Dynamin recruitment and membrane scission at the neck of a clathrin-coated pit

Emanuele Cocucci\textsuperscript{a,b}, Raphaël Gaudin\textsuperscript{a}, and Tom Kirchhausen\textsuperscript{a,b}

\textsuperscript{a}Department of Cell Biology, Harvard Medical School, and Cellular and Molecular Medicine Program, Boston Children’s Hospital, Boston, MA 02115; \textsuperscript{b}Department of Pediatrics, Harvard Medical School, Boston, MA 02115

ABSTRACT Dynamin, the GTPase required for clathrin-mediated endocytosis, is recruited to clathrin-coated pits in two sequential phases. The first is associated with coated pit maturation; the second, with fission of the membrane neck of a coated pit. Using gene-edited cells that express dynamin2-EGFP instead of dynamin2 and live-cell TIRF imaging with single-molecule EGFP sensitivity and high temporal resolution, we detected the arrival of dynamin at coated pits and defined dynamin dimers as the preferred assembly unit. We also used live-cell spinning-disk confocal microscopy calibrated by single-molecule EGFP detection to determine the number of dynamins recruited to the coated pits. A large fraction of budding coated pits recruit between 26 and 40 dynamins (between 1 and 1.5 helical turns of a dynamin collar) during the recruitment phase associated with neck fission; 26 are enough for coated vesicle release in cells partially depleted of dynamin by RNA interference. We discuss how these results restrict models for the mechanism of dynamin-mediated membrane scission.

INTRODUCTION

During clathrin-mediated endocytosis, regulated recruitment of clathrin and its associated proteins leads to assembly of a scaffold that molds a small patch of plasma membrane into an invaginated, clathrin-coated pit (Brett and Traub, 2006; McMahon and Boucrot, 2011; Jackson et al., 2012b; Kirchhausen et al., 2014). These structures capture membrane-bound cargo and pinch off to form clathrin-coated vesicles. Prompt uncoating yields vesicular carriers, which can deliver cargo to endosomes or other membrane-bound organelles.

Coated-vesicle budding requires members of the dynamin family of large GTPases (Koenig et al., 1989; Damke et al., 1994; Merrifield et al., 2002; Ehrlich et al., 2004; Macia et al., 2006; Ferguson et al., 2007; Taylor et al., 2012; Aguet et al., 2013). The first phase, which accompanies the early stages of coated pit formation, appears to regulate coated pit maturation by as-yet-undefined mechanisms (Macia et al., 2006; Aguet et al., 2013). The second phase, which generally appears as a “burst” immediately before membrane scission, is necessary for fission of the membrane neck connecting the nascent vesicle with the parent membrane (Merrifield et al., 2002; Macia et al., 2006; Taylor et al., 2011, 2012; Aguet et al., 2013).

Dynamins have an N-terminal GTPase “head,” similar in structure to Ras-like small GTPases, connected to a long, primarily \(\alpha\)-helical stalk (Chappie et al., 2009; Chappie and Dyda, 2013; Faelber et al., 2011; Ford et al., 2011). The stalk, which has a membrane-interacting PH domain at its tip, doubles back, so that the C-terminus of the polypeptide chain contacts the head. In solution, dynamin dimerizes readily; the dimers associate into tetramers at higher concentrations. Crystal structures and cryo–electron microscopic (cryo-EM) reconstructions suggest that two sets of dimer contacts are critical for polymer assembly (Chappie et al., 2011). An oblique contact between stalks of two protomers produces an X-shaped dimer, with the

Early models for membrane scission driven by GTP hydrolysis postulated a concerted change in diameter of the helical sheath or collar, with attendant distortion of the membrane (Warnock et al., 1996; Smirnova et al., 1999; Stowell et al., 1999; Praefcke and McMahon, 2004; Bashkirov et al., 2008). The inner diameter of the membrane tube around which dynamin in the GMPPCP state assembles, with ∼26 dynamins per turn of a single-start helix, is ∼7 nm (Chen et al., 2004; Figure 1). Models of membrane fission suggest that the inner diameter of a constriction must contract to ∼3 nm for a spontaneous hemifission intermediate to form (Kozlovsky and Kozlov, 2003; Bashkirov et al., 2008; Morlot et al., 2012; Shnyrova et al., 2013). It thus remains puzzling how the proposed powerstroke that attends passage to the transition state of the GTPase might couple to a local contraction of the enclosed membrane.

An estimate of the minimum number of dynamin molecules required for scission constrains models for how the dynamin powerstroke might couple to change in membrane curvature. We report here measurements that yield such a count. We applied an experimental design essentially similar to the one we developed to define molecular events associated with the initiation of coated pits (Cocucci et al., 2012). The basic principles are use of gene-edited cells, so that the relevant molecule (dynamin in the present case) with an encoded fluorescent tag (enhanced green fluorescent protein [EGFP]) is present in physiological quantities, undiluted by untagged copies, and use of total internal reflection fluorescence (TIRF) illumination to minimize background and allow single-EGFP sensitivity (Cocucci et al., 2012) or intensity-calibrated spinning-disk confocal fluorescence microscopy for molecule counting (Kural et al., 2012).

We find that a dynamin dimer is the basic assembly unit, as recruitment proceeds in steps of 2 dynamins (never 1). Accumulation of ∼26 dynamins (one turn of the dynamin-GMPPCP helix) is sufficient under some conditions to produce membrane scission; rarely do we see more than twice that amount. That is, one turn of the basic helix is enough, and two complete turns are not essential. A publication that appeared while this work was in review reported a broadly similar result, also using gene-edited cells: the authors of that study detected a minimum of 26 dynamins at the time of scission, although they often found twice that amount (Grassart et al., 2012). Because nucleotide-mediated dimer contacts between GTPase head domains bridge successive helical turns, the measurements have strong implications for models to explain how GTP hydrolysis drives membrane fission. In particular, our results are not consistent with models invoking isotropic contraction of a continuous dynamin collar, as that category of mechanism requires a full turn of GTPase contacts and therefore two full turns of the basic helix. They appear instead to favor models that invoke a GTPase-driven twist, in which contraction of the diameter of a collar comes from a reduction in the number of dynamin dimers per turn.

