Liver metastases from colorectal cancer (CRC) result in substantial morbidity and mortality. The primary treatment is systemic chemotherapy, and in selected patients, surgical resection; however, for patients who are not surgical candidates and/or fail systemic chemotherapy, liver-directed therapies are increasingly being utilized. Yttrium-90 (Y-90) microsphere therapy, also known as selective internal radiation therapy (SIRT) or radioembolization, has proven to be effective in terms of extending time to progression of disease and also providing survival benefit. This review focuses on the use of Y-90 microsphere therapy in the treatment of liver metastases from CRC, including a comprehensive review of published clinical trials and prospective studies conducted thus far. We review the methodology, outcomes, and side effects of Y-90 microsphere therapy for metastatic CRC.

Keywords: colorectal cancer, liver metastases, radioembolization, Yttrium-90 microspheres, Y-90 therapy, selective internal radiation therapy
RATIONAL OF RADIOEMBOLIZATION THERAPY

Radioembolization with Yttrium-90 (Y-90) microspheres is based on the same principle as that of hepatic artery infusion chemotherapy. The hepatic artery provides the primary vascular supply to the tumor with >80% of the blood flow to the tumor being derived from the hepatic artery whereas the normal liver parenchyma receives the majority of its blood flow via the portal vein. In addition, the microvascular density of the hepatic tumors is 3–200 times higher than the surrounding normal liver parenchyma (15) leading to a higher localized entrapment of microparticles in the tumor when the microparticles are infused through the hepatic artery. CRC cells are highly radio-sensitive and do not demonstrate any cross-resistance to radiation despite being chemotherapy-refractory. Additionally, radiation works synergistically when used with radiation-sensitizing chemotherapeutic drugs. Unlike external beam radiation, which is limited to treatment of small number of focal tumors due to concerns of liver toxicity with multi-focal disease, selective infusion of Y-90 microspheres allows selective "inside-out" radiation of multi-focal tumors through selective localization of the particles in the tumor vessels and localized emission of beta radiation in the tumor environment.

Because of this, Y-90 radioembolization is also known as "selective internal radiation therapy" (SIRT) or intra-arterial brachytherapy.

YITTRIUM-90 MICROSPHERES

The first intra-arterial infusion of Y-90 radio-isotope for treatment of pancreatic and primary liver cancer was reported in 1965 (16). Since that time, there have been significant advances in the production, distribution, and administration of these microspheres. Currently, there are two commercially available Y-90 labeled microsphere preparations – TheraSpheres (BTG International Canada Inc, Ottawa, ON, Canada) and SIR-spheres (Sirtex Medical Inc., Sydney, NSW, Australia). Both microspheres measure 20–60 μm in size (TheraSpheres 20–30 μm and SIR-spheres, 20–60 μm), and are designed to carry Y-90. Y-90 is a beta radiation emitter, with a half-life of 64.1 h and an average energy of 0.94 MeV. The radiation has a range of 1.1 cm (average 2.5 mm in the tissues) from the source, and 94% of the dose is delivered within the first 11 days following administration (14). The microspheres remain embedded in the vascular bed permanently without undergoing any physical or chemical change. The major differences between the two preparations are the density and specific activity (radiation dose per microsphere) of the particles, and their FDA approval (17, 18). TheraSpheres are made of glass and Y-90 is embedded within the glass matrix leading to higher density and specific activity (2500 Bq) of the preparation. SIR-spheres are made of resin and Y-90 is coated on the surface of the particle leading to lower density and low specific activity (50 Bq). The FDA approved TheraSpheres under the category of humanitarian device exemption for use in patients with unresectable hepatocellular carcinoma requiring on site institutional review board (IRB) oversight. SIR-spheres received FDA approval in 2002 as a brachytherapy device for treatment of unresectable hepatic metastases from CRC with adjuvant hepatic artery infusion of floxuridine.

ADMINISTRATION OF YTTRIUM-90 MICROSPHERES

A successful intra-tumoral administration of Y-90 microspheres involves careful patient selection, assessment of the hepatic arteries and hepato-pulmonary shunt, dose calculation, and intra-arterial delivery of the microspheres.

PATIENT SELECTION

Careful evaluation for optimal patient selection is required to optimize the outcomes and limit toxicities of Y-90 radioembolization. The recommended selection criteria are listed in Table 1 (19). Patients with poor performance status, limited hepatic reserve, and extensive multi-organ metases are poor candidates for this therapy. At many centers, baseline evaluation is performed with PET-CT to detect extra-hepatic disease and to assess the volume and biological activity of the tumor.

