar mass build up likely arises from dry mergers (without significant star formation). However, studies of lower redshift elliptical galaxies suggest that stellar age is minimally affected by environment densities, e.g., Thomas et al. (2010). A larger data set at high redshift is probably required to reconcile these.

SPT-CL J0205-5829 was first identified as a cluster in Reichardt et al. (2012, R12), which describes a catalog of 224 cluster candidates discovered in the first 720 deg$^2$ of the 2500 deg$^2$ SPT-SZ survey. SPT-CL J0205-5829 was detected with a signal-to-noise ratio (S/N) of 10.5 in the SPT data. Initial deep optical follow-up observations showed no obvious overdensity of galaxies in griz images, but additional infrared and Spitzer photometry confirmed the presence of extremely red clustered galaxies consistent with a redshift $z > 1.3$. Optical spectroscopy of member galaxies confirmed that the cluster is at $z = 1.322$. X-ray observations with XMM-Newton revealed a luminous and extended X-ray source. Although SPT-CL J0205-5829 is not the most massive SPT cluster, it is the highest-redshift SPT cluster that has been confirmed by spectroscopy to date, and potentially the most massive galaxy cluster known at redshift $z > 1.2$ (previous to this was XMM2235 from Rosati et al. (2009) at $z=1.39$), and second most massive at $z > 1$ (the most massive being SPT-CL J2106-5844 from Foley et al. (2011) at $z = 1.13$).

We present our initial detection and follow-up observations of SPT-CL J0205-5829 in Section 2. In Section 3 we show that SPT-CL J0205-5829 is a massive high redshift galaxy cluster with a population of normal passively evolving galaxies. We then briefly discuss the implications of the existence of such a massive, evolved cluster at $z > 1.3$ in Section 4. We summarize and conclude in Section 5. Except where otherwise stated, we assume a flat $\Lambda$CDM cosmology with $\Omega_M = 0.3$ and $h_0 = 0.7$ throughout this paper. $M_{500}$ masses are defined as the mass enclosed in a spherical region which has a density 500 times the critical density of the universe. At $z = 1.322$, 1 Mpc subtends 2.0 arcminutes and the age of the universe is 4.66 Gyr.

2. OBSERVATIONS, DATA REDUCTION, & INITIAL FINDINGS

2.1. Millimeter Observations by The South Pole Telescope

SPT-CL J0205-5829 was initially discovered in the SPT-SZ survey and reported in R12, as part of the cluster catalog identified from the 720 deg$^2$ surveyed during the 2008-2009 SPT observing seasons. The survey strategy and data analysis are detailed in the previous SPT-SZ survey papers Staniszewski et al. (2009), Vanderlinde et al. (2010), and R12. The SPT-SZ survey was completed in November 2011, and covers an area of 2500 deg$^2$ in three frequency bands at 95, 150, and 220 GHz.

As described in R12, cluster candidates were identified using a multi-band matched-filter approach, similar to that first described by Melin et al. (2006). The significance of a cluster detection (maximized across spatial filter scales and position in map), $\xi$, is used to identify cluster candidates. For the survey field containing SPT-CL J0205-5829, only the 95 and 150 GHz data was used, the SPT maps have noise levels of 45 and 16 $\mu$-arcmin in CMB temperature units at 95 and 150 GHz, respectively. In this data, SPT-CL J0205-5829 was detected with $\xi = 105$ and is among the 5% most significant detections in the R12 catalog. An image of the filtered SPT map is shown in Figure 1.

2.2. Optical and Infrared Imaging

We obtained griz imaging using the MOSAIC2 imager on the CTIO 4 m Blanco telescope on UT 18, 25 July 2010 and UT 4 July 2011 with mediocre to bad seeing (1.1 to 2.2′′) and occasional light clouds. Total integration times were 300, 300, 2350, and 1050 seconds to 10-σ point source depths of 23.8, 23.2, 22.2, and 21.1 AB magnitudes in g, r, i, and z, respectively. We also acquired 1800 seconds of deep i-band imaging of SPT-CL J0205-5829 on UT 31 January 2011 with the Inamori Magellan Areal Camera and Spectrograph (IMACS; Dressler et al. 2006) on the Baade Magellan 6.5 m telescope to 21.0 AB magnitude depth in mediocre seeing (1.2 to 1.5′′). The observation strategy and reduction procedure is described in High et al. (2010), H10, W11, and Song et al. (2012) using the PHOTPIPE pipeline (Rest et al. 2005).

