X-Box Binding Protein 1 Is Essential for Insulin Regulation of Pancreatic α-Cell Function

Masaru Akiyama,1 Chong Wee Liew,1,3 Shusheng Lu,2 Jiang Hu,1 Rachael Martinez,1 Ben Hambro,4 Robert T. Kennedy,2 and Rohit N. Kulkarni1

Patients with type 2 diabetes (T2D) often exhibit hyperglucagonemia despite hyperglycemia, implicating defective α-cell function. Although endoplasmic reticulum (ER) stress has been suggested to underlie β-cell dysfunction in T2D, its role in α-cell biology remains unclear. X-box binding protein 1 (XBP1) is a transcription factor that plays a crucial role in the unfolded protein response (UPR), and its deficiency in β-cells has been reported to impair insulin secretion, leading to glucose intolerance. To evaluate the role of XBP1 in α-cells, we created complementary in vivo (α-cell-specific XBP1 knockout [αXBPKO] mice) and in vitro (stable XBP1 knockdown α-cell line [αXBPKD]) models. The αXBPKO mice exhibited glucose intolerance, mild insulin resistance, and an inability to suppress glucagon secretion after glucose stimulation. αXBPKD cells exhibited activation of inositol-requiring enzyme 1, an upstream activator of XBP1, leading to phosphorylation of Jun NH2-terminal kinase. Interestingly, insulin treatment of αXBPKD cells reduced tyrosine phosphorylation of insulin receptor substrate 1 (IRS1) (pY896) and phosphorylation of Akt while enhancing serine phosphorylation (pS307) of IRS1. Consequently, the αXBPKD cells exhibited blunted suppression of glucagon secretion after insulin treatment in the presence of high glucose. Together, these data indicate that XBP1 deficiency in pancreatic α-cells induces altered insulin signaling and dysfunctional glucagon secretion. Diabetes 62:2439–2449, 2013

In addition to the defects in β-cell secretory function and reduced β-cell mass, patients with type 2 diabetes (T2D) frequently manifest hyperglucagonemia that contributes to uncontrolled hyperglycemia (1–3). Although it is generally accepted that α-cell dysfunction is a feature of overt T2D, the mechanism(s) that contribute to the hypersecretion by α-cells is not fully understood. In addition to glucose (4), we and others have reported that insulin signaling in α-cells plays a critical role in the regulation of glucagon secretion and that impaired insulin signaling in α-cells leads to a diabetic phenotype due to enhanced glucagon secretion (5,6). Further, the α-cell has been suggested to be regulated by other intraslet paracrine factors, such as somatostatin (7), γ-aminobutyric acid (GABA) (8), and zinc ions (Zn2+) (9), in addition to insulin.

A notable feature in patients with T2D is a gradual loss of β-cell mass while their α-cell mass is maintained relatively intact (10). Although hyperglycemia, elevated free fatty acids (11), oxidative stress, and endoplasmic reticulum (ER) stress (12,13) have all been proposed to contribute to the reduced β-cell mass, the mechanisms that underlie the relative refractoriness of α-cells that are also exposed to these factors are not fully explored. The development of ER stress is typically followed by an unfolded protein response (UPR) that is mediated by three transmembrane stress sensor proteins: PKR-like ER kinase (PERK), inositol-requiring enzyme 1 (IRE1), and activating transcription factor 6 (ATF6) (14–16). IRE1 cleaves the unspliced X-box binding protein 1 (XBP1u), a member of the cAMP-responsive element–binding protein/ATF family of transcription factors, into the highly active spliced form of XBP1 (XBP1s) (17–19). XBP1s promote ER biogenesis and activate the expression of ER chaperone genes that are required for the folding and trafficking of secretory proteins (20–22). Consistent with its critical role in facilitating protein secretion, XBP1 deficiency impairs the development and function of professional secretory cells such as plasma B cells (23) and pancreatic acinar cells (24). Furthermore, a recent study reported that β-cell–specific XBP1-deficient mice (25) exhibit activation of IRE1 and β-cell dysfunction.

In the current study, we interrogated the role of XBP1 in α-cells by creating complementary in vivo (α-cell–specific XBP1 knockout mouse) and in vitro (stable XBP1 knockdown or overexpression α-cell lines) models. We observed that XBP1 deficiency in α-cells increased ER stress without significantly impacting α-cell survival. However, XBP1-deficient α-cells exhibited alterations in the regulation of glucagon secretion in response to insulin due to defective signaling as a consequence of Jun NH2-terminal kinase (JNK) activation.