RESULTS
Gene-edited cells expressing dynamin2-EGFP
To study the molecular events associated with dynamin-mediated membrane fission at the neck of clathrin-coated pits, we established a gene-edited cell line in which we replaced the ubiquitous
dynamin2 with a dynamin2-EGFP chimera. We selected the human cell line SUM159 (Forozan et al., 1999), breast cancer–derived, mostly diploid cells, and used transcription activator-like effector nuclease (TALEN)–mediated editing to create the chimera-encoding gene (Sanjana et al., 2012). We chose to connect EGFP with a linker of six amino acids to the C-terminus of dynamin2 (Figure 2A). We isolated clone SUM-Dyn2, bearing the insertion at both alleles. Analysis of the genomic DNA by PCR showed that both alleles were dynamin2 with a dynamin2-EGFP chimera. We selected the human cell line SUM159 (Forozan et al., 1999), breast cancer–derived, mostly diploid cells, and used transcription activator-like effector nuclease (TALEN)–mediated editing to create the chimera-encoding gene (Sanjana et al., 2012). We chose to connect EGFP with a linker of six amino acids to the C-terminus of dynamin2 (Figure 2A). We isolated clone SUM-Dyn2, bearing the insertion at both alleles. Analysis of the genomic DNA by PCR showed that both alleles were
interfere with the uptake of transferrin (Liu et al., 2008). These observations show that addition of EGFP to the C-terminus of dynamin2 does not interfere with its ability to promote coated-vesicle budding.

Times series acquired by live-cell, spinning-disk, confocal microscopy from the bottom surface of SUM-Dyn2 cells expressing rat clathrin light chain a (LCa) fused to mCherry (mCherry-LCa; Figure 2E) or of hCLTA\textsuperscript{EN}/DNM2\textsuperscript{EN} cells gene edited to express dynamin2-EGFP and human clathrin LCa–red fluorescent protein (RFP; Figure 3C) confirmed the expected presence of structures containing both fluorescent clathrin and dynamin. Most of these were dynamic spots corresponding to canonical coated pits; a minority were long-lived coated plaques. The remaining fluorescent spots contained only clathrin; these were the very mobile structures associated with endosomal membranes (Ehrlich et al., 2004; Kural et al., 2012; Aguet et al., 2013). We restricted most of the analysis of dynamin presented here to its recruitment at canonical coated pits.

### Estimate of the number of dynamin molecules accumulated at the time of membrane fission

Observations in several laboratories have led to the conclusion that fission at the membrane neck of a coated pit and release of a coated vesicle from the plasma membrane coincide with a peak in dynamin recruitment (Ehrlich et al., 2004; Merrifield et al., 2005; Taylor et al., 2011, 2012; Aguet et al., 2013), but direct information concerning the number of dynamin molecules that contribute to this peak has been lacking. From in vitro studies, it has been proposed that a two-rung helical collar is the minimal membrane fission unit, with two to three rungs mediating ~80% of the fission events (Shnyrova et al., 2013). This model implies that ~50 dynamin molecules will have accumulated at the time of fission, since one rung in the constriction, GTP-bound conformation contains ~13.3 dynamin dimers. Other models might require fewer dynamins (Ford et al., 2011).

We carried out a primary selection of objects containing fluorescent dynamin and clathrin using the cmeAnalysis software with clathrin as the “master” and dynamin as the “slave” (Aguet et al., 2013); we then picked manually from the automated primary selections those objects whose clathrin fluorescent signal followed the expected continuous growth associated with canonical coated pits (see Materials and Methods and representative traces in Figure 4). This selection was important because the clathrin signal was not strong enough for reliable automated selection, and the software often incorrectly classified tracks of coated pits as abortive rather than canonical or incorrectly combined into a single event two or more pits that formed sequentially at a single location (a “hot spot”).

We followed in SUM-Dyn2 cells the recruitment of dynamin2-EGFP during the full lifetime of the selected coated pits and determined the number of molecules recruited, using spinning-disk confocal microscopy, calibrated for fluorescence intensity, as described in our previous work (Kural et al., 2012). We used this strategy instead of TIRF because spinning-disk confocal imaging is less sensitive to position along the z-axis, thereby ensuring full capture of the signal within the diffraction-limited geometry. We used SUM-Dyn2 cells stably expressing mCherry-LCa, and used alternate wavelength excitation and detection of both fluorophores with 30-ms exposures to follow recruitment of clathrin and dynamin at the same position. We collected data from the bottom surfaces of the cells using time series lasting 5 min acquired every second and analyzed the dynamics of dynamin2-EGFP recruitment from 426 clathrin-coated structures in five different cells.

In agreement with earlier results (Figure 2D; Merrifield et al., 2002; Ehrlich et al., 2004; Macia et al., 2006; Doyon et al., 2011;...
the end of assembly, immediately before the loss of the clathrin signal associated with uncoating. Similar results were reported recently using the gene-edited hCLTA<sup>Dv</sup>/DNM2<sup>SN</sup> and DNM2<sup>SN</sup> cells (Grassart et al., 2014). In view of the complete substitution in our cells and the very small proportion of dynamin 1, we used the maximum intensity of the total dynamin accumulation to determine the number of molecules recruited at the time of membrane scission. The distribution peaked at ~40 dynamins and averaged at 50 ± 19 molecules (Figure 5A). Nearly 25% of the events contained between 26 and 40 dynamins, and ~27% of the events, between 40 and 52 dynamins (Figure 5B).