ASSESSMENT OF HEPATIC ARTERIES AND HEPATO-PULMONARY SHUNT

Selective intra-arterial infusion of Y-90 microspheres requires careful angiographic evaluation of the hepatic arteries to plan for lobar or segmental delivery of the microspheres, to isolate hepatic perfusion to a few arteries (so as to minimize the number of infusions or to minimize risks of extra-hepatic delivery) and to pro-actively exclude the hepatic artery branches (such as the gastroduodenal arteries) that are at risk of non-targeted delivery of the microspheres. The hepatic arterial branches that are at risk of non-target delivery are occluded (embolized) with coils.

The hepato-pulmonary shunt can lead to non-target deposition of Y-90 microspheres in the lung. Some of the microspheres escape the liver through large (>30 μm in diameter) intra-tumoral arteriovenous shunts and get entrapped in the pulmonary capillaries. The degree of shunting is estimated through intra-arterial infusion of Tc-99 m macro-aggregated albumin (4–5 mCi) and subsequent measurement of the lung and liver activity on a gamma camera. Presence of hepato-pulmonary shunt per se is not a contra-indication for treatment with Y-90 microspheres as long as the radiation dose per treatment to the lung does not exceed 30 Gy or the cumulative dose to the lungs is within 50 Gy.

DOSE CALCULATION

Dose calculation is based on the tumor volume in the liver (20). Two methods popularly used include the empiric method and the body surface area (BSA) method. In the empiric method, 2 GBq of Y-90 dose is given for a tumor volume occupying <25% of the liver, 3 GBq if the tumor volume is 25–50% of the liver volume, and 5 GBq if the tumor volume exceeds >50% of the liver volume. BSA method takes into consideration of the BSA, liver volume, and tumor volume and is tailored to the patient and the volume of the liver treated. The calculated dose in gigabecquerel is [(BSA – 0.2) + (Tumor volume/(Tumor volume + Liver volume))]. Many centers in the US follow BSA method for dose calculation (19, 21, 22). Treatment based on the dose calculated by the empiric method (especially when the tumor volume exceeds >25%) results in very high, often fatal, radiation dose to the liver and is not recommended. The dose calculations for TheraSpheres are based on partition model with an intent to deliver 80–120 Gy of radiation dose to the treated volume of the liver.

**FIGURE 1** | Assessment of response to Y-90 therapy on PET. A PET scan (A) obtained prior to Y-90 therapy demonstrates three FDG avid lesions. A repeat PET scan (B) obtained 6 weeks after Y-90 therapy shows no FDG avid lesions suggesting complete metabolic response.

**INFUSION OF YTTRIUM-90 MICROSPHERES**

Selective infusion of Y-90 microspheres is achieved through closed circuit delivery using proprietary delivery device that is specific for each company. Both lobar and whole liver infusions are practiced; authors prefer to use lobar or segmental infusions over whole liver infusions in order to limit hepatic toxicities. Post infusion imaging of the liver through SPECT or PET is often performed (though not required) to assess the hepatic uptake pattern of the microspheres.

**PATIENT FOLLOW-UP AND SUBSEQUENT TREATMENTS**

When not contraindicated, some centers administer systemic 5-fluorouracil before and after Y-90 therapy. Toxicities are assessed at 1 and 4 weeks following Y-90 therapy. In the presence of bilobar disease, Y-90 radioembolization of the other lobe is performed at 4–6 weeks from initial therapy. A follow-up PET-CT is performed at 6 weeks after second treatment. There are no standardized guidelines on timing of follow-up imaging studies to assess tumor response. PET has been shown to be useful in assessing response and guiding further treatment (Figure 1); the role of CT attenuation change of the tumor as a surrogate marker of response is currently being explored (Figure 2) (23–25). Subsequent imaging assessment is performed at 3 month intervals with PET-CT. Additional Y-90 infusions are performed (up to two treatments per lobe) if tumor recurs.

**TOXICITIES**

Most patients report fever, lethargy, decreased appetite, and fatigue following therapy. Uncommon serious adverse events include radiation-induced gastric ulcers, lymphocytopenia, jaundice, cholecystitis, lung toxicity, hepatic abscess, radiation hepatitis, and liver failure (26–29). Patients are advised to take proton pump inhibitors to prevent gastrointestinal side effects. Use of peri-procedural steroids to prevent development of fatigue or chronic liver injury is also described (29). The hepatic injury from Y-90 appears to be secondary to development of portal triaditis (29).