SPT-CL J0205-5829 was also observed with the NEWFIRM imager (Autry et al. 2003) at the CTIO 4 m Blanco telescope on UT 6 November 2010. Data were obtained in the $K_s$ filter under photometric conditions with a 10-σ point source depth of 19.1 Vega magnitudes. At each dither position, six frames with 10 s exposure times were coadded at 18 random positions providing a total exposure time of 1080 s. NEWFIRM data were reduced using the FATBOY pipeline, originally developed for the FLAMINGOS-2 instrument, and modified to work with NEWFIRM data in support of the Infrared Bootes Imaging Survey (A. Gonzalez, private communication). Individual processed frames are combined using SCAMP and SWARP (Bertin et al. 2002), and photometry is calibrated to 2MASS (Skrutskie et al. 2006). The final image has a FWHM of 0.96″.

Infrared Spitzer/IRAC imaging was obtained in 2011 during Cycle 7 as part of a larger program to follow up clusters identified in the SPT survey. IRAC imaging is particularly important for the confirmation and study of high-redshift SPT clusters such as SPT-CL J0205-5829 where the optically faint members are strongly detected in the infrared. The on-target observations consisted of 8×100 s and 6×30 s dithered exposures in bands [3.6] and [4.5] to 10-σ depths of 20.3 and 18.8 Vega magnitudes, respectively. The deep [3.6] observations are sensitive to passively evolving cluster galaxies down to 0.1 $L^\ast$ at $z = 1.5$. The data were reduced exactly as in Brodwin et al. (2010), following the method of Ashby et al. (2009). Briefly, we correct for column pulldown and residual image effects, mosaic the individual exposures, resample to 0.′86 pixels (half the solid angle of the native IRAC pixels), and reject cosmic rays.

2.3. Optical Spectroscopy

Multislit spectroscopic observations were acquired for SPT-CL J0205-5829 on the 6.5-meter Baade Magellan telescope on UT 25-26 September 2011 using the f/2 camera on the IMACS spectrograph for a total integration time of 11 hours. The strategy and procedure were as described in Brodwin et al. (2010), with the same 300 1/mm “red” grism and WB6300-9500 filter, but without the Gismo module (in order to increase throughput). The galaxy target selection was based on the optical and infrared photometry, see Section 3. Twenty-two 30-minute exposures were made in excellent to moderately-good seeing (0.4-0.7″) using one slit mask. The resolution of the observations, as measured from the sky lines, was 5.2A. In a procedure identical to Ruel et al. (2012), the COSMOS reduction package was used for standard CCD processing, resulting in wavelength-calibrated 2D spectra. The 2D spectra were then extracted from the sum of the reduced data. Spectral features were identified by eye from inspection of the 2D and 1D spectra, and redshifts were then obtained by using RVSAO routines.

2.4. X-ray Observations

A deep X-ray observation of SPT-CL J0205-5829 was obtained by the XMM-Newton observatory (OB-SID 0675010101) on UT 19-20 June 2011 using the European Photon Imaging Camera (EPIC), which consists of two Metal-Oxide-Silicon (MOS) arrays plus one fully depleted p-n (PN) junction CCD array. The total integration times were 69 ks for the MOS arrays and 65 ks for the PN array. The data reduction and analysis were performed with SAS v11.0 utilizing the XMM-Neutron Extended Source Analysis Software package (XMM-ESAS, e.g. Snowden et al. 2008). The net clean exposure time is 57 and 39 ks in the MOS/PN arrays, respectively. Based on the De Luca & Molendi (2004) diagnostics we find a $\sim 30 - 40\%$ background enhancement in the observation due to residual quiescent soft proton contamination. The MOS2 CCD#5 was in an anomalously high state and we have removed it from further analysis.

We have also excised all point sources identified in the source detection step. We have visually inspected the excision regions and made conservative adjustments to their size. In particular, a point source associated with a bright galaxy (bluer than the passively-evolving...
model) was identified in the core region of the cluster
\((\alpha=02:05:45.4, \delta=-58:28:58.3, \sim 12'' \text{ west of the X-ray}
\text{ centroid})\) and was removed with an excision radius of
\(~11''\) (see Figure 3).