We do not know whether the gradually accumulated dynamin contributes to scission. To estimate the number of dynamins specifically recruited during the burst phase, we subtracted the maximum fluorescence from the plateau 10 s before the peak of the burst. The values plotted, as a histogram and as a cumulative distribution in Figure 5, C and D, showed a peak at 26–28 dynamins with an average of 33 ± 14 dynamins. In the low-intensity, abortive pits (events lasting <25 s), we saw no dynamin burst and detected only small and variable amounts of phase one dynamin recruitment (Figure 5, E and F). We obtained similar results from hCLTA<sup>Dv</sup>/DNM2<sup>SN</sup> cells (Figure 6). Because substitution of dynamin 2 by dynamin2-EGFP was only 50% in those cells, the agreement supports the assumption of random incorporation of tagged and untagged dynamin molecules in a ratio depending only on their relative concentrations in the cytosol.

**Effects of higher and lower membrane tension**

Scission of dynamin-coated membrane tubules in vitro requires that the tubule be under longitudinal tension (Roux et al., 2006; Morlot and Roux, 2013; Morlot et al., 2012; Bashkirov et al., 2008; Shnyrova et al., 2013). We examined the effect of membrane tension on the number of dynamins that have accumulated at the time of coated vesicle release in SUM-Dyn2 cells expressing mCherry-LCa. Lowering plasma membrane tension by acute exposure to hypotonic medium inhibits coated vesicle formation (and the associated endocytosis of cargo; Heuser and Anderson, 1989; Morlot et al., 2012). Introduction of hypotonic medium (lowering membrane tension) caused the total number of dynamins to increase (Figure 7, A and B), suggesting that a flaccid membrane needs more dynamin to rupture than does a tense one. Nonetheless, cells incubated in hypo-osmotic medium (Boulant et al., 2011) and thereby subjected to a higher plasma

**FIGURE 4:** Representative traces of clathrin-coated pits forming in SUM-Dyn2 cells. Plot of the fluorescence intensity traces of dynamin2-EGFP (blue) and mCherry-LCa (red) from SUM-Dyn2 cells recruited during formation of clathrin-coated pits in SUM-Dyn2 cells. The data are from 5-min time series obtained using spinning-disk confocal microscopy every 1 s with an exposure of 30 ms/frame. The traces highlight examples of the variability in the recruitment patterns during the first and second phases of association with clathrin-coated pits. (A) Relatively small amount of dynamin recruited during the first phase, followed by a brief but pronounced sharp recruitment during the second phase. (B) A significant amount of dynamin recruited during the first phase, followed by a distinctive recruitment burst during the second phase. (C) A significant amount of dynamin recruited during the first phase that is poorly resolved from the recruitment preceding membrane scission. (D) Dynamin is recruited as a relatively broad burst toward the end of the budding process.

Taylor et al., 2011, 2012), most (>90%) of the dynamin2-EGFP spots at the membrane colocalized with mCherry-LCa. Dynamin was generally recruited in two phases, also as previously described, although the distinction was not always as marked as in hCLTA<sup>Dv</sup>/DNM2<sup>SN</sup> cells. In the first phase, which occurs during early stages of clathrin coat assembly, dynamin accumulated gradually to a plateau of variable magnitude. The second phase was the characteristic burst at
membrane tension accumulated approximately the same number as did control cells (Figure 7, B–F). Thus there appears to be a threshold requirement for membrane scission, even when tension is unphysiologically high.

The results also showed greater number of persistent clathrin-coated structures in cells treated with hyperosmotic medium (n = 1746, from five cells) than in cells treated with hypo-osmotic medium (n = 312, from five cells) or kept in iso-osmotic conditions (n = 260, from five cells), consistent with the known inhibition of clathrin-mediated endocytosis (Heuser and Anderson, 1989; Morlot et al., 2012) associated with accumulation of clathrin-coated microcages at the plasma membrane (Heuser and Anderson, 1989) induced by transient hyperosmotic treatment. We detected a variable number of dynamins; the amount often fluctuates, without associated pinching (unpublished data).

Effect of dynamin depletion

Complete elimination of dynamin2 by disruption of all dynamin2 alleles showed that its presence is essential for budding of endocytic clathrin-coated vesicles (Liu et al., 2008). Accordingly, we found that dynamin depletion in SUM-Dyn2 cells by RNA interference (RNAi) treatment for 5 d hindered clathrin-dependent uptake of transferrin (Figure 8A). We inferred that depletion was incomplete because the fluorescence intensity of dynamin2-EGFP remaining in the cytosol was 25 ± 10% (average ± SD, 10 cells) and because a small fraction of dynamin2 molecules remained that contained both clathrin and dynamin2-EGFP. Under these conditions of partial depletion, we asked what would be the number of dynamins required for coated-vesicle budding. We analyzed 97 events in 10 cells and found that ~50% of the budding coated pits had no detectable recruitment during the first phase and on average recruited 28 ± 10 dynamins (Figure 8, B and C); the distribution of the total number of dynamins at the time of pinching (Figure 8, D and E) averaged at 32 ± 13 molecules. The results suggest that a very small number of dynamins in the first phase of recruitment is enough to allow the pit to mature and that 26–28 dynamins (one rung) are sufficient for membrane scission.

