**Abstract**

Schlemm’s canal is an important structure of the conventional aqueous humor outflow pathway and is critically involved in regulating the intraocular pressure. In this study, we report a novel finding that prospero homeobox protein 1 (Prox-1), the master control gene for lymphatic development, is expressed in Schlemm’s canal. Moreover, we provide a novel in vivo method of visualizing Schlemm’s canal using a transgenic mouse model of Prox-1-green fluorescent protein (GFP). The anatomical location of Prox-1 in Schlemm’s canal was further confirmed by in vivo gonioscopic examination and ex vivo immunohistochemical analysis. Additionally, we show that the Schlemm’s canal is distinguishable from typical lymphatic vessels by lack of lymphatic vessel endothelial hyaluronan receptor (LYVE-1) expression and absence of apparent sprouting reaction when inflammatory lymphangiogenesis occurred in the cornea. Taken together, our findings offer new insights into Schlemm’s canal and provide a new experimental model for live imaging of this critical structure to help further our understanding of the aqueous humor outflow. This may lead to new avenues toward the development of novel therapeutic intervention for relevant diseases, most notably glaucoma.

**Introduction**

Schlemm’s canal is a circumferential channel located at the iridocorneal angle in the ocular anterior chamber. It is part of the conventional aqueous humor outflow system of the anterior chamber, which accounts for 70–90% of the total aqueous humor that drains out of the eye. The endothelial cell lining of Schlemm’s canal is one of the primary sites of resistance to aqueous humor drainage and is a major determinant of intraocular pressure [1]. Intraocular pressure when elevated can often lead to glaucoma, a disease affecting approximately 60 million people worldwide and is the second leading cause of blindness globally [2]. However, the particular contribution and exact mechanisms by which this continuous endothelium monolayer of Schlemm’s canal resists aqueous humor outflow still remain largely unclear in both normal and glaucomatous eyes. It is therefore essential to enhance our knowledge on this important structure, which is a crucial prerequisite for developing new therapeutic strategies.

The cellular features and specialized functions of the canal’s endothelium have recently been speculated as being both lymphatic and blood vascular in nature [3]. It was reported earlier that the Schlemm’s canal endothelia are derived from a vascular origin and retain some properties of blood vessels [4,5]. Similarly, it is reported that the endothelial cell origins of the lymphatic vessels stem from the venous vasculature, and the transcription factor, prospero-related homeobox 1 (Prox-1), is largely responsible for the induction of lymphatic endothelial cell phenotype during development [6,7]. Interestingly, there has been recent evidence to suggest that ocular lymphatics contribute to drainage of aqueous humor from the eye [8,9,10]. However, the physical and physiological relationship between Schlemm’s canal and the lymphatic system has yet to be thoroughly assessed. To date, there has been no report linking Prox-1 to the Schlemm’s canal.

Lymphatic research has progressed rapidly in recent years and the importance of the lymphatic system is now well-recognized in health and disease [11,12]. The lymphatic system is comprised of an extensive network of vessels that penetrates through most tissues of the body and carries out important functions including tissue fluid homeostasis, immune surveillance, as well as fat absorption. Since a large portion of the fluids leaked out of the blood capillaries in the peripheral tissues are returned back to the blood circulation via the lymphatic system, lymphatic dysfunction can lead to drainage disorders such as tissue swelling or lymphedema. Prox-1, the master control gene of lymphatic development, along with several other lymphatic endothelial cell markers, such as lymphatic vessel endothelial hyaluronidase receptor-1 (LYVE-1) and vascular endothelial growth factor-3 (VEGFR-3), have been extensively used in lymphatic research to allow for identification and exploration into the active growth of...
lymphangiogenesis was induced from limbal lymphatics. From typical lymphatic vessels by lack of LYVE-1 expression and highly recognizable Prox-1 was further confirmed by in vivo gonioscopic examination as well as ex vivo immunohistochemical analysis. Moreover, we found that the highly recognizable Prox-1 Schlemm’s canal was distinguishable from typical lymphatic vessels by lack of LYVE-1 expression and absence of apparent sprouting reaction when inflammatory lymphangiogenesis was induced from limbal lymphatics.

