SUMMARY

It has been proposed that human cooperation is unique among animals for its scale and complexity, its altruistic nature, and its occurrence among large groups of individuals that are not closely related or are even strangers. One potential solution to this puzzle is that the unique aspects of human cooperation evolved as a result of high levels of lethal competition (i.e., warfare) between genetically differentiated groups. Although between-group migration would seem to make this scenario unlikely, the plausibility of the between-group competition model has recently been supported by analyses using estimates of genetic differentiation derived from contemporary human groups hypothesized to be representative of those that existed during the time period when human cooperation evolved. Here we examine levels of between-group genetic differentiation in a large sample of contemporary human groups selected to overcome some of the problems with earlier estimates, and compare them with those of chimpanzees. We find that our estimates of between-group genetic differentiation in contemporary humans are lower than those used in previous tests, and not higher than those of chimpanzees. Because levels of between-group competition in contemporary humans and chimpanzees are also similar, these findings suggest that the identification of other factors which differ between chimpanzees and humans may be needed to provide a compelling explanation of why humans, but not chimpanzees, display the unique features of human cooperation.
1. INTRODUCTION

Human cooperation is apparently unique among vertebrates in its combination of three features: the large number of individuals that can cooperate together, the high frequency of cooperation that involves individuals incurring a cost to their personal reproduction (i.e., ‘altruistic’ cooperation), and its occurrence within such large groups that cooperators are not closely related or are even strangers [1-4]. Thus, the long-term social relationships based on kin selection and reciprocity that underlie cooperation in many other animals, particularly other primates, appear to be insufficient to account for the evolution of cooperation in humans [1-4].

One potential solution to this puzzle is that high levels of lethal competition between groups (i.e., warfare) may have played a key role in the evolution of the unique facets of human cooperation [5-8]. A large body of empirical research suggests that humans pay special attention to in-group membership when cooperating [9-11], while theory suggests that altruistic cooperation can evolve via between-group competition provided that groups containing a higher proportion of altruists out-reproduce groups with fewer altruists more quickly than non-altruists out-reproduce altruists within groups [12]. For this process to occur, there should be sufficiently high levels of genetic differentiation between groups so that there are large differences among groups in the fraction of altruists that they contain. While the homogenizing effects of between-group migration would appear to make this scenario unlikely [13,14], it is only recently that attempts have been made to assess the role of between-group competition in the evolution of human cooperation using empirical data. Bowles [15,16] estimated levels of mortality due to between-group competition as well as levels of between-group genetic differentiation in contemporary and recently living hunter-
gatherers, and concluded that altruistic cooperation could evolve in humans if similar conditions applied during the period when this behaviour evolved (presumably the Late Pleistocene). However, there are several limitations to our understanding of between-group genetic differentiation in humans that limit our ability to evaluate the role of between-group competition in the evolution of human cooperation. First, as his benchmark value of between-group genetic differentiation, Bowles [15] used the median $F_{ST}$ values from a number of studies that assayed genetic variation using a variety of different marker systems, including Y-chromosome and mitochondrial DNA. In contrast to biparentally-inherited autosomal markers, such uniparentally-inherited markers can be very poor indicators of patterns of genome-wide genetic differentiation, and thus of the assortment of altruistic alleles within and between groups, if between-group migration is female- or male-biased, respectively, as typically occurs in human societies [17,18]. Second, most groups in these studies were separated by such large distances that they were very unlikely to have interacted. However, groups tend to be further away from one another and exchange fewer migrants the longer the time since they split from a common ancestral population, and so the amount of between-group genetic differentiation usually increases with geographical distance [19-21]. Thus, it is currently unknown if levels of between-group genetic differentiation measured at the more local scale at which most between-group competition occurs are sufficiently high for the evolution of altruistic cooperation in humans. Third, we have very little understanding of how levels of genetic differentiation between local competing human groups compare to those of other group-living animals. This comparison is important because any compelling explanation of the
evolution of human cooperation must also explain why other animals do not display the
unique features of human cooperation.