Preferential recruitment of dynamin dimers to coated pits

Using a TIRF configuration calibrated from single-molecule counting as previously described (Cocucci et al., 2012), we followed the accumulation of dynamin2-EGFP into coated pits at the bottom surface of SUM-Dyn2 cells. We acquired a rapid time series lasting ~20 s, with 60-ms exposure/frame at an interval of 110 ms. This protocol minimized photobleaching to not more than 20% toward the end of the time series. We analyzed 23 traces from five cells selected to have relatively low amplitude and therefore show phase 1 of dynamin recruitment. We found consecutive stepwise intensity increments of variable magnitude and a dwell time of 1.06 ± 0.57 s (Figure 9A). The number of dynamin2-EGFP molecules recruited during each of the steps was obtained by fitting the intensity distributions with different models that took into account the dynamin2 substitution by dynamin2-EGFP (98%) and alternative contributions of monomer, dimer, trimer, and so on of dynamin2-EGFP during the steps of recruitment (see Materials and Methods).

The model that gave the best fit, based on a Bayesian information criterion (BIC; Jaqaman and Danuser, 2006; see Materials and Methods; Figure 9B) had a dimer as the principal recruitment species, with events corresponding to addition of one (8%), two (49%), four (26%), six (6%), and eight (11%) dynamin molecules. The fit was performed using the ratio of dynamin2-EGFP to untagged dynamin of 49:1, corresponding to the experimental value from Westerblot analysis of a large pool of cells (Figure 2C). We found very poor fits with calculations that assumed significantly different recruitment models (Figure 9B). We conclude that a dimer is the principal species that incorporates into a coated pit.
steps of four, six, and eight within the 110-ms time resolution of our measurements, but we interpret these as two, three, or four dimers associating in rapid succession. Because photobleaching set a limit of ∼20 s for our time series, we could not follow early and late stages of a single coated pit. Dynamic accumulation was very rapid for events with high fluorescence intensities, which presumably corresponded to the burst phase, and we could not determine a step size with the available time resolution. We further conclude that monomers barely contribute and that there is no preference for a tetramer in the initial step.

**DISCUSSION**

Our analysis of dynamin recruitment during assembly of endocytic clathrin-coated pits yields two principal conclusions. First, dynamin dimers are the preferred assembly units. Second, accumulation of ∼26 dynamin molecules (∼13 dimers) at the neck of a budding vesicle is enough to drive scission. A single turn of the helical sheath formed in the presence of nonhydrolyzable GTP analogues thus appears to be both necessary and sufficient for membrane fission.

We resolved recruitment into an early, gradual phase, which parallels growth of the clathrin coat, and a late, burst phase, which accompanies scission of the coated vesicle neck. The burst invariably leads to uncoating of the budded vesicle. Recruitment is a succession of consecutive steps—usually arrival together of 2 dynamins (one dimer), less frequently of 4, and rarely of >4. Infrequently, we observe scission of consecutive steps—usually arrival together of 2 dynamins (one dimer), less frequently of 4, and rarely of >4. Infrequently, we observed recruitment of dynamin dimer distribution, which is quantized over a continuous range of times, but we interpret these as two, three, or four dimers recruited to abortive pits (n = 1523). Dotted line marks 26 dynamins. (F) Cumulative distribution of the shown in E; ∼70% of the pits recruited <26 dynamin molecules. Dotted line marks 26 dynamins.

In cells depleted of dynamin by RNAi, the distribution peaks at 26–28, with the burst accounting for nearly all of the recruited dynamin. These results, when combined with published biochemical data, are at odds with models in which the forces driving membrane fission come from concerted conformational changes in a dynamin collar based on the single-start helix generated by in vitro assembly (Warnock et al., 1996; Smirnova et al., 1999; Stowell et al., 1999; Praefcke and McMahon, 2004; Bashkirov et al., 2008); they favor instead a role for GTP hydrolysis and conformational change at or near the leading edge of a helical dynamin assembly (Morlot et al., 2012; Shnyrova et al., 2013). It is possible that the long-term depletion of dynamin2 by the small interfering RNA (siRNA) treatment might increase the expression of other proteins with compensatory activity for membrane scission, thereby reducing the dependence on dynamin. A compensatory fission activity was observed in vitro using tubular lipid templates exposed to dynamin and nonphysiological amounts (micromolar) of BAR domain–containing proteins, which presumably drove membrane tubulation (Neumann and Schmid, 2013). In vivo, where neck formation is driven primarily by the assembly of the clathrin coat, most of the budding coated pits detected in the dynamin2-depleted cells recruited 26–28 dynamin2 molecules, the same as the threshold value observed for pits in cells expressing normal amounts of dynamin2. Thus we believe that a compensatory mechanism is unlikely to have affected the number of dynamin2 molecules recruited under conditions of siRNA treatment.

**A dynamin dimer is the preferred assembly unit**

In vitro measurements using chemical cross-linking or sedimentation equilibrium show that soluble dynamin is an equilibrium mixture of monomers, dimers, and tetramers (Binns et al., 1999), with a preponderance of dimers at 60 nM (Tuma and Collins, 1995) and of tetramers at 1 μM (Hinshaw and Schmid, 1995; Muhlbeg et al., 1997; Ramachandran et al., 2009). We do not have a measurement of the