**RESEARCH DESIGN AND METHODS**

**Mouse breeding and physiological experiments.** We used male mice for all experiments. Mice were housed in pathogen-free facilities and maintained on a 12-h light/dark cycle at the Foster Biomedical Research Laboratory of Brandeis University in Waltham, Massachusetts. All protocols were approved by the Brandeis University Institutional Animal Care and Use Committee and were in accordance with National Institutes of Health (NIH) guidelines. Blood glucose was monitored with a Glucometer (Elite, Bayer), plasma insulin by ELISA (Crystal Chem, Downers Grove, IL), plasma glucagon by radioimmunoprecipitation assay (RIA; Linco, St. Charles, MO), and plasma glucagon–like peptide 1 (GLP-1) by ELISA (Linco). Glucose and insulin tolerance tests were performed as described previously (26). For the pyruvate challenge test, blood glucose was monitored at 15, 30, 60, and 120 min after an intraperitoneal pyruvate injection (2 g/kg body weight).

**Islet isolation and secretion assay.** Islets were isolated from 6-month-old mice, as described previously (26). After 24-h culture in 7 mmol/L glucose, islets were used in secretion assays, as reported earlier (27). Islets were preincubated at 37°C for 30 min in Kreb’s-Ringer buffer (KR) supplemented with 5.5 mmol/L glucose, transferred to 1.5-ml tubes (15 islets per sample),
and incubated in 500 μL KRB with 2.2 or 16.7 mmol/L glucose for 1 h at 37°C. At the end of the incubation period, aliquots from each sample were stored at −20°C for glucagon and insulin assays. Ilet DNA, glucagon, and insulin were extracted from aliquots of islets, as reported earlier (27). Glucagon and insulin were measured by RIA or ELISA, as described above.

**Histological analysis and electron microscopy.** Mice were anesthetized, and the pancreas was rapidly dissected and processed, as described previously (36), and immunostained for insulin (Abcam), glucagon (Sigma-Aldrich), and somatostatin (Abcam). Photomicrographs were obtained with a charge-coupled device camera, and the β-cell, α-cell, δ-cell, and total pancreatic area were estimated using ImageJ software. For transmission electron microscopy, islets were processed at Joslin Advanced Microscopy Core (IRC) Facility, as reported previously (27).

**Cell culture.** Glucagon-secreting αTC6 cells were cultured as reported previously (6), and experiments were performed using 80–90% confluent cells.

**Lentiviral knockdown of XBP1, overexpression, and inducible system of mouse spliced XBP1.** Lentiviral vector plasmid for murine XBP1 short hairpin RNA (shRNA) and control nonsilencing (NS) shRNA were purchased from Open Biosystems. Mouse complete spliced XBP1 open reading frame was amplified from αTC6 cDNA, after thapsigargin treatment, using PCR and cloned into pCDH-CMV-MCS-EF1-Puro lentiviral vector (System Biosciences) for overexpression, and SparQ dual promoter lentiviral vector (System Biosciences) for inducible mouse spliced XBP1. We used SpatQM Cmume Switch Intron System (System Biosciences) for splicing of XBP1. Lentivirus particles were generated by following the manufacturer’s recommendation (Open Biosystems). αTC6 cells were plated 24 h before viral infection and then incubated with lentivirus for 24 h. For generating stable cell lines, we began selection with 4 μg/mL of puromycin 4 h after infection and maintained selection for ~14 days before experiments. We generated three separate stable cell lines in each group.

**SDS-PAGE and Western blotting.** Cells were lysed in RIPA buffer, as reported earlier, and total protein concentration was determined using a bicinchoninic acid assay (Pierce) (27). Samples were resuspended in reducing SDS-PAGE sample buffer, boiled, and resolved by SDS-PAGE. Proteins were subsequently transferred onto polyvinylidene difluoride membranes, blocked in blocking buffer (Thermo Scientific), and incubated with primary antibodies overnight at 4°C. XBP1, ATF6, TATA binding protein (TBP), p-insulin receptor substrate 1 (pS307), pAkt (pT308), pAkt (pS473), total Akt, p-FoxO1, pIRE1α, PERK, pJNK, JNK, p-insulin receptor substrate 1 (IRS1) (pS632), BiP, a downstream target of XBP1s, were decreased in αXBPKD mouse, the ER was severely dilated in XBPKD cells (Fig. 3A). These data indicate that XBP1 deficiency leads to phosphorylation of IRE1α and activation of JNK.