**OUTCOMES**

Given that Y-90 radioembolization for hepatic colorectal metastases has been used at various stages of the disease and with or without systemic or regional chemotherapy, the outcomes of this
therapy are described in this manuscript according to the timing of this therapy and systemic chemotherapy.

**YTTRIUM-90 RADIOEMBOLIZATION AS FIRST LINE THERAPY**

The first prospective study that led to FDA registration of Y-90 microspheres (SIR-spheres) for treatment of hepatic metastases from CRC included 74 patients who were randomized to receive hepatic arterial chemoinfusion (HAC) of floxuridine and single whole liver Y-90 therapy through hepatic artery access port or HAC of floxuridine alone (Table 2) (30). The final analysis included 70 patients. There was significantly higher objective response rate in patients who received Y-90 microsphere therapy in addition to HAC compared to floxuridine alone. The median survival for the patients who received Y-90 in addition to HAC was 17 months, while those who received HAC alone had a median survival of 15.9 months. The objective response rate was also higher in the group that received Y-90 in addition to HAC, with 44% responding compared to 17% in the HAC alone group. The time to progression was also significantly longer in the Y-90 plus HAC group (15.9 months) compared to the HAC alone group (9.7 months). The incidence of grade 3–4 toxicities was similar between the two groups, but there was a higher incidence of grade 3 elevation of alkaline phosphatase in the group that received Y-90 plus HAC.

CR, complete response; PR, partial response; SD, stable disease; PD, progressive disease; PFS, progression free survival; EHD, extra-hepatic disease; ORR, objective response rate; OS, overall survival; CEA, carcinoembryonic antigen; TTP, time to progression; HAC, hepatic arterial chemoinfusion.
to HAC compared to those who received HAC alone (Response rate based on WHO criteria at 3 months was 44.4% vs. 17.6%, \( p = 0.01 \)) (30). More patients in the Y-90 group demonstrated 50% or more reduction in elevated CEA levels following therapy (72.2 vs. 47.1%, \( p = 0.004 \)) (30). The median time to tumor progression (TTP) was longer in the group that received Y-90 (15.9 vs. 9.7 months). Though a trend for a survival advantage in this group was observed, it did not reach statistical significance. Authors also reported 3.1 times (95% CI: 1.1–8.8) higher risk of (ORR: 90.1 vs. 0%; \( p = 0.001 \)) (30). The results supported the fact that the addition of single infusion of Y-90 microspheres resulted in significantly higher objective response rate (ORR: 90.1 vs. 0%; \( p < 0.001 \)), longer TTP (18.6 vs. 3.6 months; \( p < 0.0005 \)), and better median survival (29.4 vs. 12.8 months; \( p = 0.025 \)). This study was limited by the small patient cohort (total of 21 patients only) and use of 5-FU and leucovorin only for chemotherapy.

Sharma et al., in a phase 1 study, assessed the toxicity and maximum tolerated dose of oxaliplatin during the first three cycles of chemotherapy (FOLFOX) when used as a radiation sensitizer for Y-90 therapy that was administrated within 3–4 days of first cycle of chemotherapy (Table 2) (32). Patients received standard dose oxaliplatin from the fourth cycle of chemotherapy (FOLFOX). Most of the patients with bilobar disease received sequential lobar infusion of Y-90 microspheres. The maximum tolerated dose was 60 mg/m² of oxaliplatin for the first three cycles, with full dose FOLFOX thereafter. The toxicity was limited to grade 3 abdominal pain in five patients, Grade 3–4 neutropenia in 12 and 1 episode of Grade 3 hepatotoxicity. They reported a 90% partial response (PR) rate at 12 weeks, median progression free survival (PFS) of 9.3 months and TTP of 12.3 months. In patients with no extra-hepatic disease, the PFS was 14.2 months. This study is significant in that it demonstrated the safety of combining Y-90 therapy with standard first line systemic chemotherapy (FOLFOX). Since it is a phase I study without randomization to a chemotherapy alone arm, it is difficult to draw conclusions on the effectiveness of such combination therapy. The median PFS and overall survival reported by the authors who applied FOLFOX regimen used as first line chemotherapy without Y-90 radioembolization range from 7.6 to 9.0 months and 16.2 to 19.5 months, respectively.

