We consider strongly interacting systems of effective spins, subject to dissipative spin-flip processes associated with optical pumping. We predict the existence of novel magnetic phases in the steady state of this system, which emerge due to the competition between coherent and dissipative processes. Specifically, for strongly anisotropic spin-spin interactions, we find ferromagnetic, antiferromagnetic, spin-density-wave, and staggered-XY steady states, which are separated by nonequilibrium phase transitions meeting at a Lifshitz point. These transitions are accompanied by quantum correlations, resulting in spin squeezing. Experimental implementations in ultracold atoms and trapped ions are discussed.

DOI: 10.1103/PhysRevLett.110.257204

Exotic magnetic states play a central role in the physics of quantum many-body systems and have been explored in a wide variety of strongly correlated materials [1]. Realizing and exploring magnetic states has recently emerged as a central goal in ultracold atomic physics [2,3]. Due to highly controllable and tunable interactions, ensembles of ultracold neutral atoms and ions may provide a unique laboratory to study exotic quantum magnetism [2–9]. Among the main obstacles are relatively small energy scales associated with magnetic ordering (e.g., the superexchange scale in the Hubbard model), requiring cooling atomic systems down to very low temperatures [2], and the slow time scales involved in spin thermalization [10–12]. Furthermore, ultracold atoms are fundamentally open, driven quantum systems far from their absolute thermal equilibrium. This motivates the exploration of spin dynamics in the presence of driving and dissipation [13–30].

Recently, a number of schemes involving dissipation to create magnetic phases have been proposed. These typically use engineered reservoirs involving coupling multiple lattice sites [13–15]. At the same time, one expects single-site dissipation such as spontaneous decay to be detrimental to realizing interesting magnetic states, resulting, e.g., in unwanted decoherence. In this Letter, we demonstrate that optical pumping and spontaneous decay can instead enrich the phase diagram, resulting in new phases and phase transitions that do not exist in conventional equilibrium systems. Significantly, these novel states can be observed under conditions when the realization of conventional equilibrium states is difficult.

The key idea of this work can be understood by considering the anisotropic spin-1/2 Heisenberg model (i.e., the XYZ model), which is governed by the Hamiltonian

\[ H = \frac{1}{2d} \sum_{(mn)} (J_x \sigma^x_m \sigma^x_n + J_y \sigma^y_m \sigma^y_n + J_z \sigma^z_m \sigma^z_n), \]

where \( \sigma^x, \sigma^y, \sigma^z \) are the Pauli matrices for an effective spin \( n \). We assume that the spins are localized on a \( d \)-dimensional cubic lattice with nearest-neighbor interactions. In the presence of conventional optical pumping, this Hamiltonian is augmented with a dissipative process that flips the spins down at some rate \( \gamma \), i.e., it corresponds to the jump operator \( \sigma^+ \) on every site, where \( \sigma^+_n = (\sigma^x_n + i \sigma^y_n)/2 \).

The steady state of this open many-body system is easy to understand in the case of isotropic spin-spin interactions, namely, the XXZ model (with either ferromagnetic or antiferromagnetic couplings). For this, the Hamiltonian can be rewritten in the form \( H = (1/2d) \sum [2J_x (\sigma^+_m \sigma^-_n + \sigma^-_m \sigma^+_n) + J_z \sigma^z_m \sigma^z_n] \). This Hamiltonian conserves the total number of spins in the \( |\uparrow\rangle \) state and, therefore, does nothing to counteract the spontaneous decay. Thus, the steady state is a trivial dark state with all spins polarized, \( |\uparrow\rangle \cdots |\uparrow\rangle \), so the XXZ model never experiences a phase transition in the presence of dissipation, regardless of \( J_x \) and \( J_z \).

