Novel Characterization and Live Imaging of Schlemm’s Canal Expressing Prox-1

Tan N. Truong1,2, Hannah Li2, Young-Kwon Hong3, Lu Chen1,2,4,5*

Introduction

Schlemm’s canal is a circumferential channel located at the iridocorneal angle in the ocular anterior chamber. It is part of the conventional aqueous humor outflow system of the anterior chamber, which accounts for 70–90% of the total aqueous humor that drains out of the eye. The endothelial cell lining of Schlemm’s canal is one of the primary sites of resistance to aqueous humor drainage and is a major determinant of intraocular pressure [1]. Intraocular pressure when elevated can often lead to glaucoma, a disease affecting approximately 60 million people worldwide and is the second leading cause of blindness globally [2]. However, the particular contribution and exact mechanisms by which this continuous endothelium monolayer of Schlemm’s canal resists aqueous humor outflow still remain largely unclear in both normal and glaucomatous eyes. It is therefore essential to enhance our knowledge on this important structure, which is a crucial understanding of the aqueous humor outflow. This may lead to new avenues toward the development of novel therapeutic intervention for relevant diseases, most notably glaucoma.

Abstract

Schlemm’s canal is an important structure of the conventional aqueous humor outflow pathway and is critically involved in regulating the intraocular pressure. In this study, we report a novel finding that prospero homeobox protein 1 (Prox-1), the master control gene for lymphatic development, is expressed in Schlemm’s canal. Moreover, we provide a novel in vivo method of visualizing Schlemm’s canal using a transgenic mouse model of Prox-1-green fluorescent protein (GFP). The anatomical location of Prox-1 in Schlemm’s canal was further confirmed by in vivo gonioscopic examination and ex vivo immunohistochemical analysis. Additionally, we show that the Schlemm’s canal is distinguishable from typical lymphatic vessels by lack of lymphatic vessel endothelial hyaluronan receptor (LYVE-1) expression and absence of apparent sprouting reaction when inflammatory lymphangiogenesis occurred in the cornea. Taken together, our findings offer new insights into Schlemm’s canal and provide a new experimental model for live imaging of this critical structure to help further our understanding of the aqueous humor outflow. This may lead to new avenues toward the development of novel therapeutic intervention for relevant diseases, most notably glaucoma.

lymphatic vessels during both developmental and pathological processes [6,13,14].

In this study, we performed mouse live imaging using our newly developed advanced imaging system and a transgenic mouse model of Prox-1-green fluorescent protein (GFP) [15,16]. The expression of GFP under the Prox-1 promoter in the transgenic mice allowed for direct and convenient visualization of lymphatic vasculatures in vivo. In doing so, we discovered that besides limbal lymphatics, Prox-1 was expressed on a previously unidentified structure at the iridocorneal angle, which was Schlemm’s canal. The anatomical location of the Prox-1+ Schlemm’s canal was further confirmed by in vivo gonioscopic examination as well as ex vivo immunohistochemical analysis. Moreover, we found that the highly recognizable Prox-1+ Schlemm’s canal was distinguishable from typical lymphatic vessels by lack of LYVE-1 expression and absence of apparent sprouting reaction when inflammatory lymphangiogenesis was induced from limbal lymphatics.

**Methods**

**Mice and anesthesia**

Transgenic Prox-1-GFP mice of FVB/N or C57BL/6 background and wildtype mice (adult mice ≥ 12 weeks of age and postnatal mice of 3 weeks of age) were used in the experiments [15]. The Prox1-GFP BAC construct was created by inserting the GFP-coding sequences under the Prox-1 promoter in a Prox-1-harboring BAC through homologous recombination by the GENSAT researchers [17]. This BAC contains a mouse genomic contig harboring all regulatory elements for Prox-1 expression and it has been shown that the Prox-1-GFP mice faithfully recapitulate Prox-1 expression in lymphatic vessels with no morphologic alternation [15]. All mice were treated according to ARVO Statement for the Use of Animals in Ophthalmic and Vision Research, and all protocols were approved by the Animal Care and Use Committee of University of Southern California or University of California, Berkeley. Local anesthesia with topical 0.5% proparacaine hydrochloride ophthalmic solution (Bausch & Laumb, Rochester, NY) and general anesthesia using a mixture of ketamine, xylazine, and acepromazine (50 mg, 10 mg, and 1 mg/kg body weight, respectively) were administered for each surgical procedure.

