(Received: October 11, 2013; revised manuscript received: January 18, 2014; accepted: January 19, 2014)

INTRODUCTION

Onset of trichotillomania (TTM) typically occurs in early adolescence (Christenson & Mansueto, 1999), a developmental window characterized by vulnerability in body image. To date, no one has studied the relationship between this disorder and body esteem. Methods: 49 adolescents with DSM-IV TTM or chronic hair pulling (HP) and 23 control adolescents were administered diagnostic assessments and self-report measures of hair pulling and body esteem. Results: HP youth vs. controls reported lower levels of body esteem on all Body-Esteem Scale for Adolescents and Adults (BESAA) subscales (appearance, attribution and weight satisfaction). HP contributed to lowered body esteem, independent of comorbid anxiety or depression. As expected, HP youth with vs. without comorbid anxiety or depression reported lowered levels of body esteem. Further, greater HP severity and distress were significantly associated with lower levels of body esteem. HP severity alone but not distress/impairment predicted lower levels of body esteem, independent of comorbid anxiety and depression. Conclusions: Both hair pulling and comorbid anxiety and depression can independently impact body esteem in adolescent hair pullers.

Keywords: hair pulling, trichotillomania, body esteem
HP youth were predominantly female (n = 48) and Caucasian (n = 45) with mean (SD) age of 15.07 (1.47) years. In addition, 2.04% (n = 1) identified as Black/African-American, 2.04% (n = 1) as Hispanic/Latino, and 4.08% (n = 2) as Multi-racial. Comparison adolescents were also predominantly female (n = 20) and exclusively Caucasian with mean (SD) age of 15.20 (1.54) years. HP vs. comparison adolescents did not differ significantly (ps > .05) on gender, age or ethnicity. Psychiatric comorbidity was compared for HP vs. comparison youth using the Fisher’s exact test; it revealed significant differences on current OCD (HP: n = 8, comparison: n = 13, \( \chi^2 = 4.92, p = .029 \)), GAD (HP: n = 9, comparison: n = 0; \( \chi^2 = 4.83, p = .050 \)), and social phobia (HP: n = 8, comparison: n = 0; \( \chi^2 = 4.22, p = .049 \)).

Adolescent hair pullers were recruited from the MGH TTM clinic and the Trichotillomania Learning Center newsletter. The healthy comparison group was recruited from flyers and the MGH intranet. All study participants completed a one-time study visit to assess TTM/chronic HP and other psychiatric disorders. All adolescents were paid for participation.

Ethics

Approval was obtained from the Partners Health Care IRB. Study participants completed informed consent prior to participation. This research also complied with the Code of Ethics of the World Medical Association (Declaration of Helsinki).

Assessment materials

Self-report instruments

**Body Esteem Scale for Adolescents and Adults (BESAA).** The BESAA (Mendelson, Mendelson & White, 2001) is a 23-item measure with three subscale scores. These include subscales measuring general feelings regarding appearance (Appearance; 10 items, e.g. “My looks make me upset”), evaluations attributed to others about one’s body and appearance (Attribution; 5 items, e.g. “Other people consider me good looking”, “I’m as nice looking as most people”) and weight satisfaction (Weight; 8 items, e.g. “I’m proud of my body”). Individuals are asked to rate how often they agree with each item from “never” (1) to “always” (5). Higher subscale scores indicate more positive body esteem; negatively valenced items are reverse-scored. The appearance, weight, and attribution subscales have each shown high internal consistency with Cronbach’s alphas of 0.92, 0.94, and 0.81, respectively. Convergent validity has also been shown through correlation (r = .47 to .63) with the Rosenberg Self-Esteem Scale (Mendelson et al., 1997).

**Trichotillomania Scale for Children-Child version (TSC-C).** The TSC-C (Tolin et al., 2008) is a 12-item measure of HP. It consists of severity and distress/impairment subscales. The severity and distress/impairment subscales have each shown good internal consistency with Cronbach’s alphas of 0.76 and 0.84, respectively.