3. RESULTS

3.1. Cluster Member Galaxies

From the procedure described in S12, we measure
a redshift based on the Spitzer IRAC photometry of
\(z = 1.30 \pm 0.12\) (see Figure 2). We fit a model of passively-
evolved galaxies from Bruzual & Charlot (2003, BC03) to
the data to determine the redshift. The optical data were
not deep enough to offer any additional constraint to
the redshift except for the brightest of the cluster mem-
bers (see section 3.3). The redshift estimator identified
32 galaxies with IRAC \([3.6]-[4.5]\) colors consistent with
this redshift (a \(3.5\sigma\) overdensity compared to the back-
ground), shown in Figures 1 and 2. From this list, we
designed a multi-slit mask for the IMACS spectroscopic
observations described in Section 2.3 filling the mask
with other targets, identified as galaxies with bluer col-
ors relative to the model in the i-band and Spitzer data.

3.2. Spectroscopy

Redshifts and other spectroscopic properties of member
galaxies are listed in Table 1. Of the 47 slits designed
into the mask, one spectroscopic member was identified
from an \([\text{O II}]\) emission line, and 8 from \(\text{Ca H&K}\). Figure
3 shows the spectra of the 9 cluster members. The bright-
est cluster galaxy (BCG), defined as the brightest cluster
member in \([3.6]\), is at a redshift of \(z = 1.3218 \pm 0.0005,\)
and the combined robust (biweight) redshift of 9 clus-
ter members is \(z = 1.322^{+0.001}_{-0.002}\). We do not calculate
the velocity dispersion due to the overwhelming intrin-
sic uncertainty in the derived mass estimates with <15

members (Saro et al. 2012).

We also estimate the star formation rate (SFR) for
each cluster member from the integrated \([\text{O II}]\) flux which
was corrected for galactic extinction (reddening) using the
dust map from Schlegel et al. (1998) and scaled to
match the i-band magnitude from IMACS imaging. We
do not correct for source dust extinction as we lack a
well constrained NUV-Blue continuum measurement for
most of these galaxies. This is also consistent with our
derived extinction from SED fits of the 4 brightest central
galaxies (see Section 3.3). We measured the continuum-
subtracted flux centered on the \([\text{O II}]\) wavelength with a
bin width of 8Å \((320 \text{ km/s})\) and converted to luminosity
using the cluster redshift. The SFR was estimated from
the \([\text{O II}]\) luminosity using the scaling law from Kenni-
cutt (1998). The measured \([\text{O II}]\) flux and SFR (or \(3\sigma\)
upper limits) are given in Table 1.

3.3. Brightest Central Galaxies

We selected the brightest central galaxies to be the four
brightest galaxies consistent with the \([3.6]-[4.5]\) model,
within 1 arcminute of the SZ center. We then use an
analysis similar to the Rosati et al. (2009) spectral en-
ergy distribution (SED) fitting procedure. To constrain
the star formation history (SFH) of each of these galax-
ies, we fit an exponential-burst stellar population SED
model at solar metallicity and Chabrier IMF from BC03
to the available photometry (see Figure 4), including
magnitude lower limits, fix the redshift at \(z = 1.322,\)
and add a source reddening model from Calzetti et al.
(2000). From the fit parameters, we calculate the rest-
frame K-band luminosity, stellar mass (and correspond-
ing stellar mass-to-light ratios), and age. The uncer-
tainties for these parameters are from the \(\chi^2\) 68% con-
fidence intervals in the multi-dimensional sampled grid.
and checked by bootstrapping this procedure hundreds of times and were in good agreement. These parameters are presented in Table 2. We find that all models give well-constrained K-band luminosities, mainly because the observed Spitzer [4.5] filter corresponds to 2 μm in the rest frame. The 4000Å breaks are mainly constrained by the deep IMACS i-band measurement.

The rest-frame K-band luminosity of the brightest galaxy, at L ∼ 4 × 10^{11} L_⊙, is typical for BCGs in similar-sized clusters at z <0.25 based on previous X-ray (Haarsma et al. 2010) or optical cluster studies (Lin & Mohr 2004; Popesso et al. 2007; Brough et al. 2008), and smaller studies extending to higher redshifts (z <1) by Whitley et al. (2008). The derived stellar mass is also consistent with other studies of BCGs from X-ray samples at similar cluster masses and redshifts (Stott et al. 2010). The derived ages from the BC03 model fits listed in Table 2 suggest that the stellar mass of these brightest galaxies had formed by the time of the observed epoch was probably complete by redshift 2 or 3, or perhaps earlier, also consistent with previous studies of stellar ages of cluster galaxies at high redshift (Collins et al. 2009; Henry et al. 2010). However this does not rule out the scenario of “dry merging” hierarchical build up of these galaxies between redshift 1.3 and 3.