Chimpanzees represent a particularly relevant test for the human between-group
competition model, as they are one of humanity’s two closest living relatives and
represent the base-level of relatively simple, reciprocity- and kinship-based cooperation
from which human cooperation evolved [22,23]. Like humans, chimpanzees are one of
the few species in which members of one group make lethal coalitionary attacks against
members of other groups, a behaviour that has long drawn attention for its similarity to
warfare or raiding in traditional human societies [24,25]. Although direct comparisons are
difficult, the available evidence suggests that the fitness consequences of between-group
competition are as high in chimpanzees as they are in humans; for example, the fraction
of adult mortality due to between-group violence in chimpanzees may match [26] or even
exceed [27] that of humans living in traditional societies. However, whether levels of
genetic differentiation between competing groups are higher in humans than chimpanzees
is unknown, as almost all studies on genetic differentiation in chimpanzees have been
conducted at broad geographical scales [28,29] or have used uniparentally inherited
markers [30,31], and thus suffer from the same limitations as the data used in Bowles’
[15,16] models.

There are several reasons to suspect that levels of genetic differentiation between
competing groups may be higher in humans than in other primates. The first stems from
the fact that in contrast to most non-human primates, humans have a hierarchical social
structure, where multiple local groups are subsumed within a larger ethnolinguistic group
that shares a common language, culture, and ethnic identity [32]. Ethnographic evidence
suggests that most people marry within their ethnolinguistic group [33], and genetic
evidence indicates that ethnolinguistic identity predicts genetic differentiation between
groups independently of the effects of geographical distance and barriers [19-21]. The
second is that while dispersal in non-human primates usually involves a single individual
or small number of individuals dispersing from their natal group to join a nearby,
established group [34], in humans whole groups can engage in long-distance migrations
to settle new lands. This process can lead to competition between neighboring groups
whose genetic differentiation is elevated due to the previous long-distance geographical
separation between them. While a similar phenomenon occurs in chimpanzees when the
extinction of geographically intermediate groups brings previously separated groups into
competition [35,36], its frequency and scale throughout evolutionary history is likely
der lower than in humans.

Here we determine whether levels of autosomal genetic differentiation between
local human groups reach the levels previously suggested [15,16] as sufficient to allow
the evolution of unique facets of human cooperation via group competition, and further
examine whether values in humans exceed those in chimpanzees. In an attempt to
compensate for the necessity of using samples of contemporary humans to infer levels of
between-group genetic differentiation that existed during the time period when human
cooperation evolved, we examined between-group genetic differentiation in a large
sample of many different types of human societies across the world. While previous
studies [15,16] only considered hunter-gatherers, it has been argued that recent hunter-
gatherers live in more marginal habitats than those of Pleistocene hunter-gatherers, whose
resource-rich habitats (e.g., oceanic coasts) may have resulted in higher levels of
sedentism, population density, polygyny, and endogamy that are more similar to those of contemporary food-producing societies [37,38]. Thus, rather than limiting our comparisons to hunter-gatherers, we also examined levels of between-group genetic differentiation in traditional (i.e., non-industrialized) food-producing human societies. As a further step towards ensuring that our sample of contemporary human groups was representative of the full range of between-group genetic differentiation values possibly characteristic of Pleistocene hunter-gatherers, we also performed additional tests where we limited comparisons to pairs of human groups that belonged to different ethnolinguistic groups and spoke languages belonging to different language families.