**In vivo imaging and gonioscopic examination**

In vivo imaging of mice was performed as we reported recently [16]. Digital brightfield and fluorescent micrographs of the Prox-1 structures were taken using an advanced and customized imaging system consisting of Zeiss Axio zoom V.16 (Carl Zeiss AG, Gottingen, Germany) and an adjustable eye and head stage holder. This non-contact imaging system with large stereomicroscope field of view allowed for imaging of whole cornea in separate brightfield and fluorescence contrast. Z-stack image captures were processed with Helicon Focus imaging software (Heliconsoft Ltd.) to obtain extended focus images with increased depth of field. Additionally, utilizing this system in conjunction with a specialized 2.0 mm mouse goniopirism (Ocular Instruments, Bellevue, WA) allowed for in vivo non-invasive brightfield and fluorescent microscopic imaging of the iridocorneal angle of the anterior chamber [18]. The experiment was repeated at least twice with six mice included in the study.

**Electron microscopy**

Eyeballs were sectioned with anterior angle intact and fixed in 2% glutaraldehyde 0.1M sodium cacodlate buffer. Tissues were then post-fixed with 1% osmium tetroxide followed by incubation with 0.5% aqueous uranyl acetate. Samples were dehydrated with series of increasing acetone concentration followed by resin embedding. Tissue blocks from 3 to 5 different locations were sectioned and mounted on copper grids. After staining with uranyl acetate and lead citrate, samples were imaged with Tecnai 12 transmission electron microscope (FEI, Hillsboro, OR).

**Suture-induced inflammatory lymphangiogenesis**

The standard suture placement model with 11-0 nylon sutures (AROSurgical, Newport Beach, CA) was used to induce corneal inflammatory lymphangiogenesis, as reported previously [19,20,21]. Sutures were placed intrastromally without penetrating into the anterior chamber. The experiment was repeated twice with four Prox-1-GFP transgenic mice included in the study.

**Immunohistochemical assays and epifluorescent and confocal microscopy**

The experiments were performed similarly as reported previously [19,20]. Briefly, 1% paraformaldehyde or acetic acid was used for tissue fixation. Cryosections of eyeballs or whole-mount full thickness tissues were blocked in 10% donkey serum and immunostained with one or two of the following antibodies: LYVE-1 (Abcam, Cambridge, MA), alpha smooth muscle actin (αSMA, Abcam), CD31 (BD Pharmingen, San Jose, CA), Prox-1 (AngioBio, Del Mar, CA), and VE-cadherin (Abcam). Samples were visualized by subsequent staining with FITC and/or Cy-3 conjugated donkey anti-rabbit and/or anti-rat antibodies (Jackson ImmunoResearch Laboratories, West Grove, PA). Samples were covered with Vector Shield mounting medium (Vector Laboratories, Burlingame, CA) and examined by an Axiomager M1 epifluorescence deconvolution microscope with AxioVision 4.8 software (Carl Zeiss AG, Gottingen, Germany). In addition, whole-mount corneal samples together with the limbal area were evaluated with a LSM 780 NLO AxioExaminer confocal microscope (Carl Zeiss AG), and z-stack images were processed with NIH Image-J and Imaris processing software to generate three-dimensional images and videos (Bitplane, Zurich, Switzerland) [22]. The experiment was repeated at least three times with eight Prox-1 transgenic and six wildtype eyes from adult mice. An additional six eyes at the postnatal age of 3 weeks were used for developmental analysis.

**Results**

**High Prox-1 GFP expression at the iridocorneal angle**

Our initial in vivo microscopic survey of the adult Prox-1-GFP transgenic mouse eye revealed a large continuous band of Prox-1 expression near the corneal limbus (Figure 1A). The in vivo diameter of this band was larger than that of the limbal or conjunctival lymphatic vessels. Further ex vivo examination confirmed there were two distinct Prox-1+ structures around the limbal area (Figure 1B and 1C). The first and more superficial structure belonged to limbal lymphatics at the ocular surface. The second and deeper structure ran along the iridocorneal angle where the cornea and the iris met. Since both trabecular meshwork and Schlemm’s canal are anatomically located at this angle, our findings suggested that this deeper Prox-1 structure was most likely either the trabecular meshwork or Schlemm’s canal.