Methods

Mice and anesthesia

Transgenic Prox-1-GFP mice of FVB/N or C57BL/6 background and wildtype mice (adult mice ≥ 12 weeks of age and postnatal mice of 3 weeks of age) were used in the experiments [15]. The Proxl-GFP BAC construct was created by inserting the GFP-coding sequences under the Prox-1 promoter in a Prox-1-harboring BAC through homologous recombination by the GENSAT researchers [17]. This BAC contains a mouse genomic contig harboring all regulatory elements for Prox-1 expression and it has been shown that the Prox-1-GFP mice faithfully recapitulate Prox-1 expression in lymphatic vessels with no morphologic alternation [15]. All mice were treated according to ARVO Statement for the Use of Animals in Ophthalmic and Vision Research, and all protocols were approved by the Animal Care and Use Committee of University of Southern California or University of California, Berkeley. Local anesthesia with topical 0.5% proparacaine hydrochloride ophthalmic solution (Bausch & Lomb, Rochester, NY) and general anesthesia using a mixture of ketamine, xylazine, and acepromazine (50 mg, 10 mg, and 1 mg/kg body weight, respectively) were administered for each surgical procedure.

In vivo imaging and gonioscopic examination

In vivo imaging of mice was performed as we reported recently [16]. Digital brightfield and fluorescent micrographs of the Prox-1 structures were taken using an advanced and customized imaging system consisting of Zeiss Axio zoom V.16 (Carl Zeiss AG, Gottingen, Germany) and an adjustable eye and head stage holder. This non-contact imaging system with large stereomicroscope field of view allowed for imaging of whole cornea in separate brightfield and fluorescence contrast. Z-stack image captures were processed with Helicon Focus imaging software (Heliconsoft Ltd.) to obtain extended focus images with increased depth of field. Additionally, utilizing this system in conjunction with a specialized 2.0 mm mouse gonioprism (Ocular Instruments, Bellevue, WA) allowed for in vivo non-invasive brightfield and fluorescent microscopic imaging of the iridocorneal angle of the anterior chamber [18]. The experiment was repeated at least twice with six mice included in the study.

Electron microscopy

Eyeballs were sectioned with anterior angle intact and fixed in 2% glutaraldehyde 0.1M sodium cacodylate buffer. Tissues were then post-fixed with 1% osmium tetroxide followed by incubation with 0.5% aqueous uranyl acetate. Samples were dehydrated with series of increasing acetone concentration followed by resin embedding. Tissue blocks from 3 to 3 different locations were sectioned and mounted on copper grids. After staining with uranyl acetate and lead citrate, samples were imaged with Tecnai 12 transmission electron microscope (FEI, Hillsboro, OR).

Suture-induced inflammatory lymphangiogenesis

The standard suture placement model with 11-0 nylon sutures (AROSurgical, Newport Beach, CA) was used to induce corneal inflammatory lymphangiogenesis, as reported previously [19,20,21]. Sutures were placed intrastromally without penetrating into the anterior chamber. The experiment was repeated twice with four Prox-1-GFP transgenic mice included in the study.

Immunohistochemical assays and epifluorescent and confocal microscopy

The experiments were performed similarly as reported previously [19,20]. Briefly, 1% paraformaldehyde or acetone was used for tissue fixation. Cryosections of eyeballs or whole-mount full thickness tissues were blocked in 10% donkey serum and immunostained with one or two of the following antibodies: LYVE-1 (Abcam, Cambridge, MA), alpha smooth muscle actin (aSMA, Abcam), CD31 (BD Pharmingen, San Jose, CA), Prox-1 (AngioBio, Del Mar, CA), and VE-cadherin (Abcam). Samples were visualized by subsequent staining with FITC and/or Cy-3 conjugated donkey anti-rabbit and/or anti-rat antibodies (Jackson ImmunoResearch Laboratories, West Grove, PA). Samples were covered with Vector Shield mounting medium (Vector Laboratories, Burlingame, CA) and examined by an AxiosImager M1 epifluorescence deconvolution microscope with Axiovision 4.8 software (Carl Zeiss AG, Gottingen, Germany). In addition, whole-mount corneal samples together with the limbal area were evaluated with a LSM 780 NLO AxioExaminer confocal microscope (Carl Zeiss AG), and z-stack images were processed with NIH Image-J and Imaris processing software to generate three-dimensional images and videos (Bitplane, Zurich, Switzerland) [22]. The experiment was repeated at least three times with eight Prox-1 transgenic and six wildtype eyes from adult mice. An additional six eyes at the postnatal age of 3 weeks were used for developmental analysis.