2. MATERIALS AND METHODS

We used autosomal microsatellite genotypes to estimate levels of genetic differentiation between potentially competing groups of chimpanzees and humans. Using DNA extracted from feces [39], we genotyped 19 autosomal loci in 486 individuals from 18 chimpanzee groups from 3 locations (Figure 1). Genotypes from five chimpanzee groups were previously published [22,40-42], while genotypes for 13 groups were newly generated for this study. We used a two–step amplification method, where all 19 loci were combined with template DNA in an initial multiplex PCR reaction, with dilutions of the resultant PCR products subsequently amplified in singleplex PCR reactions using fluorescently labeled forward primers and unlabelled nested reverse primers [43]. We performed the necessary number of PCR replications to produce error rates of < 1%, as established in previous work [43]. Eleven of the chimpanzee groups were habituated or semi-habituated to human observation, facilitating the collection of fecal samples from
identified adult individuals. In the remaining seven unhabituated chimpanzee groups, genotypes were assigned to individuals and individuals assigned to groups following procedures described in [42]. We classified as potentially competing 25 pairs of chimpanzee groups that were separated from one another by \( \leq 20 \) km, as determined by the centre of their sampling locations (unhabituated groups) or the centre of their territory (habituated groups).

We used published autosomal microsatellite genotypes to measure levels of genetic differentiation between potentially competing human groups (Africans [44,45], Aboriginal Australians [46], Pacific islanders [47], and Native Americans [48]). Details of the laboratory procedures followed to produce autosomal genotypes are provided in the individual publications. Because the seafaring technology that would have allowed frequent competition between groups separated by oceans likely did not evolve until late in the Holocene, we only considered human groups that occupied the same land mass. Distances between human groups were determined by their sampling location, or if unavailable, the centre of their traditional territory. As the geographical scale at which most between-group competition occurred during the period when human altruism evolved is unknown, we examined several different cut-off points for potentially competing human groups: those separated by \( \leq 100 \) km, \( \leq 200 \) km, \( \leq 300 \) km, \( \leq 400 \) km, and \( \leq 500 \) km. As expected, we found the highest levels of between-group genetic differentiation among potentially competing groups when we included pairs separated by up to 500 km. As we found that between-group genetic differentiation was not higher in humans than chimpanzees even when including human groups separated by up to 500 km (see results section below), we do not present the results for the more geographically
restrictive classifications of potentially competing human groups, even if it is more likely that most competition occurs at these more local scales, particularly among direct neighbors.

Genetic differentiation between groups was calculated using $D$ [49] and $F_{ST}$ [50]. $D$ measures the actual relative degree of differentiation of allele frequencies among the groups of a population. $F_{ST}$, in contrast, was designed to estimate one of the causes of differences in allele frequencies between groups, the amount of migration (other factors include mutation rate, bottlenecks, founder effects, etc.). Unlike $F_{ST}$, which is mathematically bound by the amount of within-population diversity, $D$ increases monotonically with increasing levels of allelic differentiation. Thus, $D$ is a more appropriate measure to approximate the assortment of altruistic alleles within- and between-groups, and we used $D$ values for statistical comparisons of levels of between-group genetic differentiation in chimpanzees versus humans.

We used a bootstrapping procedure to assess the statistical significance of differences in the mean of pairwise between-group $D$ values of chimpanzees and humans. Here we generated 95% confidence intervals (C.I.s) by calculating means based on 10,000 resamples (with replacement) of the pairwise $D$ values, and determined the statistical significance of differences by examination of the overlap of the 95% C.I.s. We also repeated all of our analyses with $F_{ST}$, but as they did not qualitatively change any of our conclusions concerning average levels of between-group genetic differentiation in chimpanzees versus humans, we only report $F_{ST}$ when making comparisons with the $F_{ST}$ values used by Bowles in his earlier work on this topic. In addition to comparing average pairwise $F_{ST}$, we also examine the percentage of pairwise $F_{ST}$ values in chimpanzees and
our newly assembled human data sets that are as large or larger than the benchmark value Bowles used in his original work on this topic (0.076, [15]), as well as the minimum value he considered in subsequent work (0.022, [16]). We make these comparisons because it is possible that although chimpanzees and humans do not differ in average pairwise genetic differentiation, values that are sufficiently high for the evolution of altruism may occur more frequently in humans than in chimpanzees.

We compare levels of between-group genetic differentiation in chimpanzees with three sets of human groups: (1) both groups in a dyadic comparison are hunter-gatherers (HG-HG comparisons), (2) both groups are food-producers (FP-FP), and (3) one group is a hunter-gatherer and the other group is a food-producer (HG-FP). We repeated each of these comparisons with restricted human data sets that only included pairs of groups that belonged to different ethnolinguistic groups and spoke languages belonging to different language families.