3.4. NIR Luminosity Function

As a further check on the cluster galaxy properties, we measure the observed [3.6] (roughly rest H-band) luminosity function of galaxies with [3.6]-[4.5] colors consistent with the BC03 model from our initial redshift estimate. Galaxies selected as cluster members are within 1 Mpc (physical distance) of the SZ-derived center and have [3.6]-[4.5] colors within 2σ (based on each galaxy’s photometric uncertainty) of the BC03 model. We then measure the number density in 0.4 magnitude bins from the brightest cluster galaxy to 1 magnitude brighter than the measured 10σ magnitude limit (to reduce any systematic errors due to incompleteness in the catalog). Field galaxy contamination was corrected by measuring the same quantity outside of the 1 Mpc aperture and subtracting. We used the Schechter luminosity function,

\[ \Phi(m) = \Phi(*) \cdot 10^{-0.4m} \cdot \int_{0}^{\infty} \exp(-10^{0.4m}) \, dm, \]

where \( \mu = m - m^* \) and allowed \( \Phi^*, \), \( \alpha, \) and \( m^* \) to vary. The final derived parameters and uncertainties are from the least squares fit to the data and bootstrapping the whole procedure thousands of times from the catalog selection stage. We found the [3.6] best fit parameters are \( \Phi^* = 2.73 \pm 0.31 \text{arcsec}^{-2}, \alpha = -1.02 \pm 0.11 \) and \( m^* = 16.58 \pm 0.29 \text{ Vega} \), which are roughly consistent with our previous model assumptions of \( \alpha = -1.0 \) and \( m^* = 17.09 \). At this redshift, calculated from the evolving stellar population BC03 models, normalized to the Coma cluster luminosity function (see H10 for a discussion). Recent measurements of the luminosity function in evolved z > 1 clusters find a similarly flat faint-end slope, \( \alpha \) (Mancone et al. 2012). In contrast, less evolved high-redshift clusters have a paucity of faint galaxies, indicated by a shallower faint-end slope (e.g. Rudnick et al. 2012; Lemaux et al. 2012).

This best fit luminosity function also corresponds to a richness measurement of N_{gal}=47±4 using the H10 procedure (integrating the luminosity function down to m+1 within a 1 Mpc physical radius of the BCG) and is consistent with the H10 sample of SPT-SZ clusters which are drawn from the same SPT-SZ significance although sampled at a different wavelength (observed i-band).

3.5. SZ Mass Estimate

We use an SZ mass estimate as described in R12 and Benson et al. (2011), which is calculated from the Markov chain Monte Carlo (MCMC) method using available CMB, BAO, SNe, and SPT_{CL} (from the R12 cluster sample) data. The masses reported are posterior estimates based on the probability density function using the \( \xi \) and redshift for SPT-CL J0205-5829, marginalized over uncertainties in the SZ and X-ray (Y_{X}) observable-mass scaling relations and cosmology. In Table 3 we quote mass estimates with and without a Bayesian prior assumption on the underlying population of clusters. The expected bias on the flat-prior mass estimate is related to Eddington bias and affects the SPT-CL J0205-5829 mass estimate at the ~10% level. This bias is due to the steeply falling mass function which makes it more likely for SPT-CL J0205-5829 to be a lower mass cluster that scattered up, than a higher mass cluster scattering down. The total uncertainty in mass (~20%) is dominated a combination of the intrinsic scatter and the uncertainty in the normalization of the SZ-mass scaling relation.
The top panel shows the excess of surface density of galaxies (above background) consistent within 2σ of the SED model as a function of redshift. The RMS level of the overdensity is shown in dotted red. The peak overdensity is at z = 1.30 at 3.5σ above the background RMS. The middle panel shows the color-magnitude diagram of all objects within 2 arcminutes of the SPT center coordinates with red-filled black circles showing the selected galaxies from the passively-evolving model at z = 1.30 at 3.5σ above the background RMS. The bottom panel shows the Spitzer [3.6] galaxy luminosity function for SPT-CL J0205-5829. The dotted vertical line shows the best fit m* in [3.6], and the dashed line shows the [3.6] magnitude limit.