However, new types of magnetic order emerge for strongly anisotropic couplings. The crucial role of anisotropy can be understood as follows. Each spin experiences...
an effective magnetic field \((J_x, J_y, J_z)\), which depends on the direction of its neighbors [Fig. 2(a)]. It precesses about this effective field and also decays towards \(|\rangle\). In order for the spin to point away from \(|\rangle\) in steady state, its precession must be strong enough to counteract the decay. In the isotropic case, the spin is always parallel to the magnetic field, so there is no precession at all. On the other hand, when the couplings are sufficiently anisotropic (e.g., \(J_x = -J_y\)), the spin is roughly perpendicular to the magnetic field, so the precession is strong enough to point the spin away from \(|\rangle\) [Fig. 2(a)]. This is in sharp contrast to the thermal equilibrium state, in which the spin tries to call the staggered-dynamics spontaneous breaking of this symmetry leads to a phase we continuous symmetry emerges for certain couplings; the systems of trapped ions or systems of ultracold atoms with interactions \([32,33]\), but generally do not exist in nearest-neighbor spin models. In addition, we find that a phases that do not exist in equilibrium. The spin-density-wave diverges \([31]\); such Lifshitz points can take any value.\[\text{Equation (2)}\]

\[
\dot{\rho} = -i[H, \rho] + \gamma \sum_n \left[ \sigma_n^+ \rho \sigma_n^- + \frac{1}{2} (\sigma_n^+ \rho \sigma_n^- + \rho \sigma_n^- \sigma_n^+) \right].
\]

We begin by solving for the steady states of the model Eq. (2) at the level of mean-field theory. We allow the mean field to vary on each site to account for static exchange interactions in \(J_{xy}\) XY phases as well as spin-density-wave and staggered-XY phases that do not exist in equilibrium. The spin-density-wave, paramagnetic, and ferromagnetic phases meet at phase transitions. We describe the following phenomena outlined above. The dynamics of the many-body system are given by a master equation for the density matrix \(\rho\),

\[
\dot{\rho} = -i[H, \rho] + \gamma \sum_n \left[ \sigma_n^+ \rho \sigma_n^- + \frac{1}{2} (\sigma_n^+ \rho \sigma_n^- + \rho \sigma_n^- \sigma_n^+) \right].
\]

Equation (2) has a unique steady-state solution \([39]\), and we are interested in whether the steady state exhibits a phase transition as the parameters \(J_x, J_y, J_z\) change. Note that the decay is independent for each spin, in contrast with the Dicke model \([29,40]\). Furthermore, the spins are not in equilibrium with the environmental bath. Thus, in contrast with the spin-boson model \([41,42]\), the steady state is not the joint ground state of the system and environment.

The master equation has a \(Z_2\) symmetry \((\sigma_n^z, \sigma_n^\pm \rightarrow \sigma_n^z, -\sigma_n^\pm)\), which is spontaneously broken in the ordered phases. In practice, there may also be dephasing noise, leading to dissipative terms in Eq. (2) such as \(\sigma_n^\pm \rho \sigma_n^\mp\), since the \(Z_2\) symmetry is unaffected by these terms, the phase transitions we describe are robust to dephasing, although the phase boundaries are shifted.

**Mean-field theory.**—We begin by solving for the steady states of the model Eq. (2) at the level of mean-field theory. We allow the mean field to vary on each site to account for spatially inhomogeneous states \([21]\). The mean-field equations, which are simply nonlinear Bloch equations, are

\[
\frac{d\langle \sigma_n^+ \rangle}{dt} = -\frac{\gamma}{2} \langle \sigma_n^+ \rangle + \frac{1}{d} \sum_m \left[ J_x \langle \sigma_n^x \sigma_m^x \rangle - J_y \langle \sigma_n^y \sigma_m^y \rangle - J_z \langle \sigma_n^z \sigma_m^z \rangle \right],
\]

\[
\frac{d\langle \sigma_n^- \rangle}{dt} = -\frac{\gamma}{2} \langle \sigma_n^- \rangle + \frac{1}{d} \sum_m \left[ J_x \langle \sigma_n^x \sigma_m^x \rangle - J_y \langle \sigma_n^y \sigma_m^y \rangle - J_z \langle \sigma_n^z \sigma_m^z \rangle \right],
\]