The ethnolinguistic identities, language families and subsistence systems of human groups were determined from information reported in the original publications from which we got the genetic data, and along with human and chimpanzee D and $F_{ST}$ values, are reported in the Electronic Supplementary Material. Despite the fact that African Pygmies typically speak languages that combine their native tongues with those of their immediate non-Pygmy neighbours [51], we classified all pairs of African Pygmy groups as having languages of the same language family, and all Pygmy/non-Pygmy pairs as having languages of different language families, as we felt that this classification would more closely reflect the purpose of the language family variable, namely, to assay
levels of genetic differentiation between groups where large cultural differences may inhibit between-group migration.

3. RESULTS

Overall, we found that genetic differentiation was the same or greater between pairs of chimpanzee groups than between human groups (Figure 2). Using D, the most appropriate measure of genetic differentiation for assaying the assortment of altruistic alleles within- and between-groups, we found that average genetic differentiation was significantly higher in chimpanzees ($D = 0.076, 95\%$ C.I. = 0.063 - 0.088, N = 25 pairs of groups) than in hunter-gatherers ($D = 0.040, 95\%$ C.I. = 0.035 - 0.045, N = 253). The average $D$ of hunter-gatherers doubled to 0.085 when comparisons were made only between groups with different ethnolinguistic affiliations and speaking languages belonging to different families, but did not significantly differ ($95\%$ C.I. = 0.073 - 0.099, N = 14) from that of chimpanzees.

Similarly, although genetic differentiation was higher in hunter-gatherer/food-producer ($D = 0.068, 95\%$ C.I. = 0.065 - 0.071, N = 223) and food-producer/food-producer ($D = 0.075, 95\%$ C.I. = 0.071 - 0.078, N = 539) comparisons than in hunter-gatherer/hunter-gatherer comparisons, in neither of these sets of groups were average $D$ values significantly higher than in chimpanzees. Unlike in the hunter-gatherer/hunter-gatherer comparisons, average $D$ values among hunter-gatherer/food-producer ($D = 0.068, 95\%$ C.I. = 0.065 - 0.071, N = 178) and food producer/food-producer ($D = 0.080, 95\%$ C.I. = 0.076 - 0.085, N = 254) comparisons did not substantially increase when restricted to comparisons of groups with different ethnolinguistic affiliations and speaking languages from different families.
Very similar results were obtained with the more widely used estimator of genetic differentiation, $F_{ST}$ (Table 1). The average genetic differentiation of hunter-gatherers was once again low, and values for none of the sets of human groups were higher than among chimpanzees. Notably, human pairwise $F_{ST}$ values rarely reached levels used in prior assessment of the models exploring the potential for the evolution of human cooperation via between-group competition [15,16] (Table 1). It was actually more common for chimpanzees to reach the minimum pairwise $F_{ST}$ value (0.022) recently suggested necessary for the evolution of altruism [16] than it was for hunter-gatherer/hunter-gatherer and hunter-gatherer/food-producer pairs. Only in food-producer/food-producer pairs was the percentage of pairwise comparisons that met the minimum value of 0.022 higher than in chimpanzees.

4. DISCUSSION

Using the measure of genetic differentiation (D) most appropriate for interpopulation and interspecies comparisons, we showed that average levels of small-scale genetic differentiation between human groups, even when limited to groups exhibiting marked cultural differences, are not higher than levels observed in chimpanzees. In addition, while individual pairwise estimates of $Fst$ infrequently reached threshold levels deemed sufficient for the evolution of cooperation via group competition [15,16], this occurred in both humans and chimpanzees with no consistent difference between the two species. The apparent lack of higher local genetic differentiation in humans relative to chimpanzees is surprising given our expectations based on how cultural barriers to between-group migration could lead to higher levels of genetic differentiation between local competing groups of humans than chimpanzees. However, it is also important to consider how other differences between the
species could produce the opposite effect. Of particular relevance in this regard is the lower level of autosomal genetic variation in humans than chimpanzees, likely due to a bottleneck at the recent origin of *Homo sapiens* some 200 kya, which may limit the extent of differentiation in allele frequencies between groups that have all recently diverged from the same source population [29].