**FIGURE 6:** Number of dynamin molecules recruited to coated pits at the time of membrane fission in hCLTA2/DNM2 cells. The number of dynamin molecules recruited to clathrin-coated structures was obtained as described in Figure 5 from three cells. The substitution of endogenous dynamin2 by dynamin2-EGFP in hCLTA2/DNM2 cells was ∼50%. (A) Histogram of the total number of dynamin molecules recruited to coated pits at the time of membrane fission (337 pits). (B) Cumulative distribution of the data in A; ∼19% of the coated pits recruited between 26 and 40 dynamin molecules, and ∼23% recruited between 40 and 52 dynamins. (C) Histogram of the number of dynamin recruited during the final burst (337 pits) shows a peak at ∼26 dynamins. Dotted line marks 26 dynamins. (D) Cumulative distribution of the data in C; ∼27% of the pits recruited between 26 and 40 dynamins, and ∼24% recruited between 26 and 40. Dotted lines mark 26 and 40 dynamins. (E) Histogram of the maximum number of dynamin molecules recruited to abortive pits (n = 1523). Dotted line marks 26 dynamins. (F) Cumulative distribution of the shown in E; ∼70% of the pits recruited <26 dynamin molecules. Dotted line marks 26 dynamins.
absolute abundance of dynamin in a cell, but assuming 0.05% of total protein, we estimate that its concentration falls between these numbers. Consider as an example 400 pg of protein in a HeLa cell; if 90 kDa is the mean molecular weight, then there is $10^{14}$ mole/cell or $10^{17}$ mole of dynamin at 0.05%; if the HeLa cell has a radius of 15 μm, then $V = 10^3 \mu m^3$ or $10^5 \mu l$, and concentration is $\sim 0.5 \mu M$.

As shown in Figure 9C, recruitment steps having amplitudes of two and four dynamins, respectively, were in a ratio of roughly 2:1; steps with larger amplitudes made up <20% of the total. We probably failed to resolve some successive dimers (or tetramers) because of the sampling interval, limited by the 110-ms time resolution of our configuration.

The data do not, of course, specify the molecular contacts present in the dimeric species that predominates. We regard it as unlikely that the recruited dimer has a head–head contact. The rate of spontaneous GTP hydrolysis for dynamin in solution is $\sim 0.04$ s$^{-1}$; the rate for assembled dynamin is at least 50- to 100-fold higher (Warnock et al., 1996; Binns et al., 1999; Stowell et al., 1999). The latter presumably derives from the interdimer head–head contacts that develop when two (or more) dimers come together on the same membrane. Head–head contacts in solution would produce futile cycles of GTP hydrolysis. The interaction likely to form the dimeric assembly unit is an extensive twofold contact in the crystal structures of PRD-dynamin1 (Figure 1). The contacts in both structures (rat and human) are essentially identical, and the interacting amino acid residues are strictly conserved among all dynamins1 and 2. This dimer fits well into the cryo-EM reconstruction of a GMPPPC-stabilized dynamin tube (Chappie et al., 2011; Figure 1).

Minimum number of dynamins in a productive burst

The distribution of burst amplitudes, measured in gene-edited hCLTA5/DNM2EN cells (Figure 6), with $\sim 50\%$ of dynamin2 retaining its EGFP tag, and in gene-edited SUM-Dyn2 cells (Figure 5), with all of dynamin2 tagged, shows that $\sim 30$–$40\%$ of the scission-producing events occur with a burst of 26–28 dynamin molecules, although some transfer of dynamins from the pool accumulated during the gradual phase into the burst-producing structure will probably raise this estimate. These experiments were carried out in both cell types, with $\sim 50\%$ loss of the EGFP tag in one and negligible loss in the other, so the estimate of the size of the burst is independent of apparent substitution level. Depletion of total dynamin by RNAi often reduced the plateau of the first phase to the level of background, and in those experiments, a substantial fraction (50%) of the events contained 26–30 dynamins. These results indicate that about one turn of the single-start helix is sufficient to produce scission, whether or not dynamins in the initial phase contribute.

Biochemistry of dynamin GTP hydrolysis

Two observations from the literature are relevant to any consideration of models for dynamin action. One shows a relatively modest degree of cooperativity, despite the apparent requirement for coordinated action of a large number of molecules. Thus several studies of GTP hydrolysis by assembled dynamin yield a Hill coefficient of $\sim 2$ (Tuma and Collins, 1994; Stowell et al., 1999). This result leads to the likely conclusion that GTP hydrolysis at the interface of two GTPase heads, each with an active site, is the only source of measurable cooperativity. The other relevant observation is the number of GTP hydrolysis events, $\sim 15$, needed to break a lipid tube under modest tension (Morlot et al., 2012). Roughly seven or eight pairs of heads must engage to produce this number, or fewer if there is repeated use of one or more paired GTPases.

Models for the scission mechanism

What constraints on a picture of dynamin-generated scission do our data impose? We consider the helical EM reconstruction of a GMPPPC-stabilized dynamin assembly as the most likely model for the initial state of a dynamin collar at the neck of a coated pit. Fitting models derived from x-ray crystal structures into the cryo-EM map (Chappie et al., 2011) shows that one turn of the prominent spiral of density on the outside of the tube contains between 13 and 14 dynamin dimers, with their GTPase heads projecting alternately in opposite directions along the helix axis. If dynamin assembly proceeds by successive addition of dimers along this helical path, head–head contacts (and hence stimulated GTPase activity) will begin to form only during assembly of the second turn of the single-start helix. More specifically, head–head contacts are between dimers $i$ and $i + 12$. Our data then show that accumulation of even a small segment of the second turn can lead to scission.