**RESULTS**

**α-Cell specific deletion of XBP1 causes glucose intolerance and insulin resistance due to dysregulated glucagon secretion.** α-Cell-specific XBP1 knockout (αXBPKO) mice were generated by crossing mice carrying the Xbp1lox allele (25,29) with mice expressing Cre recombinase driven by the glucagon promoter (6,30). The efficiency of recombination by G4mCre was consistent with our previous report (6), with ~90% of α-cells expressing β-gal (Fig. 1A).

αXBPKO mice were born normally and did not exhibit abnormalities in the postnatal period. Body weight, nonfasting blood glucose, insulin, and glucagon levels did not show significant differences between groups until age 6 months (Fig. 1B–E), when αXBPKO mice exhibited glucose intolerance (Fig. 1F) and insulin resistance (Fig. 1G). An intraperitoneal injection of glucose failed to suppress glucagon secretion in αXBPKO mice compared with a significant suppression in controls (Fig. 1H). Hepatic glucose production after pyruvate injection was also higher in αXBPKO mice compared with controls (Fig. 1I). Insulin and plasma GLP-1 levels were not significantly different between groups (Fig. 1J and K).

To investigate the potential defects in secretory function, independent of systemic signals, we examined hormone secretion from freshly isolated islets. As expected, exposure of control islets to high glucose (16.7 mmol/L) suppressed glucagon release compared with low glucose (2.2 mmol/L), whereas glucagon secretion from αXBPKO islets was unaffected by high glucose levels (Fig. 1L). However, both groups exhibited a similar insulin secretory response to high glucose stimulation (Fig. 1M), and the glucagon and insulin content of isolated islets were not significantly different (Fig. 1N and O). Taken together, these data suggest that XBP1 deficiency in α-cells leads to dysregulation of glucagon secretion and altered glucose homeostasis.

**XBPKO deficiency in pancreatic α-cells promotes ER stress without altering islet architecture.** Histomorphometric analyses of pancreatic sections in 6-month-old αXBPKO mice showed normal islet architecture (Fig. 2A and B), and no significant differences were evident in the relative areas of insulin, glucagon, or somatostatin-positive cells between groups (Fig. 2C–E). Evaluation of apoptosis by TUNEL staining and BrdU incorporation into α-cells revealed no differences between groups (data not shown).

To examine whether absence of XBP1 promotes ER stress, we performed ultrastructural analyses of pancreas sections using electron microscopy. α-Cells could be distinguished from β- and δ-cells by their distinct secretory granules (31). In the αXBPKO mouse, the ER was severely dilated in ~70% of α-cells compared with normal architecture in controls (Fig. 2F and G). These data indicate that XBP1 deficiency promotes ER stress in α-cells.

**XBPK1 deficiency leads to phosphorylation of IRE1α and activation of JNK.** To begin to investigate the mechanisms underlying the phenotype, we generated three independent stable αTC6 cell lines, each with a XBP1 knockdown (αXBPKO) or overexpressing mouse spliced XBP1 (mXBPI; αXBPOE). Stable expression of shRNA of XBP1 or mXBPIs was achieved using a lentiviral vector to transduce αTC6 cells. Nonsilencing shRNA and empty vector were used as controls for knockdown and overexpression cells, respectively. The effectiveness of knockdown or overexpression of the target protein was confirmed by Western blotting (Fig. 3A and D). In αXBPKO cells, the expression of XBPIs was reduced by ~85% after thapsigargin treatment compared with controls, and the expression of XBPIs in αXBPOE cells was ~10-fold higher than in control cells in the basal state.