Results

High Prox-1 GFP expression at the iridocorneal angle

Our initial in vivo microscopic survey of the adult Prox-1-GFP transgenic mouse eye revealed a large continuous band of Prox-1 expression near the corneal limbus (Figure 1A). The in vivo diameter of this band was larger than that of the limbal or conjunctival lymphatic vessels. Further ex vivo examination confirmed there were two distinct Prox-1 structures around the limbal area (Figure 1B and 1C). The first and more superficial structure belonged to limbal lymphatics at the ocular surface. The second and deeper structure ran along the iridocorneal angle where the cornea and the iris met. Since both trabecular meshwork and Schlemm’s canal are anatomically located at this angle, our findings suggested that this deeper Prox-1 structure was most likely either the trabecular meshwork or Schlemm’s canal.

Gonioscopic examination of the iridocorneal angle

As shown in Figure 2, additional evaluation of the iridocorneal angle was performed with in vivo gonioscopic examination using a specialized mouse gonioprism. As shown in Figure 2A and 2B,
views through the peripheral mirror lens allowed for a direct and unobstructed view of the iridocorneal angle. Prox-1+ expression was detected at the angle in areas absent of iris processes (IP), which were bands of pigmented tissue extending from the iris and bridging over the angle structure.

Electron microscopic examination of the Schlemm’s canal

It has been shown that the Prox-1-GFP mice faithfully recapitulate the expression pattern of Prox-1 in cells and structures without causing morphological change [15]. This is also confirmed by our electron microscopic examination of the Prox-1-GFP mice where normal and typical morphology of Schlemm’s canal and trabecular meshwork was observed, as shown in Figure 3. While the outer wall of Schlemm’s canal was lined with a monolayer of endothelial cells, typical giant vacuoles were seen on the inner wall protruding from the trabecular meshwork where characteristic intertrabecular spaces were observed.

A typical giant vacuole (arrowhead) was observed on the inner wall of Schlemm’s canal. Scale bars, 4 μm (A); 2 μm (B, C).

doi:10.1371/journal.pone.0098245.g003
Identification of Schlemm’s canal by immunohistochemical analysis

To further identify the Prox-1 structure at the iridocorneal angle, we next performed a series of cross-sectional immunohistochemical assays using specific antibodies against CD31, LYVE-1, and αSMA. As illustrated by a schematic diagram of the structures surrounding the iridocorneal angle and cross-sectional views of the Prox-1-GFP mice, our initial examination under both light and fluorescent microscopes showed that Prox-1 was expressed on limbal lymphatics and the iridocorneal angle where Schlemm’s canal was located (Figure 4A). Our additional evaluation by a series of immunohistochemical assays further confirmed that the Prox-1 angle structure was Schlemm’s canal. It contained a typical central lumen in the shape of an elongated ellipse and expressed CD31 (Figure 4C), a known panendothelial cell marker present in Schlemm’s canal [23]. Moreover, this structure was negative for αSMA expression, which was detected in the ciliary muscle adjacent to the canal (Figure 4D). In contrast to the high expression of LYVE-1 on Prox-1 limbal lymphatics, LYVE-1 was not detected on the Prox-1 Schlemm’s canal (Figure 4B). The presence of this Prox-1CD31 but LYVE-1 Schlemm’s canal was also confirmed in wildtype/non Prox-1-GFP mice, as shown in Figure 5. This structure also expressed vascular endothelial (VE) cadherin, as reported previously [23]. Additionally, we have confirmed the expression pattern of Prox-1CD31 but LYVE-1 in the Schlemm’s canal at a developmental stage (3 weeks postnatal) in both Prox-1-GFP and wildtype mice (Figure S1 and S2) [24].