Clinician-administered diagnostic measures

**Kiddie-SADS-Present and Lifetime Version (K-SADS-PL).** The K-SADS-PL (Kaufman et al., 1997) is a semi-structured interview used to assess psychopathology in adolescents using DSM-IV diagnostic criteria.

**Trichotillomania Diagnostic Interview-Revised (TDI-R).** The TDI-R is a DSM-IV-TR adaptation of the TDI (Rothbaum & Ninan, 1994), a semi-structured interview for TTM diagnosis.

Statistical analyses

Independent samples t-tests were used for group comparisons on all continuous variables. To assess the relationships between continuous variables, Pearson product-moment correlations were used. Multiple regression analyses were used to identify variables predicting body esteem scores.

For purposes of analysis, comorbid anxiety was defined to include OCD, GAD, social phobia, panic disorder with agoraphobia, PTSD and avoidant disorder. Comorbid depression included diagnoses of depression with and without psychotic features. We were unable to include eating disorders in our analyses as only one HP youth had such a diagnosis.

RESULTS

**Do HP vs. comparison youth differ on body esteem?**

For our a priori hypothesis regarding the appearance subscale (g = 1.04), HP youth (M = 18.79, SD = 9.04) had significantly lower body esteem scores than comparison youth (M = 27.32, SD = 5.34; t(68) = –4.92, p < .001). On the attribution subscale (g = .45), HP youth (M = 9.71, SD = 3.15) had marginally significantly lower scores than comparison youth (M = 11.09, SD = 2.86; t(69) = –1.78, p = .080). Exploratory group comparison on the weight subscale (g = .55) indicated that HP youth (M = 16.07, SD = 9.74) also had significantly lower scores than comparison youth (M = 21.18, SD = 8.15; t(64) = –2.12, p = .038).

To test our a priori hypotheses, multiple linear regression was used to examine the extent to which group condition (HP vs. comparison) and comorbid diagnoses (anxiety or depression) predicted body esteem appearance and attribution scores (Table 1). Assumptions for multiple linear regression were met. Multicollinearity amongst predictors was not found. The total variance in BESAA appearance explained by this model was 33.8% (adjusted R² = .32; F[2, 67] = 17.12, p < .001). Group condition and comorbid anxiety or depression were significant predictors of BESAA appearance scores, with group condition showing a larger effect size (B = –9.04) than comorbid anxiety or depression (B = –3.15).

**Table 1. Multiple regression analyses of condition and comorbid diagnoses in predicting BESAA scores**

In addition to the group condition and comorbid anxiety or depression, the BESAA appearance score was also significantly predicted by the Trichotillomania Scale for Children measure (TSC-C) for HP youth only (M = 13.90, SD = 4.82; \( \beta = .45 \), \( p < .001 \)). The TSC-C measure explained 33.8% of the variance in BESAA appearance scores for HP youth (F[2, 67] = 17.12, p < .001).
Do HP youth with and without psychiatric comorbidity differ on body esteem?

HP youth without comorbidity \( (n = 25) \) scored significantly higher on BESAA appearance \( (M = 23.00, \text{SD} = 7.58) \) than HP youth \( (n = 24) \) with anxiety and depressive comorbidity \( (M = 14.58, \text{SD} = 8.53; t(46) = 3.61, p = .001) \). No significant differences were found for the BESAA attribution subscale. Exploratory group comparison revealed similar findings for weight satisfaction as for the appearance subscale (HP without comorbidity: \( M = 20.43, \text{SD} = 7.60 \); HP with comorbidity: \( M = 11.29, \text{SD} = 9.71; t(42) = 3.50, p = .001) \).

To what extent are HP severity and distress negatively associated with body esteem?