Next, we examined the proteins associated with the ER stress response to high glucose stimulation (Fig. 3A), for which we carried out Western blotting. As expected, the expression of BiP, a downstream target of XBP1s, was decreased in αXBPKD cells (Fig. 3B and C). However, pIRE1α, a protein upstream of XBPI, was increased in αXBPKD cells, even
FIG. 1. α-Cell specific deletion of XBP1 promotes glucose intolerance, insulin resistance, and hyperglucagonemia. A: Immunofluorescence staining for glucagon (red), β-gal (green), and DAPI (blue) of pancreatic sections from glucagon-Cre/ROSA26-LacZ mice. Scale bar, 100 μm. B: Body weights (n = 6–10 in each group). Nonfasting blood glucose (C), nonfasting insulin (D), and nonfasting glucagon (E) in 6-month-old male mice (n = 6 in each group). F: Intraperitoneal glucose tolerance test (ipGTT; glucose 2 g/kg body weight [BW]) in 6-month-old male mice (n = 6 in each group). G: Whole-body insulin sensitivity by insulin tolerance test (ITT; insulin 0.75 units/kg BW) in 6-month-old male mice (n = 7–11 in each group). H: Plasma glucagon levels before and after intraperitoneal glucose injection (glucose 2 g/kg BW) in 6-month-old male mice (n = 7 in each group). J: Intraperitoneal pyruvate challenge (pyruvate 2 g/kg BW) in 6-month-old male mice (n = 8–10 in each group). J: Plasma insulin levels before and after intraperitoneal glucose injection (glucose 2 g/kg BW) in 6-month-old male mice (n = 7 in each group). K: GLP-1 levels before and after oral glucose gavage (at glucose doses 1 g/kg BW; n = 3–4 in each group). Total glucagon (L) and total insulin (O) content of islets expressed per microgram of total DNA (n = 3–4 in each group). Data are expressed as means ± SEM. *P < 0.05, **P < 0.01, ***P < 0.001; n.s., not significant; control vs. αXBPKO.
in the basal condition (Fig. 3B and C). These results confirm the feedback regulation of IRE1α by XBP1 in α-cells, a feature that has been reported in other cell types, including β-cells (25). Examination of other UPR markers revealed increased active ATF6 and reduced pPERK in αXBPKD cells compared with control cells (Fig. 3A–C). To explore the effects of ER stress on activation of JNK (32), we examined the expression of pJNK in the αXBPKD cells. As expected, pJNK was upregulated in αXBPKD cells compared with controls (Fig. 3B and C). The expression levels of BiP, pIRE1α, and pJNK in αXBPOE cells were virtually opposite to that observed in αXBPKD cells.

FIG. 2. α-Cell specific deletion of XBP1 causes ER stress but not cell death. Immunofluorescence staining (shown by grayscale) for insulin, glucagon, and somatostatin of pancreatic sections from control mice (A) and αXBPKO mice (B) at age 6 months (scale bar, 200 μm). Areas positive for insulin (C), glucagon (D), and somatostatin (E) are shown relative to total pancreas at age 6 months (n = 3 in each group) for control and αXBPKO mice. Data are expressed as means ± SEM. Ultrastructural analysis of pancreatic α-cells using electron microscopy was performed on islets from control (F) and αXBPKO (G) mice at age 6 months (scale bar, 2 μm). The magnification for the enlarged inset is × 43,860 (F) and × 32,520 (G).
However, active ATF6 and pPERK showed a trend that was similar in αXBPKD and αXBPOE cells compared with their respective controls (Fig. 3D–F). Taken together, these data suggest feedback mechanisms between XBP1 and IRE1α and that XBP1 deficiency activates IRE1α and phosphorylation of JNK. The alterations in ATF6 and PERK warrant further investigation.

**XBP1 deficiency impairs insulin signaling and insulin suppression of glucagon secretion.** We next examined the effects of activation of JNK on phosphorylation of IRS1. As expected, IRS1 serine phosphorylation, which has been shown to have a negative effect on IRS1 signaling in some studies (33), was significantly increased in the basal state in αXBPKD cells compared with controls (Fig. 4A and B). In contrast, IRS1 tyrosine phosphorylation was significantly lower, and consequently, Akt Thr308 and Akt Ser473 phosphorylation were both markedly decreased in αXBPKD cells after insulin stimulation (Fig. 4A and B). In
FIG. 4. XBP1 deficiency impairs insulin signaling. Western blotting for insulin receptor (IR) tyrosine phosphorylation (pIR), IR, IRS1 tyrosine phosphorylation, IRS1 Ser307 phosphorylation, total IRS1, Akt Thr308 phosphorylation, total Akt, and β-actin (loading control) in control or αXBPKD cell lines (A) and in control or αXBPOE cell lines (D) before and after insulin (Ins) treatment for 10 min (100 nmol/L). Quantification of pIRS1(Y)/IRS1, pIRS1(Ser)/IRS1, pAkt(T308)/Akt, and pAkt(S473)/Akt in control or αXBPKD cell lines (B) and in control or αXBPOE cell lines (E). Data are expressed as means ± SEM. *P < 0.05, **P < 0.01, ***P < 0.001. Glucagon secretion from control or αXBPKD cell lines (C) and control or αXBPOE cell lines (F) was assessed by static incubation for 60 min under various glucose concentrations, without or with 100 nmol/L insulin (Ins), and expressed per microgram of total DNA (n = 3–6 in each group). Data are expressed as means ± SEM. *P < 0.05, **P < 0.01; n.s., not significant.
αXBPOE cells, however, we observed decreased IRS1 serine phosphorylation after insulin stimulation, although IRS1 tyrosine phosphorylation, Akt Thr308 phosphorylation, and Akt Ser473 phosphorylation were not significantly different compared with control cells (Fig. 4D and E).