The structural morphology of Schlemm’s canal was further examined by whole-mount tissue immunohistochemical analysis. As shown in Figure 6A, the Prox-1LYVE-1 Schlemm’s canal was readily distinguishable from the Prox-1LYVE-1 limbal vessels (Figure 6A). The diameter of the Schlemm’s canal varied along the circumference of the angle. Even at the thinnest portion of the canal, its diameter was equal to or greater than that of the limbal lymphatics. This confirmed our noted in vivo observation that the annular Prox-1 angle structure, now identified as Schlemm’s canal, had a larger diameter relative to conjunctival or limbal lymphatic vessels. It was also confirmed that the limbal lymphatics were clearly in focus and Schlemm’s canal was defocused when focusing the microscope objective anteriorly at the ocular surface where LYVE-1 non-endothelial cells were also present [12,25]. In contrast, the exact opposite was the case when the objective was focused more posteriorly with Schlemm’s canal in clear focus while the limbal vessels were defocused (Figure 6B).

Schlemm’s canal shows no apparent sprouting reaction during inflammatory lymphangiogenesis from limbal vessels

To further distinguish the two Prox-1 structures we identified at the limbus and the iridocorneal angle, we assessed sprouting reaction using the standard suture-induced inflammatory lymphangiogenesis model. Our results showed that after suture placement, the Prox-1 limbal structure generated new lymphatic branches (Figure S3). The newly formed lymphatics expressed LYVE-1 (Figure 7A; 7B, left panel). In contrast, no apparent new branches were detected from the Schlemm’s canal, which remained LYVE-1 negative as well (Figure 7B, right panel). This observation was also confirmed with three-dimensional rendering of confocal z-stacks (Figure 7C, Video S1).

Discussion

To our knowledge, this study provides the first evidence showing the high expression of the lymphatic marker Prox-1 on Schlemm’s canal endothelium. It also provides a new method for in vivo visualization of the canal in its entirety. Moreover, we have shown that the Schlemm’s canal is distinguishable from typical lymphatic endothelium by lack of LYVE-1 expression and absence of apparent sprouting reaction when inflammatory lymphangi-
genetics was induced from limbal lymphatics. The suture placement
model used in this study is a relatively mild stimulus of
inflammation. It offers us an ideal tool to identify the difference
between limbal lymphatics and Schlemm’s canal. It is possible that
alternative methods with more robust stimulation may induce
sprouting from the Schlemm’s canal, which warrants further
investigation.

In a previous ex vivo study on human donor eyes, it was
indicated that lymphatic markers of Prox-1, LYVE-1 and
podoplanin were not expressed in the Schlemm’s canal [26]. In
the current mouse study, we detected negative expression of
LYVE-1 and podoplanin (data not shown) but positive expression
of Prox-1 both in vivo and ex vivo. The in vivo live imaging
technique has many advantages over ex vivo analysis. It allows for
direct detection and visualization of the Prox-1 structure at its
natural location and physiological state. This in vivo method also
eliminates possible morphological change or structural damage
with ex vivo assays that require multiple processes of tissue
sampling, fixation, and staining [16]. The current study should
therefore provide more direct and accurate information on the
expression pattern of Prox-1 in Schlemm’s canal. Nevertheless, it is
yet to be determined whether there is a discrepancy between Prox-1
expression in human and mouse Schlemm’s canal, which is an
unlikely case based on multiple studies on Prox-1 in other tissues
and sites.

The significance of the study is threefold. First, the new finding
that Schlemm’s canal endothelium expressed a lymphatic specific
marker further suggests its closer similarities with lymphatic
Figure 7. Differential responses of the Prox-1+ structures during corneal inflammatory lymphangiogenesis. canal endothelial cells (Table 1). Furthermore, this sorting method will simplify the exclusion criteria currently used for sorting Schlemm’s canal endothelial cells and will result in better endothelial cell harvesting efficiency.

Lastly, we have provided a new model for Schlemm’s canal research with the Prox-1-GFP transgenic mouse. Needless to say, live imaging has many advantages over conventional ex vivo investigation with dead tissues. This in vivo model for visualizing and studying Schlemm’s canal is a new tool that we hope will allow researchers to study normal and pathological aqueous outflow in real time. It should also help researchers to better understand the canal’s relationship with the lymphatic system and to what extent the lymphatic system determines intraocular pressure. Humans and mice share many common features of the aqueous outflow system more than those of rabbits and primates [29]. Thus, we believe that there is great potential that novel findings arising from this mouse model will someday translate into human clinical therapy for the treatment of ocular diseases associated with aqueous outflow, most importantly glaucoma.