In a retrospective review, Kosmider et al. reported results of combination therapy with Y-90 microspheres and systemic chemotherapy with FOLFOX or 5-FU + leucovorin as first line therapy for hepatic metastases from colon cancer (Table 2) (33). The reported objective response rate was 84% with a median PFS of 10.4 months and median survival of 29.4 months. The median

survival was significantly better in patients with no extra-hepatic disease (37.8 vs. 13.4 m). This study is limited by small number (only 19 patients), retrospective nature, and varied chemotherapy regimens used.

In summary, Y-90 therapy in combination with first line chemotherapy is safe and may improve tumor response rates. Although a trend toward improved overall survival is reported, more data is required to establish its role in improving overall survival outcomes. There are a few large ongoing clinical studies (SIRFLOX trial: NCT00724503 and FOXFIRE trial:ISRCTN83867919) that include current standard of care chemotherapy regimens (with biological agents) with Y-90 and may help establish the benefit of Y-90 as part of first line therapy.

### Yttrium-90 Radioembolization in Combination with Second- or Third-Line Chemotherapy

Van Hazel et al. reported results of concomitant therapy of Y-90 ranged from 11 to 100% (median 41%) with most of the cases had 12 months, the overall acute toxicities were moderate, and 25% had grade 4 toxicity. Two patients from their cohort were downsized with 60 days (liver failure) after treatment, all of whom survived the median survival was 12.2 months. Grade 3–4 toxicities occurred in 12 (48%) patients.

In another study, Lim et al. reported results from a heterogeneous group of patients (n = 30) who were treated with 5-FU as first line chemotherapy (Table 3) (35). Eight of these patients failed 5-FU, 14 patients failed 5-FU and subsequent oxaliplatin and irinotecan, and 8 patients failed 5-FU and subsequent oxaliplatin or irinotecan. Thirty-three percent had PR and TTP was 5.3 months. There was 13% incidence of duodenal/gastric ulcers from non-target embolization of Yttrium-90 microspheres.

### Yttrium-90 Radioembolization as a Salvage Treatment for Chemotherapy-Refractory Disease

Multiple retrospective studies reported outcomes when Y-90 was used as salvage therapy in chemorefractory patients (Table 4) (19, 21, 22, 36–40). Bester et al. reported the results of a retrospective study to evaluate the safety and survival of patient with chemotherapy-refractory metastatic CRC to the liver treated with resin microsphere Y-90 (n = 224) compared with patients who underwent standard/supportive care (n = 51) (Table 4) (39). The median overall survival after radioembolization was 11.9 months compared to 6.3 months for the standard care cohort. The incidence of duodenal/gastric ulceration was 3.2%.

In a phase II multi-centered clinical trial for chemotherapy-refractory colorectal liver metastasis, Cosimelli reported an overall response rate of 24% using the RECIST criteria (38). The median time to progression was 3.7 months and the median overall survival was 12.6 months. Apart from two deaths at 40 days (from renal failure) and 60 days (liver failure) after treatment, all of their adverse events were classified within the WHO Grade 1/2 category. Two patients from their cohort were downsized with radioembolization to enable potential curative resection. A recent systematic review by Saxena et al. (n = 979) reported a median time to intrahepatic progression of 9 months and a median overall survival of 12 months, the overall acute toxicities ranged from 11 to 100% (median 41%) with most of the cases being mild – Grade 1/2 (median 39%), which resolved without intervention (22).

Overall, median survival is in the range of 10–12 months in these studies. The response rates are at 31% PR and 41% SD (22). Presence of large volume disease (>25% of liver volume), extra-hepatic disease, poor response to Y-90, and ≥3 lines of prior chemotherapy portend poor prognosis (22). Given that the median survival of patients who failed third line chemotherapy is in the range of 4–6 months, therapy with Y-90 may improve survival outcomes. The utility of concomitant chemotherapy needs to be further explored.

### Conclusions

Yttrium-90 microsphere therapy is being increasingly used for treatment of colorectal metastases to the liver. Patients who have failed systemic chemotherapy appear to benefit from this therapy. Concurrent use of Y-90 in first and second line chemotherapy is currently being investigated. Future trials need to focus on identifying specific target populations who may benefit most from this therapy.

### Recommendations

Yttrium-90 therapy is recommended for chemorefractory patients with liver-only or liver-predominant disease and in patients who do not wish to have systemic chemotherapy. Use of Y-90 therapy in conjunction with standard first line or second line chemotherapy requires more rigorous data and is recommended in a clinical trial setting. The use of Y-90 is not recommended in patients with extensive extra-hepatic disease or extensive biliar hepatic involvement. Similarly, patients with poor performance status (ECOG PS > 2) are not suitable for Y-90 therapy.