On the basis of our previous report that impaired insulin signaling in α-cells leads to enhanced glucagon secretion (6), we hypothesized that αXBPKD cells would exhibit an inability to suppress glucagon secretion by insulin. Examination of control cells revealed that glucagon secretion was maximally suppressed at 5.5 mmol/L glucose compared with 0.5 or 25 mmol/L glucose (Fig. 4C and F). These results are consistent with previous reports showing maximal suppression of glucagon secretion at ~7 mmol/L glucose concentration but paradoxically increased at higher glucose (>10 mmol/L) (34). In addition, insulin in the concentration range between 1 pmol/L and 1 μmol/L that has been reported to suppress glucagon secretion from αTC6 cells in the presence of high glucose (25 mmol/L) (35). However, the failure of 100 nmol/L insulin to suppress glucagon secretion in the presence of high glucose (25 mmol/L) suggests impaired insulin signaling in αXBPKD cells (Fig. 4C). Glucagon secretion was not significantly different between control and αXBPOE cells (Fig. 4F).

Consistent with the data in αXBKO mouse α-cells, our observation in αXBPKD cells suggests that XBPI deficiency impairs insulin signaling and induces the inability of insulin to suppress glucagon secretion.

Alterations in cytoplasmic Ca2+ in XBPI-deficient α-cells. Next, we measured cytoplasmic Ca2+ concentrations ([Ca2+]i) to assess the mechanism of dysregulation of glucagon secretion in αXBPKD cells. Consistent with previous reports (4,34), cytoplasmic [Ca2+]i oscillations in control cells were dampened by application of high glucose and insulin (Fig. 5A, C, and F). A similar trend was evident in αXBPKD cells, although the response was blunted compared with control cells (Fig. 5A, B, and F). However, the average [Ca2+]i level in αXBPKD cells when incubated in 0.5 or 25 mmol/L glucose or in 25 mmol/L glucose with 100 nmol/L insulin, was not significantly different from control cells (Fig. 5A, B, and E). On the other hand, the basal [Ca2+]i was significantly higher in αXBPOE cells compared with controls, although the [Ca2+]i oscillations were similar in the two groups (Fig. 5C–F). These data suggest that alterations in [Ca2+]i are unlikely to underlie the dysregulation of glucagon secretion in XBPI deficient α-cells. Further studies are warranted to carefully dissect the alterations in [Ca2+]i when the expression levels of XBPI are manipulated.

Chronic XBPI deficiency in α-cell line leads to decreased glucagon gene expression. Because our experiments in αXBPKD cells suggested a role for XBPI in the regulation of glucagon secretion, we next examined potential effects at the transcriptional level. Consistent with earlier reports (36,37), glucagon gene expression in control cells was significantly suppressed by insulin at a glucose concentration of 10 mmol/L but not at 2.8 mmol/L (Fig. 6A and B). In contrast, glucagon gene expression in αXBPKD cells was not suppressed by insulin, although basal glucagon gene expression was lower (Fig. 6A). On the other hand, interestingly, the ability of exogenous insulin to inhibit glucagon gene expression was obvious in αXBPOE cells (Fig. 6B).

We next examined the expression of nuclear FoxO1 because it has been reported to directly bind the proglucagon gene promoter and regulate glucagon gene expression (37). In αXBPKD cells, nuclear FoxO1 was already decreased compared with control cells in the basal state, and insulin stimulation did not promote further exclusion of FoxO1 from the nucleus (Fig. 6C and E). In contrast, stimulation of αXBPOE cells with exogenous insulin had a significant effect on FoxO1 exclusion from the nucleus (Fig. 6D and E). Together, these data suggest that XBPI regulates glucagon gene expression via the FoxO1 pathway in α-cells.

