Background: Mammalian target of rapamycin (mTOR) inhibitors are used in a variety of malignancies. Infections have been reported with these drugs. We performed an up-to-date meta-analysis to further characterise the risk of infections in cancer patients treated with these agents.

Methods: Pubmed and oncology conferences’ proceedings were searched for studies from January 1966 to June 2012. Studies were limited to phase II and III randomised controlled trials (RCTs) of everolimus or temsirolimus reporting on cancer patients with adequate safety profiles. Summary incidences, relative risks (RRs), and 95% confidence intervals (CIs) were calculated.

Results: A total of 3180 patients were included. The incidence of all-grade and high-grade infections due to mTOR inhibitors was 33.1% (95% CI, 24.5–43.0%) and 5.6% (95% CI, 3.8–8.3%), respectively. Compared with controls, the RR of all-grade and high-grade infections due to mTOR inhibitors was 2.00 (95% CI, 1.76–2.28, P < 0.001) and 2.60 (95% CI, 1.54–4.41, P < 0.001), respectively. Subgroup analysis found no difference in incidences or risks between everolimus and temsirolimus or between different tumour types (renal cell carcinoma (RCC) vs non-RCC). Infections included respiratory tract (61.7%), genitourinary (29.4%), skin/soft tissue (4.2%), and others (4.9%).

Conclusion: Treatment with mTOR inhibitors is associated with a significant increase in risk of infections. Close monitoring for any signs of infections is warranted.

Mammalian target of rapamycin (mTOR) inhibitors are targeted agents that have developed into an important therapeutic drug class used in a variety of malignancies. Everolimus (Afinitor, Novartis Pharmaceuticals, East Hanover, NJ, USA) is currently approved by the Food and Drug Administration (FDA) for the treatment of several malignancies including advanced renal cell carcinoma (RCC; Motzer et al, 2008, 2010), progressive pancreatic neuroendocrine tumours (PNET; Yao et al, 2011), subependymal...
mTOR inhibitors do not usually produce the systemic toxicities that are traditionally seen with chemotherapy such as nausea, vomiting, alopecia, and bone marrow suppression. However, as more targeted agents are developed their different class-specific toxicities are emerging. Trials exploring the safety and efficacy of everolimus and temsirolimus reported some unique side effects including rash, mucositis, infection, pneumonitis, hyperlipidaemia, and hyperglycaemia (Hutson et al., 2008; Ravaud, 2011; Eosen et al., 2012). Specifically, infections were reported in both everolimus and temsirolimus trials as a common side effect, as a cause of treatment disruption, and in some cases led to fatalities (Galani et al., 2005; Ansell et al., 2008; Krueger et al., 2010; Motzer et al., 2010; Sakaria et al., 2010; Tarhini et al., 2010; Budde et al., 2012; Choueiri et al., 2013).

The association of infection with mTOR inhibitors and its possible clinical significance warrants further characterisation. We sought out to assess the magnitude of this problem by looking at the incidence and risk of infections in patients receiving mTOR inhibitors in a large, up-to-date meta-analysis of randomised control trials.

MATERIALS AND METHODS

Study selection. An independent review of the Pubmed databases from January 1966 to June 2012 was conducted. Searches were performed, limited to only human studies, with either the key terms ‘everolimus,’ ‘Afinitor,’ ‘RAD-001’ or ‘temsirolimus,’ ‘Torisel,’ ‘CCI-779.’ Citations investigating mTOR inhibitors in a non-oncological setting were excluded. Potentially relevant abstracts were collected and independently coded by four investigators (MDK, GS, CJR, and TKC). The full texts of the selected abstracts were obtained and analysed for appropriate trial design and safety reporting. Only randomised phase II or III studies with a placebo/control arm were used in order to properly calculate relative risk (RR). The Jadad scale was used to assess study quality based on study randomisation, double-blinding practice, and handling of withdrawals (Jadad et al., 1996). When more than one publication was drawn from the same clinical trial, the most recent or most complete report was used. The most recent package insert for each agent was assessed for the most current clinical information, and the manufacturer and/or the overall investigator was contacted to obtain clarification on infection information. The process was duplicated using the same search terms and limitations in the American Society of Clinical Oncology online databases of meeting abstracts from 2000 to 2012.