Our results, while suggesting that between-group genetic differentiation in contemporary humans is not greater than in chimpanzees, do not necessarily disprove the hypothesis that high levels of competition between genetically differentiated groups led to the evolution of the unique aspects of human cooperation. Although we found that the frequency of pairwise genetic differentiation values thought to be sufficient for the evolution of altruistic cooperation was not markedly higher in contemporary humans than in chimpanzees, even when comparisons were limited to the most genetically differentiated types of human groups, we cannot definitively rule out the possibility that altruistic cooperation in humans might have evolved due to the existence of occasional or even single instances of high genetic differentiation of an isolated population. In addition, although we have attempted to infer levels of between-group genetic differentiation present at the critical time of the evolution of human cooperation in the Late Pleistocene by examining genetic differentiation in a large and diverse sample of contemporary human groups, there is as currently no way of knowing how successful we have been in this regard. This situation may change in the future as improvements in the ability to extract reliable DNA sequence information from ancient remains [52] may eventually permit the analysis of sufficient samples to describe the population structure of the observed diversity.
We suggest that while the direct and indirect fitness benefits that humans derive from between-group competition have likely been important in the evolution of human cooperation, our results imply that additional factors should be considered to explain why cooperation is so different in humans than in other animals, like chimpanzees, who also gain fitness benefits from between-group competition. In his original work on this topic, Bowles [15] argued that unlike non-human primates, where reproduction is skewed towards dominant individuals, humans possess distinctive practices which limit the ability of selfish individuals to outcompete altruists within groups, including culturally-mandated resource and information sharing, consensus decision making, collective restraints on potential aggrandizers, and monogamy. However, as some critics have noted [53,54], these ‘reproductive leveling’ mechanisms may rest on exactly the same altruistic behavior that the model purports to explain, and Bowles’ [16] subsequent model did not include a reproductive leveling term. While it is possible that variance in lifetime reproductive success is lower in humans than in chimpanzees for reasons that do not themselves rely on altruism (i.e, ecological constraints that limit the ability of particular individuals to monopolize fitness-limiting resources), the extremely slow life-history of chimpanzees means that the data necessary to make the necessary comparisons are currently unavailable.

Contemporary humans and chimpanzees differ in their cognitive abilities and capacity for language, and such factors may also have played a role in facilitating the evolution of altruistic cooperation in humans. Humans are noteworthy in the extent to which socially learned, culturally transmitted information leads to between-group variation in adaptive behavior. A number of factors, including the tendency of emigrants...
to adopt the cultural traits of their new group, can lead to more cultural than genetic
differentiation between human groups [54,55]. In this regard, our results leave open the
possibility that both genetic and cultural differentiation between groups played a role in
the evolution of altruistic cooperation [1-3,54,55].

5. ACKNOWLEDGEMENTS

We thank S. Pääbo for comments on an earlier version of the manuscript, R. Mundry for
statistical assistance, S. Tüpke for assistance with the figures, C. Boesch for discussion and
for facilitating collection of Tai chimpanzee samples, J. Mitani, D. Watts, J. Lwanga, J.
Lloyd, the Uganda Wildlife Authority and the Uganda National Council of Science and
Technology for facilitating collection of Ngogo and Kanyanchu chimpanzee samples, and J.
Friedlaender, F. Friedlaender, P. Verdu, J. Buckleton and S. Walsh for providing detailed
human genetic data. The manuscript was greatly improved by the comments of two
anonymous referees and R. Bshary. This research was supported by the Alexander von
Humboldt Foundation, the Max Planck Society, the National Science Foundation (USA), the
Leakey Foundation, the Wenner-Gren Foundation, and the Cleveland Metroparks Zoo.