Acute induction of spliced XBPI promotes apoptosis, whereas XBPI deficiency blocks apoptosis signaling. Histological analyses of pancreas sections from αXBKO mice showed a normal complement of islet cells, indicating that absence of XBPI does not enhance α-cell death in the basal state in vivo (Fig. 2). Therefore, we next sought to study the effects of XBPI on cell growth and apoptosis in our in vitro models. First, examination of growth in αXBPKD and αXBPOE cells did not show significant differences between groups when compared with their respective controls (Fig. 7A and B). CHOP, a proapoptotic protein induced by ER stress, and active caspase 3 were significantly lower in αXBPKD cells in the basal state and after thapsigargin treatment (Fig. 7C and D). Surprisingly, αXBPOE cells also exhibited a decrease in CHOP expression after thapsigargin treatment, whereas expression of active caspase 3 was not significantly altered (Fig. 7E and F). One potential explanation for this conflicting result is that αXBPOE is a stable cell line that expresses high levels of XBPIs. This prompted us to design an experiment to examine the effects of “acute” overexpression of XBPIs by using cumate to induce XBPIs (38). After confirmation of induction of XBPIs by Western blotting (Fig. 8A), and consistent with an increased expression of XBPIs, the downstream target BiP was upregulated in the basal state (Fig. 8B). Interestingly, CHOP and active caspase 3 expression were both significantly increased after acute induction of XBPIs (Fig. 8B). Although there was no difference in the expression of pIRE1α, phosphorylation of JNK was significantly upregulated by acute induction of XBPIs (Fig. 8B). The activation of JNK is possibly related to apoptosis induced by acute induction of XBPIs, because JNK is generally activated by various cellular stress pathways (39). The expression of active ATF6 and pPERK after induction of XBPIs showed a trend that was similar to that observed in αXBPOE cells (Fig. 8A and B). These results from complementary models suggest that acute induction of XBPIs promotes, whereas a knockdown of XBPI attenuates apoptosis in α-cells.

DISCUSSION

To directly examine the role of XBPI, a transcription factor that plays a crucial role in the unfolded protein response in pancreatic α-cells, we created and phenotyped mice with a conditional knockout of XBPI (αXBKO mice). Here, we report that αXBKO mice exhibit dysregulation of glucagon secretion and impaired glucose tolerance that is secondary to activation of the IRE1α-JNK pathway and consequent inhibition of IRS1 signaling leading to altered insulin action.

Although impaired glucose utilization due to insulin resistance contributes to the hyperglycemia in patients with T2D, an increase in hepatic glucose production due to altered gluconeogenesis also contributes (40). In normal
subjects, the plasma glucagon concentration falls after oral glucose ingestion, whereas in subjects with T2D, the levels remain high (41), and some patients also exhibit a paradoxical increase in glucagon levels (42). Thus, an inability to suppress glucose production from the liver due to increased glucagon levels is associated with postprandial hyperglycemia in T2D patients. One possible mechanism underlying the hyperglucagonemia in T2D is impaired insulin signaling in $\alpha$-cells that prevents the appropriate suppression of glucagon secretion. Indeed, mice with functional disruption of insulin receptors in $\alpha$-cells ($\alpha$-IRKO) exhibit enhanced glucagon secretion and a diabetic phenotype (6). The similar phenotypes of the $\alpha$XBKO and $\alpha$IRKO models support the notion that ER stress in $\alpha$-cells is linked to altered insulin signaling and contributes to the postprandial hyperglucagonemia in T2D.

Among secretory cells, the $\beta$-cell is highly susceptible to ER stress (12,13), which may partly contribute to a significant reduction in $\beta$-cell mass in T2D, whereas $\alpha$-cell mass is relatively normal (10), despite being exposed to high glucose and/or high free fatty acid levels. Our observation that absence of XBP1 did not affect $\alpha$-cell mass in the $\alpha$XBKO mice or cell growth in the $\alpha$XBPKD cells indicates that $\alpha$-cells are relatively resistant to ER stress. One
possible reason that α-cell development and/or survival are unaffected by lack of XBP1 is a relatively lower demand for glucagon secretion compared with insulin. Nevertheless, the selective regulatory effect of XBP1 on hormone secretion but not on cell growth in the α-cell requires further investigation. It is also worth noting that XBP1 plays diverse roles in other cell types. For example, XBP1-deficient lymphoid chimeric mice are completely deficient in normal plasma B cells, although the number of activated B lymphocytes are normal (23), suggesting that XBP1 is required for the terminal differentiation of B lymphocytes to plasma cells. On the other hand, the deletion of XBP1 in pancreatic acinar cells (24) and intestinal Paneth cells (43) promoted death by apoptosis during development. In hepatocytes and salivary gland acinar cells, XBP1 deficiency led to a modest reduction of secretory protein (24,29) but did not result in cell death or any other overt pathology in these cells, suggesting that XBP1 is essential in a small subset of highly secretory cells.