\[
\frac{d\langle \sigma_n^0 \rangle}{dt} = -\gamma \langle \sigma_n^0 \rangle + \frac{1}{d} \sum_m \left[ J_x \langle \sigma_n^x \sigma_m^x \rangle - J_y \langle \sigma_n^y \sigma_m^y \rangle - J_z \langle \sigma_n^z \sigma_m^z \rangle \right],
\]

where the sum over \(m\) is taken over nearest neighbors of \(n\). (A related model with only dephasing noise was studied in Refs. \([43,44]\). Another related model with an external field and nonlinear damping was studied using the Landau-Lifshitz-Gilbert equation \([45,46]\).)

Clearly, there is always a fixed-point solution, \(\langle \sigma_n^x \rangle = \langle \sigma_n^y \rangle = 0, \langle \sigma_n^z \rangle = -1\), in which all the spins are pointing down. We call this the paramagnetic (PM) phase, since it does not break the \(Z_2\) symmetry of Eq. (2). We now consider the linear stability of the PM phase as a function

![FIG. 2 (color online). (a) Bloch-sphere plot, showing mean-field values of \(\langle \hat{\sigma} \rangle\) (solid red arrow) and effective magnetic field (dashed blue arrow) for \(J_x = -J_y = 1, J_z = 0\). The vectors are normalized to unit length. \((b)\) and \((c)\) sXY phase in the \(xy\) plane of the Bloch sphere; \((b)\) one possible stable configuration. Black (pointing upper left) and red arrows (pointing lower right) correspond to sublattices \(A\) and \(B\). (c) The \(A\) sublattice (black solid arrow) generates a magnetic field (gray dashed arrow) that the \(B\) sublattice (red solid arrow) precesses around. Similarly, the \(B\) sublattice generates a magnetic field (pink dashed arrow) that the \(A\) sublattice precesses around. The angle \(\theta\) can take any value.](257204-2.png)
of $J_x$, $J_y$, $J_z$ [47]. We consider $d$-dimensional perturbations with wave vector $\vec{k} = (k_1, k_2, \ldots, k_d)$ where $k_\ell = 2\pi/a_\ell$ and $a_\ell$ is an integer. We find that the PM phase is unstable to perturbations of wave vector $\vec{k}$ when

$$\left(\frac{\partial J_z}{\partial k_\ell} \sum_{\ell=1}^d \cos k_\ell - J_z\right) \left(\frac{\partial J_z}{\partial k_\ell} \sum_{\ell=1}^d \cos k_\ell - J_z\right) < -\frac{\gamma^2}{16} \quad (4)$$

This condition is satisfied only when the couplings are sufficiently anisotropic.

When the PM phase is unstable, the system ends up in a time-independent steady state with $\langle \sigma^x_i \rangle$, $\langle \sigma^y_i \rangle \neq 0$, so it breaks the $Z_2$ symmetry of the master equation. There are four types of ordered phases. (i) A spatially uniform state, which we call the ferromagnetic (FM) phase, resulting from instability of the PM phase to $k_\ell = 0$ for all $\ell$. (ii) A spatially modulated state with a period of two lattice sites in all directions; i.e., the system divides into two sublattices. We call this the antiferromagnetic (AFM) phase, and it results from instability to $k_\ell = \pi$ for all $\ell$. (iii) A spatially modulated state with a period greater than two lattice sites in at least one direction, which we call the spin-density-wave (SDW) phase. This results from instability to all other $k_\ell$. (iv) When $J_z = 0$, there is also a staggered-XY (sXY) phase, resulting from instability to both $k_\ell = 0, \pi$, which is discussed below. The phase diagram is shown in Fig. 1. The transitions from the PM phase are continuous, whereas the FM-AFM transition is discontinuous.