**Gonioscopic examination of the iridocorneal angle**

As shown in Figure 2, additional evaluation of the iridocorneal angle was performed with in vivo gonioscopic examination using a specialized mouse goniopirism. As shown in Figure 2A and 2B,
views through the peripheral mirror lens allowed for a direct and unobstructed view of the iridocorneal angle. Prox-1+ expression was detected at the angle in areas absent of iris processes (IP), which were bands of pigmented tissue extending from the iris and bridging over the angle structure.

(C) Magnified right boxed region in (A) showing outer wall of Schlemm’s canal lined with endothelial cells (arrow). A typical giant vacuole (arrowhead) was observed on the inner wall of Schlemm’s canal. Scale bars, 4 μm (A); 2 μm (B, C). doi:10.1371/journal.pone.0098245.g003

Electron microscopic examination of the Schlemm’s canal

It has been shown that the Prox-1-GFP mice faithfully recapitulate the expression pattern of Prox-1 in cells and structures without causing morphological change [15]. This is also confirmed by our electron microscopic examination of the Prox-1-GFP mice where normal and typical morphology of Schlemm’s canal and trabecular meshwork was observed, as shown in Figure 3. While the outer wall of Schlemm’s canal was lined with a monolayer of endothelial cells, typical giant vacuoles were seen on the inner wall protruding from the trabecular meshwork where characteristic intertrabecular spaces were observed.
Identification of Schlemm’s canal by immunohistochemical analysis

To further identify the Prox-1+ structure at the iridocorneal angle, we next performed a series of cross-sectional immunohistochemical assays using specific antibodies against CD31, LYVE-1, and αSMA. As illustrated by a schematic diagram of the structures surrounding the iridocorneal angle and cross-sectional views of the Prox-1-GFP mice, our initial examination under both light and fluorescent microscopes showed that Prox-1 was expressed on limbal lymphatics and the iridocorneal angle where Schlemm’s canal was located (Figure 4A). Our additional evaluation by a series of immunohistochemical assays further confirmed that the Prox-1+ angle structure was Schlemm’s canal. It contained a typical central lumen in the shape of an elongated ellipse and expressed CD31 (Figure 4C), a known panendothelial cell marker present in Schlemm’s canal [23]. Moreover, this structure was negative for αSMA expression, which was detected in the ciliary muscle adjacent to the canal (Figure 4D). In contrast to the high expression of LYVE-1 on Prox-1+ limbal lymphatics, LYVE-1 was not detected on the Prox-1+ Schlemm’s canal (Figure 4B). The presence of this Prox-1+CD31+ but LYVE-1− Schlemm’s canal was also confirmed in wildtype/non Prox-1-GFP mice, as shown in Figure 5. This structure also expressed vascular endothelial (VE) cadherin, as reported previously [23]. Additionally, we have confirmed the expression pattern of Prox-1+CD31+ but LYVE-1− in the Schlemm’s canal at a developmental stage (3 weeks postnatal) in both Prox-1-GFP and wildtype mice (Figure S1 and S2) [24].

The structural morphology of Schlemm’s canal was further examined by whole-mount tissue immunohistochemical analysis. As shown in Figure 6A, the Prox-1+LYVE-1− Schlemm’s canal was readily distinguishable from the Prox-1+LYVE-1+ limbal vessels (Figure 6A). The diameter of the Schlemm’s canal varied along the circumference of the angle. Even at the thinnest portion of the canal, its diameter was equal to or greater than that of the limbal lymphatics. This confirmed our noted in vivo observation that the annular Prox-1+ angle structure, now identified as Schlemm’s canal, had a larger diameter relative to conjunctival or limbal lymphatic vessels. It was also confirmed that the limbal lymphatics were clearly in focus and Schlemm’s canal was defocused when focusing the microscope objective anteriorly at the ocular surface where LYVE-1+ non-endothelial cells were also present [12,25]. In contrast, the exact opposite was the case when the objective was focused more posteriorly with Schlemm’s canal remaining LYVE-1 negative as well (Figure 7B, right panel). This observation was also confirmed with three-dimensional rendering of confocal z-stacks (Figure 7C, Video S1).