Correlational analyses were used to analyze our \textit{a priori} hypotheses that HP severity and distress would be negatively associated with BESAA attribution and appearance scores. Exploratory analyses were conducted with the weight satisfaction scale. Neither HP severity nor distress was significantly associated with BESAA attribution scores. HP severity and distress/impairment were significantly negatively correlated with BESAA appearance and weight satisfaction scores, such that greater HP severity and distress were associated with lower body esteem regarding both appearance (TSC severity: \( r = -.38, p = .009 \); TSC distress: \( r = -.32, p = .031 \)) and weight satisfaction (TSC severity: \( r = -.30, p = .052 \); TSC distress: \( r = -.31, p = .044 \)).

Multiple linear regression was used to analyze our \textit{a priori} hypotheses examining the extent to which HP severity or distress and comorbid diagnoses of anxiety or depression predicted body esteem appearance and attribution scores (Table 2). Assumptions for multiple regression were tested and met. Multicollinearity was not found. Separate models were used with HP severity and distress as predictors since they were highly correlated \( (r = .73, p < .001) \). The total variance in BESAA appearance explained by HP severity and comorbid diagnoses was 32.6\% (adjusted \( R^2 = .29; F[2, 43] = 10.38, p < .001) \). Both HP severity and comorbid diagnoses were statistically significant predictors of appearance scores. The total variance in BESAA appearance explained by HP distress and comorbid diagnoses was 28\% (adjusted \( R^2 = .25; F[2, 43] = 8.38, p = .001) \) with only comorbid diagnoses as a significant predictor. The models predicting BESAA attribution scores were not significant. Exploratory analyses were conducted with the BESAA weight satisfaction scale. The total variance in BESAA weight satisfaction predicted by HP severity and comorbid diagnoses was 31.5\% (adjusted \( R^2 = .28; F[2, 39] = 8.97, p = .001) \) with comorbid diagnoses as the only significant predictor though HP severity was a marginally significant predictor. The total variance in BESAA weight satisfaction predicted by HP distress and comorbid diagnoses was 30.5\% (adjusted \( R^2 = .27; F[2, 39] = 8.55, p = .001) \). Again only comorbid anxiety or depression was a significant predictor.

Our results show that body esteem is compromised in all domains (appearance, attribution, and weight) in HP youth when compared to an age- and gender-matched control sample. Both comorbid anxiety or depression and group condition significantly predicted feelings regarding appearance. Although diagnosis of anxiety or depression was a stronger predictor, group condition predicted variance in appearance scores independent of comorbid anxiety and depression. Contrary to our predictions, group condition did not significantly predict one’s thoughts attributed to others regarding appearance (attribution subscale) but neither did comorbid diagnoses. Only comorbid anxiety or depression significantly predicted weight satisfaction.

As predicted, HP youth with comorbid anxiety or depression vs. youth with HP alone reported lower levels of body esteem surrounding feelings about appearance. Thus, both HP and comorbidities compound difficulties in body esteem. Although not predicted, HP youth with comorbidity also reported lowered levels of weight satisfaction.

HP severity and distress in hair pullers were associated with lower levels of body esteem surrounding feelings about appearance and weight satisfaction. Similar to our group comparison, no significant correlation was found between HP distress or severity with the attribution subscale. These results were unanticipated given known distress and embarrassment surrounding HP, particularly the concern that sufferers have regarding the thoughts of others.

Follow-up analyses demonstrated that while anxiety and depressive comorbidity play a role, HP severity also predicts body esteem involving feelings surrounding one’s appearance. It is not surprising that HP severity was found to be predictive of the appearance subscale, as this is the subscale most consistently predictive of self-esteem (Mendelson et al., 2001). HP severity measures the urges to pull, frequency of hair pulling, and the amount of hairs pulled. This

Body esteem in adolescent hair pullers

Hair pulling as well as comorbid anxiety and depression can impact body esteem in adolescent hair pullers. Clinicians should assess body esteem in HP youth and provide targeted intervention when needed to preclude compounded difficulties later in development.

CONCLUSIONS

CONFLICT OF INTEREST: Erin Altenburger and Esther Tung report no financial or other relationship relevant to the subject of this article.