Hepatocytes and adipocytes have both been reported to be susceptible to ER stress in response to obesity and exhibit inhibition of insulin signaling (44), whereas neuronal cells in the brain manifest altered leptin signaling (45). Further, XBP1 deficiency in the liver or adipose tissue induces the activation of IRE1α and of JNK, with a consequent inhibition of insulin signaling (44), a finding that is also evident in the αXBPKD cells. Taken together, our findings suggest that downregulation of PI3K-Akt signaling is associated with unsuppressed glucagon secretion in XBP1-deficient α-cells. However, the recent report that IRS1 serine phosphorylation is beneficial to insulin signaling (46) suggests the effects mediated by the IRS1/JNK pathway are dependent on context and/or cell type. The reduction in nuclear translocation of XBP1s in the livers of obese mice (47) suggests that obesity promotes XBP1s deficiency in hepatocytes. Whether obesity similarly affects other tissues, including α-cells, with consequent defects in dysregulation of glucagon secretion and hyperglucagonemia is not understood and requires investigation.

The lack of a significant alteration in \([\text{Ca}^{2+}]\) in αXBPKD cells, despite an increase in glucagon secretion, suggests cAMP is a dominant second messenger in the regulation of glucagon secretion in α-cells (48). Consistent with this possibility, other studies have reported that glucagon secretion at high glucose concentrations does not require elevation of \([\text{Ca}^{2+}]\) (34).

The complementary alteration in glucagon gene expression in αXBPKD and αXBPOE cells indicates that XBP1 regulates glucagon gene expression via FoxO1 and is consistent with previous reports in hepatocytes that XBP1 directly interacts with FoxO1 (49). However, the significantly lower basal glucagon gene expression in αXBPKD cells, despite a relatively normal glucagon secretion, suggests the regulation of glucagon translation is independent of mechanisms that modulate gene expression. It is possible that the mammalian target of rapamycin complex 1 pathway, a downstream target of Akt that
regulates protein synthesis (50), is involved in this mechanism.

In summary, we report that XBP1 interacts with proteins in the insulin-signaling pathway to regulate glucagon secretion in \( \alpha \)-cells. We propose that ER stress in \( \alpha \)-cells contributes to hyperglucagonemia and altered glucose homeostasis and that ER chaperones could be used in therapeutic approaches to modify \( \alpha \)-cell function in T2D.

FIG. 8. Acute induction of spliced XBP1 promotes apoptosis. Western blotting for spliced XBP1, active ATF6, and TBP (loading control) using nuclear fraction (A) and BIP, CHOP, cleaved caspase 3, pIRE1\( \alpha \), IRE1\( \alpha \), pPERK, PERK, pJNK, JNK, and \( \beta \)-actin (loading control) (B) in cells before and after induction of mouse spliced XBP1 by cumate (Cu, 30 \( \mu \)g/mL) without/with thapsigargin (Tg) treatment for 4 h (100 nmol/L). The blot is representative of independent experiments repeated three times.

No potential conflicts of interest relevant to this article were reported.

M.A. designed and performed research, analyzed data, and wrote the manuscript. C.W.L., J.H., R.M., and B.H. performed the experiments on \( \alpha \)-cell lines. S.L. and R.T.K. performed the experiments on Ca\(^{2+}\) measurements. R.N.K. supervised the project, designed the research, and wrote the manuscript. M.A. and R.N.K. are the guarantors of this work and, as such, had full access to all the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

The authors thank Jonathon N. Winnay, PhD (Joslin), for discussions, Christopher Cahill (Joslin), for assistance with electron microscopy, Laurie Glimcher, PhD (Weill Cornell Medical School, NY), for XBP1 floxed mice, and
Pedro Herrera, PhD (Geneva, Switzerland), for sharing the glucagon-Cre mice.