Schlemm’s canal shows no apparent sprouting reaction during inflammatory lymphangiogenesis from limbal vessels

To further distinguish the two Prox-1+ structures we identified at the limbus and the iridocorneal angle, we assessed sprouting reaction using the standard suture-induced inflammatory lymphangiogenesis model. Our results showed that after suture placement, the Prox-1+ limbal structure generated new lymphatic branches (Figure S3). The newly formed lymphatics expressed LYVE-1 (Figure 7A; 7B, left panel). In contrast, no apparent new branches were detected from the Schlemm’s canal, which remained LYVE-1 negative as well (Figure 7B, right panel). This observation was also confirmed with three-dimensional rendering of confocal z-stacks (Figure 7C, Video S1).

Discussion

To our knowledge, this study provides the first evidence showing the high expression of the lymphatic marker Prox-1 on Schlemm’s canal endothelium. It also provides a new method for in vivo visualization of the canal in its entirety. Moreover, we have shown that the Schlemm’s canal is distinguishable from typical lymphatic endothelium by lack of LYVE-1 expression and absence of apparent sprouting reaction when inflammatory lymphangio-
genesis was induced from limbal lymphatics. The suture placement model used in this study is a relatively mild stimulus of inflammation. It offers us an ideal tool to identify the difference between limbal lymphatics and Schlemm’s canal. It is possible that alternative methods with more robust stimulation may induce sprouting from the Schlemm’s canal, which warrants further investigation.

In a previous ex vivo study on human donor eyes, it was indicated that lymphatic markers of Prox-1, LYVE-1 and podoplanin were not expressed in the Schlemm’s canal [26]. In the current mouse study, we detected negative expression of LYVE-1 and podoplanin (data not shown) but positive expression of Prox-1 both in vivo and ex vivo. The in vivo live imaging technique has many advantages over ex vivo analysis. It allows for direct detection and visualization of the Prox-1 structure at its natural location and physiological state. This in vivo method also eliminates possible morphological change or structural damage with ex vivo assays that require multiple processes of tissue sampling, fixation, and staining [16]. The current study should therefore provide more direct and accurate information on the expression pattern of Prox-1 in Schlemm’s canal. Nevertheless, it is yet to be determined whether there is a discrepancy between Prox-1 expression in human and mouse Schlemm’s canal, which is an unlikely case based on multiple studies on Prox-1 in other tissues and sites.

The significance of the study is threefold. First, the new finding that Schlemm’s canal endothelium expressed a lymphatic specific marker further suggests its closer similarities with lymphatic endothelium than with blood endothelium. As summarized in Table 1 [6,13,23,25], all three types of endothelium are known to express CD31, Prox-1 [23,27]. However, the morphology of the canal endothelium more resembles that of the lymphatic endothelium in that they both have a discontinuous basement membrane with similar extracellular matrix support structures [3]. Interestingly, it is commonly accepted that both endothelia have similar vascular origins, with both differentiating from preexisting blood vascular endothelial cells during development [4,6,7]. There has been no evidence till now that the canal expresses a lymphatic specific marker. It is important to emphasize that the expressed marker, Prox-1, is a master control gene shown to drive the vascular endothelial differentiation into the lymphatic phenotype during development and maintain this phenotype during maturity. Understanding what role Prox-1 plays during the development and maintenance of the Schlemm’s canal endothelium will be invaluable to our better understanding of this unique structure. It is possible that the vascular endothelial cells of the Schlemm’s canal is programmed for Prox-1 expression as other typical lymphatics but is somehow arrested for subsequent expression of other lymphatic markers, such as LYVE-1, to achieve its unique features and distinctive functions in the outflow pathway, which requires further exploration.

Secondly, the panel of protein markers used in this study will allow researchers to better identify, isolate, and characterize Schlemm’s canal endothelium. For example, research with Schlemm’s canal endothelium has lagged behind that of trabecular meshwork due to lack of a distinguishing protein marker [28]. Our results suggest that sorting for CD31, Prox-1, and Lyve-1 cells should provide a homogeneous population of Schlemm’s
Figure 7. Differential responses of the Prox-1\(^+\) structures during corneal inflammatory lymphangiogenesis.