Data extraction. Data extraction was conducted according to the Preferred Reporting Items for Systemic Reviews of Meta-Analyses statement (Moher et al., 2009). Any discrepancies between reviewers’ classifications of publications were resolved by consensus. The following information was extracted from each study: first author’s name, year of publication, trial phase, underlying malignancy, number of enrolled patients, treatment arms, median age and range, median treatment duration and range, median overall survival and 95% confidence interval (CI), number of patients available for analysis, number of all-grade infections attributed to study drug, and number of high-grade infections attributed to study drug. All-grade and high-grade infections were defined according to the National Cancer Institute Common Toxicity Criteria version 3.0 in all trials used for the analysis.

Statistical analysis. We extracted the number of patients with all-grade and high-grade infections and the number of patients who were treated with mTOR inhibitors or control from the selected clinical trials to calculate incidence. The proportion of patients with all-grade infections and 95% CIs were derived from each trial. RRs and 95% CIs were also calculated by comparing the incidence of all-grade infection in patients assigned to mTOR inhibitors with the incidence among controls in the same trial. For studies reporting zero events in a treatment or control arm, we applied a classic half-integral continuity correction to calculate the RR and variance. We then repeated this for high-grade infections.

Statistical heterogeneity among trials included in the meta-analysis was evaluated using Cochrane’s $Q$ statistic (Cochran, 1954), and inconsistency was quantified with the $I^2$ statistic that estimates the percentage of total variation across studies due to heterogeneity rather than chance (Higgins et al., 2003). The assumption of homogeneity was considered invalid for $P$-values <0.1. To calculate the summary incidence or RRs of all-grade or high-grade infections, we combined trial-specific estimates using random-effects or fixed-effects models depending on the heterogeneity of included trials. When no substantial heterogeneity among trials was found, the summary estimate calculated on the basis of the fixed-effects model was reported by using the inverse variance method. When substantial heterogeneity among trials was observed, the summary estimate calculated on the basis of the random-effects model was reported by using the DerSimonian and Laird (1986) method that considers both within-study and between-study variations. For trials with multiple treatment groups examining varying doses of mTOR inhibitors, we combined the treatment groups for the overall analysis.

To explore the possible reasons for the heterogeneity, we conducted meta-regression analyses to see whether there was a variation in risk estimates by type of drug, underlying malignancy, type of trial, and Jadad score. In addition, we conducted sensitivity analyses by omitting one study at a time to see the influence of each trial on the overall effect estimate. Finally, publication bias was evaluated through funnel plots (that is, plots of study results against precision) and with the Begg’s and Egger’s test (Begg and Mazumdar, 1994; Egger et al., 1997). A two-tailed $P$-value of <0.05 was considered statistically significant. All statistical analyses were performed using Stata SE version 12.0 software (Stata Corporation, College Station, TX, USA).

RESULTS

Population characteristics. Our initial search yielded a total of 366 potentially relevant abstracts in Pubmed, with 309 abstracts searching for everolimus studies and 57 abstracts searching for temsirolimus studies. Two hundred and thirty-five everolimus studies and two hundred and fifty-one temsirolimus studies were immediately excluded for not being oncological studies. One study from the temsirolimus search was excluded for not relating to an mTOR-inhibiting drug. Subsequently, an additional 118 studies were excluded for one of the following reasons: non-randomised trials, phase I trials, commentaries, review articles, editorials, letters, or only study design reporting. Four everolimus studies were excluded for being duplicates or subgroup-only analyses of previously reported trial data (Motzer et al., 2010; Elsen et al., 2011; Hudes et al., 2007). Specifically, infections were reported in both everolimus and temsirolimus trials as a common side effect, as a cause of treatment disruption, and in some cases led to fatalities (Galani et al., 2005; Ansell et al., 2008; Krueger et al., 2010; Motzer et al., 2010; Sakaria et al., 2010; Tarhini et al., 2010; Budde et al., 2012; Choueiri et al., 2013).