We note two unusual features of this phase diagram. First, along the boundary between the PM and SDW phases, the $\vec{k}$ value at which the instability of the PM occurs approaches 0, meaning that the period of the SDW diverges [Fig. 3(a)]. This line culminates in a multicritical Lifshitz point [31] between the PM, FM, and SDW phases. Lifshitz points occur in magnetic models with competing interactions [32,33] but are not found in equilibrium nearest-neighbor magnets; thus, their existence in nearest-neighbor magnets out of equilibrium indicates that nonequilibrium phase diagrams can be qualitatively richer than those in equilibrium. Lifshitz points show enhanced fluctuation effects relative to conventional critical points [31] and, hence, offer a rich venue for studying quantum fluctuations away from equilibrium.

The second distinctive feature of the phase diagram is that the ordered phase breaks a continuous symmetry when $J_z = 0$. In this case, the system divides into two sublattices as in the AFM phase. However, the angle between the two sublattices can take any value. In the specific case of $J_x = -J_y$, the spins on the $A$ and $B$ sublattices are at angles $\theta$ and $-\theta$ relative to the $x = y$ line on the Bloch sphere [Fig. 2(b)]. Any value of $\theta$ corresponds to a stable configuration, since the sublattices remain perpendicular to each other’s magnetic field [Fig. 2(c)]. Upon ordering, this continuous $U(1)$ symmetry between the sublattice spin orientations is spontaneously broken, leading to a phase we call the sXY phase. This phase has vortexlike topological defects around which the relative orientation between $A$- and $B$-sublattice spins rotates by $2\pi$.

Comparison with equilibrium.—It is instructive to contrast the above results with the equilibrium case (for $d > 1$). The equilibrium ground state of Eq. (1) is ordered for any $J_x$, $J_y$, $J_z$ [48]. The magnetization axis is determined by the strongest of the coupling constants, and the sign of that coupling determines whether the ordering is ferromagnetic or antiferromagnetic. Evidently, the nonequilibrium phase diagram exhibits qualitatively different behavior from this equilibrium case. The qualitative differences between equilibrium and nonequilibrium remain even in the limit $\gamma \to 0$, although the steady state takes an increasingly long time to reach.

Fluctuation effects.—We now turn from mean-field theory to an analysis of fluctuations. Such an analysis was recently performed for driven polariton condensates [49] and suggests that the static critical properties (i.e., renormalization-group fixed points) of a driven Markovian system are related to finite-temperature equilibrium critical properties. This would indicate that the dissipative XYZ model discussed here undergoes true phase transitions in two or more dimensions.

We estimate fluctuation effects and squeezing in the Gaussian approximation by mapping the spins to hard-core bosons [48]: $\sigma^x_i \to b^\dagger_i b_i$, $\sigma^y_i \to 2b^\dagger_i b_i - 1$. This gives a reliable approximation in the PM phase, where $\langle \sigma^z_i \rangle = -1$. To Gaussian order (which includes relaxing the hard-core constraint), the resulting Hamiltonian is

$$H = \frac{1}{2d} \left\{ (J_x + J_y) \sum_{\langle mn \rangle} (b^\dagger_m b_n + b_m b^\dagger_n) + (J_x - J_y) \right.$$

$$\times \sum_{\langle mn \rangle} (b^\dagger_m b_n + b_m b_n) - 4dJ \sum_n b^\dagger_n b_n \right\}.$$  

257204-3
and the dissipative terms in the master equation are 
\[ \gamma \sum_i (b_i \rho b_i^\dagger - (1/2)(b_i^\dagger b_i \rho + \rho b_i^\dagger b_i^\dagger)) \]. We now use standard Keldysh path-integral techniques [50] to compute the relaxation rate, \( \langle \sigma \rangle \) and the squeezing. We summarize the results here and provide details in the Supplemental Material [37].