FIGURE 7: Effect of membrane tension on the number of dynamin molecules recruited to coated pits at the time of membrane fission. The total number of dynamin molecules recruited to clathrin-coated pits was determined as in Figure 5 using Sum-Dyn2 briefly exposed for 10 min to media of different osmolarities. Five cells were used per condition. (A) Histogram of the total number of dynamin molecules recruited to coated pits of cells incubated in hyper-osmotic medium at the time of membrane fission (78 pits). (B) Cumulative distribution of the data in A; $\sim 16\%$ of the pits recruit between 26 and 40 dynamins, and 13% recruited between 40 and 52 dynamins. (C) Histogram of the total number of dynamin molecules recruited to coated pits of cells incubated in hypo-osmotic medium at the time of membrane fission (210 pits). (D) Cumulative distribution of the data in C; $\sim 38\%$ of the pits recruit between 26 and 40 dynamins, and $\sim 27\%$ recruited between 40 and 52 dynamins. (E) Histogram of the total number of dynamin molecules recruited to coated pits of cells incubated in iso-osmotic medium at the time of membrane fission (312 pits). (F) Cumulative distribution of the data in E; $\sim 30\%$ of the pits recruited between 26 and 40 dynamins, and $\sim 30\%$ recruited between 40 and 52 dynamins.
The radius of the membrane tubule within a GMPPCP dynamin sheath is ~5 nm (from the axis to the center of the bilayer; Chappie et al., 2011). Spontaneous hemifission is believed to require a radius of ~3 nm (Kozlovsky and Kozlov, 2003). Conformational changes in a dynamin collar could produce such a contraction either by a rotation of the stalks toward a more radial orientation, forcing the PH domains inward while leaving the helical parameters of the outer layer more or less unchanged, or by a decrease in the number of dynamins per turn of the helix, reducing both its outer and inner diameter without changing the radial disposition of the stalks. These two alternatives correspond roughly to the models proposed by Chappie et al. (2011) and by Smirnova et al. (1999) and Faellber et al. (2011). The former is, in its simplest form, an isotropic squeeze (Figure 10A); the latter, a circumferential twist (Figure 10B and Supplemental Movies S1–S3). The isotropic contraction model requires nearly a full turn of paired GTPase domains—that is, nearly two turns of the basic helix. The circumferential twist model requires simply that the assembly reach a state in which one or more pairs of GTPase domains interact. Our data appear to favor the latter picture.

A progressive, circumferential twist model is consistent with the properties of a mutation, Q40E, at the GTPase dimer interface (Liu et al., 2013). The mutation has no effect on the basal GTPase activity, and it does not prevent formation of a dynamin sheath, either in vitro or in vivo. It does, however, eliminate assembly-stimulated GTPase activity. When coassembled with wild-type dynamin, it has a strong, dominant-negative effect on membrane tubule fission in vitro but little dominant-negative effect on the wild-type, assembly-stimulated GTPase activity. Any process requiring a number of successive steps will be more sensitive to poisoning of any one of those steps than will a concerted process, which can generally bring along with it changes in any inactive but still compliant components. Thus we expect a progressive twist mechanism to be more sensitive to introduction of GTPase heads that cannot pair functionally with another GTPase one helical turn away than a concerted contractile mechanism.

Any twist model for constriction must include a mechanism to prevent the membrane neck from expanding back against the dynamin collar. That is, the collar must retain its integrity, even if one turn slides against another. Concerted GTPase activity throughout the region in which one turn overlaps the next could cause the structure to pass through a transition point in which weak GTPase domain contacts would allow the membrane and collar to spring back. Uncoordinated GTP hydrolysis implies that transient instability of one interturn contact will not disengage the entire assembly.

Studies of dynamin activity on membrane tubules in vitro show that scission occurs at the edge of an extended dynamin sheath, where an abrupt change in membrane curvature alters the membrane elastic energy (Morlot et al., 2012; Shnyrova et al., 2013). A bead attached to the sheath rotates with respect to the membrane tubule, and measurements of the corresponding torque on the membrane indicate that the forces involved are strong enough to overcome the barrier to hemifission, the likely intermediate in a leakage-free process (Bashkirov et al., 2008; Morlot et al., 2012). These observations imply a change in the helical parameters of the dynamin assembly at the edge of the sheath, but they do not require a concerted change throughout its length. Indeed, the rate of tubule breakage is independent of sheath length, over a range from 150 nm to 10 μm, indicating that whatever conformational changes occur are probably confined to the edge (Morlot et al., 2012). A mechanism in which GTP hydrolysis generates constriction by a motor-like mechanism, with one or more dynamin dimers at the edge of a
sheath “walking” along those in the next turn, is analogous to a propagating dislocation at the edge of a two-dimensional crystal. Contacts between heads in the GTP-bound state (represented by GMPPCP) are weaker than those in the transition state (represented by GDP-AlF$_4^-$) (Chappie et al., 2011), and the conformational change on passage of one or more paired heads from a substrate-bound conformation to a transition-state conformation might in principle drive a shift in register of the remaining pairs in the overlap region. Available structures do not yet allow us to decide on the plausibility of this sort of model—for example, whether the “swing” of the BSE could move one turn a reasonable distance with respect to another in a zone of partial overlap. A propagating dislocation model is nonetheless fully compatible with our finding that one complete turn of the dynamin helix will drive budding of a coated pit, because it suggests that the mechanism of scission at the edge of sheath is essentially the same as scission by a one-turn collar.

MATERIALS AND METHODS

Reagents

Human SK-MEL-2 cells and the corresponding gene-edited hCLTA$^{EN}$/DNM2$^{EN}$ cells were a kind gift of D. Drubin (University of California, Berkeley, Berkeley, CA); the alleles of dynamin2 and clathrin light chain A in hCLTA$^{EN}$/DNM2$^{EN}$ were replaced with dynamin2 fused at its C-terminus to EGFP and clathrin light chain A fused at its C-terminus to RFP, respectively. J. Brugge (Harvard Medical School, Boston, MA) kindly provided the human SUM159 cells. The mammalian expression vector mCherry-LCa based on pmCherry-LCa (Clontech, Mountain View, CA) was made by fusing mCherry to the N-terminus of rat brain clathrin light chain A.

Mouse monoclonal antibody against dynamin1 (Clone D5; Oncogene Research Products, San Diego, CA), goat polyclonal antibody against dynamin2 (C-18; Santa Cruz Biotechnology, Dallas, TX), and horseradish peroxidase–conjugated secondary antibodies (GE Healthcare, Little Chalfont, United Kingdom, or Invitrogen, Carlsbad, CA) were used for Western blot analysis.