The association of infection with mTOR inhibitors and its possible clinical significance warrants further characterisation. We sought out to assess the magnitude of this problem by looking at the incidence and risk of infections in patients receiving mTOR inhibitors in a large, up-to-date meta-analysis of randomised control trials.
292 patients or 61.7% of all infections due to mTOR inhibitors. The most common were respiratory tract infections, representing studies that reported on the underlying type of infection (infection was not otherwise specified in the studies). Of the six reported infections on mTOR inhibitors in which the type of the infection, the incidence for everolimus was 4.5% (95% CI, 2.3–8.6%) and the incidence for temsirolimus was 7.1% (95% CI, 5.2–9.7%). The incidence for the placebo/control arm was 15.5% (95% CI, 10.2–22.8%) for all-grade infections and was 1.6% (95% CI, 0.8–3.1%) for high-grade infections.

Overall incidence and types of infection. All mTOR inhibitor treatment arms were included in the analysis to calculate the overall incidence of infections. All-grade infections due to mTOR inhibitors occurred in 735 patients, representing an incidence of 33.1% (95% CI, 24.5–43.0%), whereas high-grade infections occurred in 100 patients, representing an incidence of 5.6% (95% CI, 3.8–8.3%). When subgrouped by drug type, the incidence of all-grade infections was 27.1% (95% CI, 16.5–41.0%) for everolimus and 41.8% (95% CI, 26.6–58.7%) for temsirolimus. For high-grade infection, the incidence for everolimus was 4.5% (95% CI, 2.3–8.6%) and the incidence for temsirolimus was 7.1% (95% CI, 5.2–9.7%). The incidence for the placebo/control arm was 15.5% (95% CI, 10.2–22.8%) for all-grade infections and was 1.6% (95% CI, 0.8–3.1%) for high-grade infections.

All of the studies used in the meta-analysis documented the rates of both all-grade and high-grade infections, with the exception of one temsirolimus study that did not indicate the incidence of high-grade infections. There were 262 (35.6%) reported infections on mTOR inhibitors in which the type of the infection was not otherwise specified in the studies. Of the six studies that reported on the underlying type of infection (N = 473), the most common were respiratory tract infections, representing 292 patients or 61.7% of all infections due to mTOR inhibitors.

the phase subgroups for either grade (all-grade \( P = 0.33 \); high-grade \( P = 0.57 \)). To assess the influence of each study on the overall RRs of all-grade and high-grade infection, we performed a sensitivity analysis by omitting one study at a time and found that there were no studies that had a significant impact on the overall RR.

Finally, we attempted to assess the possible association between risk of infection and increased exposure to mTOR inhibitors. In convention with other studies, we calculated the mean of the median durations of therapy as a cut-off, which was found to be 5.8 months. When comparing the RRs of all-grade and high-grade infections due to mTOR inhibitors amongst long-coursed trials

and short-coursed trials, we did not observe a statistically significant difference (all-grade \( P = 0.33 \); high-grade \( P = 0.80 \)).

**Publication bias.** The Begg’s test and the Egger’s test were conducted on the incidence and RR of all-grade infection, and both showed no evidence of publication bias (for RR of all-grade infection, Begg’s \( P = 0.54 \) and Egger’s \( P = 0.31 \)). Similarly, the Begg’s and Egger’s tests were performed on the incidence and RR of high-grade infection, and no evidence of publication bias was found (for RR of high-grade infection, Begg’s \( P = 0.55 \) and Egger’s \( P = 0.97 \)).