(1) Relaxation rate.—The rate at which the steady state is approached can be read off from the poles of the retarded Green’s function. For notational simplicity, we assume \( d = 1 \) here. In the Gaussian approximation, the lowest pole has complex frequency \(-i\gamma/2 \pm 2\sqrt{(J_x \cos K - J_y)(J_x \cos K - J_y)}\). A continuous phase transition occurs when the frequency of this pole approaches zero; this precisely recovers Eq. (4).

(2) Below-threshold fluctuations.—Near the transition, one expects to find nonanalytic behavior in the number of up spins, \( \sum_i \langle \sigma_i^z \rangle \). For \( J_z = 0 \), this scales as \( \langle \sigma_z \rangle \sim (\gamma^2 + 16J_x J_y)^{(d-2)/2} \). The divergence for \( d = 1 \) renders the Gaussian approximation inconsistent and is related, as we shall show in a future work, to the absence of a phase transition in one dimension (consistent with the polariton-BEC case [49]).

(3) Squeezing.—We find that spin squeezing, a measure of quantum correlations, persists near the transition. It can be calculated using the definition of squeezing for bosons \([51]\) \( \xi^2 = 1 + 2(\langle b_i^\dagger b_i \rangle - \langle b_i \rangle^2) - 2(\langle b_i^\dagger \rangle - \langle b_i \rangle)^2 \). For the case of \( J_z = 0 \), as the phase boundary is approached, \( \xi^2 \rightarrow 1/2 \) in the thermodynamic limit for the \( k = 0 \), \( \pi \) modes, signaling the presence of quantum correlations [Fig. 3(b)].

Comparison with numerics.—We have also simulated the Eq. (2) in one dimension (1D) using the method of quantum trajectories [52]. Although there is presumably no phase transition in 1D, the numerical results already show qualitative features predicted by mean-field theory. For example, when mean-field theory predicts FM, the correlation \( \langle \sigma_m \sigma_n \rangle \) is positive for all distances [Fig. 4(a)]. When there should be AFM, the correlation alternates sign. When there should be SDW, the correlation varies with a wavelength that matches the mean-field value. When there should be sXY, \( \langle \sigma_m \sigma_n \rangle \) is 0 for odd distances and positive for even distances [Fig. 4(b)]. Furthermore, the gap of the Liouvillian approaches 0 at the boundary of the PM phase, consistent with the Gaussian approximation (see Supplemental Material [37]).

Experimental realization.—The dissipative XYZ model can be implemented experimentally using trapped ions. One can use \(^{171}\)Yb\(^+\) and let \(|\downarrow\rangle\) and \(|\uparrow\rangle\) correspond to \( ^2S_{1/2} (F = 0, m_F = 0) \) and \( ^2D_{3/2} (F = 2, m_F = 0) \). In the presence of laser beams judiciously detuned from certain motional sidebands, the ions interact via Eq. (1) \([4,34,35]\).

\( J_x, J_y, J_z \) can be on the order of \( 1\text{–}5 \text{kHz} \), and their magnitudes and signs can be varied by changing the laser detunings [4]. By admixing a small component \((10^{-4})\) of \( ^2P_{3/2} \) using an off-resonant laser, one broadens the

![FIG. 4 (color online). Correlation function \( \langle \sigma_m^x \sigma_n^x \rangle \) for 1D chain of 16 spins, from simulating the master equation. (a) \( J_z/\gamma = 1 \), showing remnant of FM for \( J_z/\gamma = 2 \), \( J_z = 0 \) (blue circles, solid line); remnant of AFM for \( J_z/\gamma = -2 \), \( J_z = 0 \) (green triangles, dashed line); remnant of SDW for \( J_z/\gamma = 4 \), \( J_z/\gamma = 2 \) (red squares, dash-dotted line). The period of the SDW matches the mean-field prediction (5.3 sites). (b) \( J_z/\gamma = -J_x/\gamma = 1 \), \( J_z/\gamma = 0 \), showing remnant of sXY phase.](image)