Biotinylated fibronectin was prepared by 1-h incubation at room temperature of 0.2 μM fibronectin (Sigma-Aldrich, St. Louis, MO) with 1 μM NHS-LC-Biotin (Pierce, Rockford, IL) freshly made in phosphate-buffered saline (PBS), followed by overnight dialysis (Slide-A-Lyzer, minidialysis unit; size cutoff, 10$^4$ Da; Thermo Scientific, Barrington, IL) at 4°C against filtered PBS. Biotinylated fibronectin was stored at −20°C in the presence of 20% glycerol.
open reading frame encoding EGFP was obtained by PCR using 800 nucleotides downstream of the dynamin2 stop codon. The primers F1-R1 and F3-R3 spanned DNA mini kit (Qiagen, Valencia, CA); the fragments obtained with actions from DNA extracted from SUM159 cells using the QiaAmp genomics were obtained using two independent PCR amplification recombination steps was generated by fusion of two downstream (Figure 1A).

5′-TGCGTGAGGCCCCCCCGAGA-3′ results in the GTPase activation and conformational change of the opposing domains (green and red) associated with the next power stroke. A limited number of such sequential additions would be sufficient to tighten the rung, eventually leading to membrane hemifission and membrane scission. Chemicals were purchased from Sigma-Aldrich unless specified otherwise.

Cell handling

All cells were grown and imaged at 37°C and 5% CO2. SUM159 cells were grown in DMEM/F12/Glutamax (Life Technologies, Grand Island, NY), supplemented with 5% fetal bovine serum (FBS), 100 U/ml penicillin and streptomycin (Life Technologies), 1 μg/ml hydrocortisone (H-4001; Sigma-Aldrich), 5 μg/ml insulin (128-100; Cell Applications, San Diego, CA), and 10 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), pH 7.4. Sum-Dyn2 cells stably expressing mCherry-LCa were obtained by transfection. hCLTA2/DNM2EN cells were grown in DMEM/F12/Glutamax supplemented with 10% FBS and 100 U/ml penicillin and streptomycin. Cells (2 ml of medium containing 4 × 10^5 cells) were placed on top of a coverslip in a six-well plate and imaged 12–24 h after plating.

Gene editing

SUM159 cells were gene-edited to replace dynamin2 with dynamin2 fused at its C-terminus to EGFP using a TALEN-based protocol (Sanjana et al., 2012). The upstream targeting sequence 5′-TCCCTGCTCGACTAGCCCTC-3′ overlapped the dynamin2 TAG stop codon (underlined), whereas the downstream targeting sequence 5′-TGGCTGAGGCCCTCCCCGAGA-3′ was located 13 nucleotides downstream (Figure 1A).

The “donor construct” used as template for the homologous recombination step was generated by fusion of two 800-nucleotide fragments of genomic DNA upstream and downstream of the stop codon of dynamin2 and the open reading frame of EGFP into the pCR8/GW TOPO vector (Life Technologies). The genomic fragments were obtained using two independent PCR amplification reactions from DNA extracted from SUM159 cells using the QiaAmp DNA mini kit (Qiagen, Valencia, CA); the fragments obtained with primers F1-R1 and F3-R3 spanned 800 nucleotides upstream and 800 nucleotides downstream of the dynamin2 stop codon. The open reading frame encoding EGFP was obtained by PCR using primers F2-R2 from an expression plasmid vector. The PCR products were purified, mixed and used for overlap PCR amplification using primers F1 and R3. The resulting 2300-nucleotide product was introduced into pCR8/GW TOPO by TA ligation cloning and verified by DNA sequencing. The sequence of the primers (Integrated DNA Technologies, Coralville, IA) was as follows:

Dyn2 up F1 GAGCGTGTTTGGCAAAGTGACCTC
Dyn2 up R1 GTCGAGCAGGGATGGCTCGGCT
Dyn2 EGFP F2 GCCGAGCCATCCCTGCTCGAGatcaccggtcgccaccCTG
Dyn2 EGFP R2 CCGAGAGACGCAGCCCCCTCGAGGCaactgcttgacctgcttaccag
Dyn2 down F3 GGGCGGTGCTCTCGGG
Dyn2 down R3 GAATACAGAGTGCAGGAGCCTAAG

SUM159 cells were cotransfected with 600 ng each of the upstream and downstream targeting sequences and the pCR8/GW vector containing the donor construct dissolved in a total volume of 250 μl of OptiMEM (Life Technologies) into which 5.4 μl of TransIT 2020 Transfection Reagent (Mirus Bio, Madison, WI) was then added for a 15-min incubation at room temperature; the transfection mixture was added dropwise to 1.5 × 10^5 SUM159 cells plated the day before in six-well plates containing 1.5 ml of complete medium. Identification of cells gene-edited in both alleles for dynamin2-EGFP took ~3 wk and was carried out by a combination of cell sorting as follows: transfected cells were transferred from the single six-well dish into a T175 dish and subjected to fluorescence-activated cell sorting (FACS) upon reaching confluency (~10 × 10^5 cells). FACS was carried out using a FACSAria 2-SORP (BD Biosciences, San Jose, CA) instrument equipped with a 300-mW, 488-nm laser and a 70-μm nozzle; cells were detached by trypsinization, centrifuged briefly at 400 × g, resuspended in 2 ml of PBS, and filtered through a 40-μm sterile cell strainer (BD Biosciences). Approximately 10^4 of SUM159 cells (1%) showing a fluorescence signal significantly higher than controls were selected and analyzed by flow cytometry to confirm gene editing.
than that of control nontransfected cells were sorted and grown to confluence in a T175 flask; these cells were subjected to a second round of FACS, and ~5% (those with the highest fluorescence signal) were isolated, expended in a T175 flask, and frozen. Generation of clonal lines for cells gene-edited in both alleles for dynamin2-EGFP expression was carried out by single-cell flow cytometry sorting in a 96-well plates and then maintained in 12-well plates and split 1:6 at the time they reached confluence. Identification of clone D3, here- with named SUM-Dyn2, with both alleles modified to express dynamin2-EGFP was done by genomic PCR amplification from genomic DNA purified with the QIAamp DNA Mini Kit (Qiagen) using GoTaq Polymerase (Promega, Madison, WI) and the forward 5’-GT- CAAAACAGAGCCGGATTG-3’ and reverse 5’-CAGCGTGAAGGAA- GAGGCCA-3’ primers. These two primers map in the genomic se-
quence of dynamin2 in the region close to the stop codon: the amplification wild-type dynamin2 corresponds to a 395-base pair product, whereas insertion of EGFP results in a 1130-nucleotide product. Expression of dynamin2-EGFP instead of dynamin2 was confirmed by Western blot analysis.