**DISCUSSION**

Our meta-analysis combined eight RCTs investigating mTOR inhibitors for the treatment of cancers. To our knowledge, this is the first large study of RCTs demonstrating a significant increase in the risk of infection with the use of mTOR inhibitors in cancer patients. Our analysis found that the risk of developing an infection of any grade was two-fold higher in patients treated with mTOR inhibitors. And, more importantly, there is a 2.6-fold increase in the risk of high-grade infection associated with the use of mTOR inhibitors. The observed infection risk can possibly be explained by the potential immunosuppressant effects of mTOR inhibitors. Everolimus and sirolimus, the principal active metabolite of temsirolimus, are known to inhibit interleukin (IL)-2-, IL-7-, and IL-15-driven proliferation of activated T cells and B cells (Lai and Tan, 1994; Schuler et al, 1997; Shegal, 2003; Chapman and Perry, 2004).

Although there were no statistically significant differences between temsirolimus and everolimus when comparing their RRs, there was a heavier contribution from everolimus to the RR of infection, likely because of the larger number of everolimus patients and studies used in the analysis rather than a distinctive quality of the drug.

With an increased RR of treatment-related infections, it is clear that proper monitoring, immediate intervention, and effective management is crucial to achieve the maximal therapeutic benefit of mTOR inhibitors. After reporting the incidence of infection in everolimus-treated RCC patients, which was similar to the incidence in our analysis (37% vs 33.1%; Motzer et al, 2010), the RECORD-1 Study Group subsequently published recommendations for the management of infections and other adverse events according to the grade of the event (Porta et al, 2011; Ravaud, 2011). These recommendations can be used by clinicians to effectively manage treatment-related infections. Fungal infections such as Candida and Aspergillosis, mycobacterial infections such as tuberculosis, and viral infections such as hepatitis and herpes occurred in the studies used in our analysis and were reported in the prescribing information (Novartis, 2012; Pfizer, 2012). Patients must be appropriately screened for viral, mycobacterial and fungal infections in the right clinical context. Clinicians must fully treat patients with any active infection before the initiation of mTOR inhibitors and must monitor patients during the course of treatment (Porta et al, 2011). Typically, patients with active or recently active infections are excluded from clinical trials; therefore, the true incidence of these infections could be widely under-reported. More trials and reporting on these patients must be done in order to gain more insight into the management of this subgroup of patients.

A randomised, double-blinded multicenter trial evaluated the pharmacokinetics of temsirolimus and suggested that there may indeed be a correlation between the cumulative exposure of temsirolimus and certain adverse effects including infection (Boni et al, 2005). In our meta-analysis, patients in the studies with longer treatment durations did not have more risk to develop infections than patients on studies with shorter treatment durations (\( P > 0.05 \) for all-grade and high-grade). The findings do not support the association of infection risk and cumulative exposure; however, information on the time of occurrence of infection and individual data points on treatment duration may be needed to properly investigate the association.

Despite the size of this meta-analysis, our study has several limitations. First, we only had access to the available data published in the clinical trials, so there were patient variables that were not known, such as co-morbidities, previous treatment exposure, concomitant medications, and dose interruptions. Second, patients in trials have adequate organ and haematological function, which may not be the case in common oncology practice. It is conceivable that the true incidence and risk of treatment-related adverse effects is higher in actual practice. Third, not all of the included studies were double-blinded, but blinding is not always possible with parenteral administration. Although some of the included studies were not blinded, they were all of good methodological quality. Lastly, and despite our attempts, the reported safety data did not disclose the specific aetiologies of all the infections that occurred.

In conclusion, the mTOR inhibitors everolimus and temsirolimus are associated with an increased risk of all-grade and high-grade infections. These targeted agents are of great clinical benefit in various malignancies and the benefits outweigh the risks in the vast majority of cases, and thus their FDA approval. However, the immediate detection and effective management of the potential bacterial, viral, and fungal infections that can occur with these agents is crucial for optimal patient outcomes.