Table 3 the mass estimates are given as $M_{500}$, defined as the mass within a radius in which the cluster has a density 500 times the critical density of the universe. We can convert between this $M_{500}$ and $M_{200}$ with respect to $\rho_{\text{mean}}$, defined as the mass within a radius in which the cluster has a density 200 times the mean density of the universe, by assuming an NFW profile (Navarro et al. 1997) and the mass-concentration relation by Duffy et al. (2008). Using this conversion, the $M_{200}$ masses are a factor of ~1.8 times larger, such that the unbiased SZ mass-estimate is $M_{200}=(8.7 \pm 1.8) \times 10^{14} h_{70}^{-3} M_{\odot}$.

3.6. X-ray spectroscopy with XMM-Newton

We estimate the X-ray physical parameters of SPT-CL J0205-5829 using an iterative process over the cluster radius. We measure the core-excised X-ray temperature, $T_X$, within $r_{500}$, defined as the radius inside which the mass density is higher than 500 times the critical density of the universe. We iterate over values of $r_{500}$ so that the measured $T_X$ maintains consistency with the $M-T$ relation from Vikhlinin et al. (2009, V09).

For each value of $r_{500}$, we extract spectra and redistribution and ancillary response files. We excise all detected point sources from both the source and background regions as well as the central radius $r < 0.15 r_{500}$ cluster core region. Given the significant residual quiescent contamination (Sect. 2.4), we opt to use a local background model in the fitting procedure. For each camera, we subtract a background spectrum extracted from an annulus centered on the cluster between 160′′ and 320′′ in radius. These radii were selected based on the cumulative count rate profiles so that the annulus is not contaminated by cluster emission while still lying on the same MOS chips as the source. The total number of background-subtracted source counts is ~5500 for all three cameras. We use Xspec v12.5 to fit the spectra with a MeKaL model (Mewe et al. 1985) and the mass-concentration relation from Vikhlinin et al. (2009, V09) using C-statistics on minimally binned spectra (i.e., binning only channels to obtain ≥1 counts/bin).

From this fit to the spectrum, we measure the X-ray temperature. We then use the measured X-ray temperature and the redshift from optical spectroscopy to infer a $M_{500}$ mass from the V09 $M - T$ relation, which we also convert to a corresponding $r_{500}$ value. Given this new value of $r_{500}$, we iterate on this process until two successive $r_{500}$ estimates differ by ≤ 2.5′′ (equal to the bin size of our X-
The redshift to vary during fitting the best fit value from PN and MOS2 and more weakly in MOS1. If we allow the rest frame. 

Maughan et al. 2008). The luminosity within r is Maughan et al. 2000; Tozzi et al. 2003; Z=0.26, which is consistent with a typical mean metallicity for the ICM in a massive galaxy cluster (Z=0.3Z⊙) at lower redshifts (e.g. Matsumoto et al. 2000; Tozzi et al. 2003 Maughan et al. 2008). The luminosity within r is L_X (0.5–2.0 keV) = (3.91 ± 0.05) x 10^{44} erg s^{-1} in the rest frame.

We also note that we detect the Fe K line clearly in PN and MOS2 and more weakly in MOS1. If we allow the redshift to vary during fitting the best fit value from the joint fit is z=1.39 ± 0.02, which is ~5% larger than the optical spectroscopic redshift of z = 1.322 ± 0.001. The redshifts derived from individual cameras are 1σ consistent with the joint PN+MOS1+MOS2 fit (except MOS1 which gives a slightly lower redshift). This is one of the highest redshifts measured from X-ray spectra (cf., Lloyd-Davies et al. 2011).

3.7. Combined Mass Estimate

We follow Foley et al. (2011) and calculate a joint estimate using the SZ mass and X-ray mass estimates of SPT-CL J0205-5829. We assume the uncertainties are

Note. — Unbolded masses indicate Eddington-biased mass estimates, calculated using flat priors on mass. Note that the SZ (untargeted) flat-prior measurement suffers from a considerably different Eddington bias than the T_X (targeted) flat-prior estimate. The T_X mass estimate and the unbiased SZ ξ mass estimate were used to generate the combined mass estimate based on their probability distributions. (see Section 3.7).
uncorrelated between the two masses. This allows for a more straightforward evaluation of the posterior probability distribution function (PDF),

$$P(M|\xi, T_X) \propto P(M)P(\xi|M)P(T_X|M),$$

(2)

where $P(M)$ is the Tinker halo mass function [Tinker et al. 2008], $P(\xi|M)$ is the flat-prior SZ mass estimate PDF, and $P(T_X|M)$ is the flat-prior $T_X$ mass estimate PDF. As calculated in Sections 3.5 and 3.6, we use the X-ray and SZ mass estimates derived from the observables $T_x$ and $\xi$, respectively, which were marginalized over uncertainties in their scaling relations and cosmology. We find a combined, unbiased, mass estimate to be $M_{500} = (4.8 \pm 0.8) \times 10^{14} h^{-1} M_\odot$. Converting to $M_{200}$ as above gives $M_{200} = (8.8 \pm 1.4) \times 10^{14} h^{-1} M_\odot$.

4. DISCUSSION

The galaxy members in SPT-CL J0205-5829 were identified via $[3.6]-[4.5]$ color, and the significant overdensity of these is how this cluster was initially confirmed after it was identified by the SZ effect. The measured overdensity (richness) of these galaxies is consistent with other SPT-SZ clusters, a sample that has a median mass of $M_{500} \sim 3 \times 10^{14} h^{-1} M_\odot$. From SED fitting, the BCG and 3 other bright central galaxies have luminosities and stellar masses typical of central galaxies in clusters of similar mass at lower redshift and have derived stellar population ages greater than $\sim 3$ Gyr. This suggests that most of the eventual stellar mass in these galaxies are already present at $z \sim 1.3$ and the vast majority of these stars were formed by $z \sim 3$. The actual assembly scenario of these galaxies cannot be constrained yet.

The quiescent SEDs and the amount of $[\text{O II}]$ in the spectra of the central galaxies suggest there is very little ongoing star formation ($< 0.5 M_\odot/yr$) in the center of SPT-CL J0205-5829, meaning there is no strong cooling flow mechanism depositing new gas into these galaxies [Hu et al. 1985; Heckman et al. 1989; Crawford et al. 1999; Hatch et al. 2007; McDonald et al. 2010]. However, it should be noted that only a very strong cool-
...and producing a posterior statistical mass estimate higher redshift. We compute the expected number of clusters at higher mass and higher redshift. We follow Foley et al. (2011) and compute the probability of finding a cluster at higher mass and higher redshift. We do not see any indication of a major merger either in the X-ray morphology or galaxy distribution.

From the X-ray spectrum, we found that the cluster gas has a metallicity consistent, albeit with significant uncertainty, with massive clusters at lower redshift. This is also consistent with several studies (see Baldi et al. 2012, for a review) of ICM metal abundances over a range of redshifts that found little or no evidence of evolution from z < 1.4. Several studies have found that enrichment can happen over a timescale of 1 Gyr (Pipino & Matteucci 2004) and settle into the central region within a cluster crossing time (1 Gyr). The best-fit metallicity of SPT-CL J0205-5829 would suggest that the bulk of the metal production could have been completed by z ~ 2.5, however more X-ray observations are needed to say this with high statistical significance.

The optical and infrared data have shown that the stellar populations of the most massive central galaxies are already well-evolved, suggesting that the assembly of these galaxies happened within the preceding 2-4 Gyr. It has been suggested that this timeline may depend on the mass of the cluster, as there is some evidence that the BCGs at z > 1 in lower mass clusters have not fully assembled (Stott et al. 2010). It may become possible to see this change over the full SPT mass range and may probe different regimes where other feedback modes dominate. Such a study of a large SZ-selected sample has the potential to directly measure the build up of the stellar mass as a function of redshift and cluster mass.

4.1. Rarity

Although SPT-CL J0205-5829 was included in the sample used in R12 for cosmological analysis, we did not assign a goodness of fit to the model, so it is interesting to quantify the probability of having found this cluster in the full 2500 deg^2 SPT-SZ survey. We use the full 2500 deg^2 SPT-SZ survey area in order to avoid a posteriori selection of the area in which SPT-CL J0205-5829 was found, which could artificially boost the apparent rarity. We follow Foley et al. (2011) and compute the probability of finding a cluster at higher mass and higher redshift than SPT-CL J0205-5829. We do so by sampling the cosmological and scaling relation constraints of the CMB+BBN+BAO+HST+SN+SPT CL chain from R12 and producing a posterior statistical mass estimate \( P(M|\xi,z) \) at each step in the chain. We then compute the expected number of clusters at higher mass and higher redshift

\[
\hat{x}_{\geq z>M} = \int_0^\infty \int_0^\infty \frac{dN}{dM'dz'} \int_0^{M'} P(M''|\xi,z) dM'' dz' dM',
\]

where \( \frac{dN}{dM'dz'} \) is the mass function as calculated following Tinker et al. (2008). The median point in cosmological and scaling relation parameter space predicts \( \hat{x}_{\geq z>M} = 0.07 \) clusters at higher mass and higher redshift than SPT-CL J0205-5829 in 2500 deg^2.

However, as noted by Hotchkiss (2011), Hoyle et al. (2012); Waizmann et al. (2012a,b), this statistic has a small expectation value due to the fact that it requires a cluster of simultaneously higher mass and higher redshift than a particular object. This statistic does not consider the fact that many similarly rare clusters could exist with a slightly higher mass and lower redshift or lower mass and higher redshift. Instead, we follow the treatment of Hotchkiss (2011) and compute the probability of finding the particular value of \( \hat{x}_{\geq z>M} = 0.07 \) corresponding to SPT-CL J0205-5829 for an ensemble of simulated 2500 deg^2 surveys. We then create a normalized histogram of the resulting values of \( \hat{x}_{\geq z>M} \) for the rarest cluster in each catalog and integrate the area under the curve from 0 to the value of \( \hat{x}_{\geq z>M} \) for the particular cluster in question. This statistic, unlike \( \hat{x}_{\geq z>M} \) itself, has an expectation value of 0.5. We note that it depends only very weakly on the details of the simulation or the point in cosmological or scaling relation space at which the simulations are performed. This metric suggests that this cluster is not at all surprising with a probability of 0.69 of finding at least one cluster as rare as SPT-CL J0205-5829 in 2500 deg^2.

As a comparison to other more rare clusters in the SPT-SZ survey, using the same statistic we find 0.21 for SPT-CL J2106-5844, which was considered in Foley et al. (2011) and 0.05 for SPT-CL J0102-4915 (ACT-CL 0102-4915), currently the rarest cluster in 2500 deg^2 SPT-SZ survey.

5. SUMMARY AND CONCLUSIONS

We report the massive galaxy cluster SPT-CL J0205-5829 at z = 1.322 discovered in the first 720 deg^2 of the SPT-SZ survey and present results of follow up observations at optical, infrared, and X-ray wavelengths. The galaxy population of this cluster shows a strong red sequence with a luminosity function consistent with that of lower redshift SZ-selected clusters. Galaxy SED fits to an exponentially decaying SFR stellar population, the [Fe] abundance from the X-ray spectrum, and the lack of [O II] emission in most of the optical galaxy spectra suggest that the bulk of the star formation happened at an earlier epoch (z > 2.5). Optical spectroscopy of 9 galaxies confirms the cluster redshift at \( z = 1.322_{-0.002}^{+0.002} \), also roughly consistent with X-ray spectroscopy which gives \( z = 1.39 \pm 0.02 \). This Establishes SPT-CL J0205-5829 as the highest-redshift SZ-selected galaxy cluster verified by spectroscopy, and the second most massive SZ-selected cluster known at z > 1. Based on the X-ray temperature, SPT-CL J0205-5829 is consistent with being more massive than XMM2235 at \( z = 1.39 \) with \( T_X = 8.6_{-1.2}^{+1.3} \) from Rosati et al. (2009) (but the uncertainties in both temperatures are much larger than the measured difference).
The measured mass observables (from the SZ and X-ray temperature) are consistent and give a combined mass estimate of $M_{500} = (4.8 \pm 0.8) \times 10^{14} h_{70}^{-1} M_{\odot}$. Although not the most massive SZ-discovered cluster, it demonstrates that a cluster of this mass has enough time to form during the first 5 Gyr of the universe, and the existence of this rare object appears to be fully consistent with general expectations for a flat $\Lambda$CDM cosmological model.

In general, we find that SPT-CL J0205-5829 has properties similar to clusters with the same mass at lower redshift. This is extremely important in the context of an ultimate goal of an unbiased and low scatter mass-calibration of clusters over a wide range of redshifts for cosmological studies, and provides new insight to the assembly of the rarest and most massive structures in the universe.