Glass coverslip preparation
Glass coverslips (#1.5; Warner Instruments, Hamden, CT) were cleaned and then coated with a copolymer of poly-L-lysine (PLL) and biotinylated polyethylene glycol (PEG; Susos AG, Dübendorf, Switzerland) as described (Böcking et al., 2011; Cocucci et al., 2012). These PEG-modified coverslips were coated with fibronectin and used to plate cells imaged with TIRF microscopy. Clean coverslips without the PEG modification were used to plate cells imaged with spinning-disk fluorescence microscopy. Clean coverslips were also used to capture dynamin2-EGFP molecules and then used to cali-
brate the fluorescence intensity signal of single molecules of EGFP visualized by TIRF or spinning-disk fluorescence microscopy; diluted cytosol containing dynamin2-EGFP was placed on clean coverslips immediately after a 3-min glow discharge period at 50 mA (Electron Microscopy Science, Hatfield, PA).

Cell extracts and Western blotting
Cytosolic extracts were prepared from bovine brain (Boll et al., 1996) or from three 10-cm dishes containing SUM-Dyn2 or hCLTA2H/ DNMT2H cells grown to confluency. Cells were washed three times in PBS and solubilized at 4°C for 5 min in 300 μl of 50 mM HEPES, pH 7.4, 150 mM NaCl, 15 mM MgCl2, 1 mM ethylene glycol tetra-
cetic acid, 10% glycerol, 1% Triton X-100, and a protease inhibitor cocktail (Roche, Branford, CT); nuclei were removed by low-speed centrifugation (800 × g, 5 min, 4°C, Centrifuge 5417R; Eppendorf, Hauppauge, NY). Western blot analysis was carried out as described (Cocucci et al., 2012).

Transferrin uptake by flow cytometry
SUM159 cells, plated in 12-well plates and grown to 80% conflu-
ency, were washed in PBS and incubated for 10 min with 5 μg/ml Transferrin-Alexa Fluor 647 (transferrin-A647; Life Technologies) at 4 or 37°C. After incubation, the plates were cooled on ice, rinsed with ice-chilled PBS, and briefly incubated or not twice with 150 mM NaCl, 1 mM MgCl2, 0.125 mM CaCl2, and 0.1 M glycine, pH 2.5, to remove the surface-bound transferrin-A647. The cells were then re-
suspended for 3 min at 37°C by treatment with 0.05% trypsin-EDTA (Life Technologies), rinsed with 700 μl SUM media, and resuspended in 200 μl of PBS containing 1% bovine serum albumin and 0.5 mM EDTA at 4°C. The amount of transferrin associated with each cell, reflecting the extent of endocytosis, was determined by flow cytometry as the mean fluorescence intensity of transferrin-A647 after the acid wash using the 633-nm laser line of the FASCSRanto2 (BD Biosciences).

Depletion of dynamin2 by siRNA treatment and selection of cells for visualization
siRNA treatment of SUM-Dyn2 cells was carried out by transfection of cells grown in six-well plates to a density of 80%. We used 20 nM siRNA (Dharmacon, Fisher Scientific, Pittsburgh PA) of sequence 5’-GACAUGAUCCUGAUGUCAU-3’ or a scrambled negative control for transfection with Lipofectamine RNAiMAX (Life Technol-
ologies). The day after transfection, the cells were trypsinized and re-
plated at ~20% confluency in six-well plates and allowed to grow for additional 3 d, after which ~50 × 10^6 cells were plated onto coverslips placed in a six-well plate and imaged 24 h later.

Before imaging, the coverslip was placed for 10 min on a tem-
perature- and humidity-controlled microscope stage containing 1 ml of prewarmed MEMx without phenol red (Gibco, Langley, OK) supplemented with 1% FBS to allow temperature equilibration to 37°C. At this point, transferrin-A647 was added at 5 μg/ml and cells incubated for 7 min. Cells with normal or depleted levels of dynamin2-EGFP were selected for imaging as follows: cells with normal levels of dynamin showed active coated-pit dynamics and accumulation of transferrin in endosomes; cells depleted of dyna-
mrin were impaired in coated-pit dynamics at the cell surface together with increased fluorescence intensity of the clathrin struc-
tures, decrease of the cytosolic diffuse signal of dynamin2-EGFP, and accumulation of fluorescence transferrin at the cell surface. Western blot analysis of dynamin2 levels in cells treated with siRNA was not deemed informative as a way to determine the overall ef-

ciency of dynamin2 depletion because <10% of the cells showed full loss of active pit dynamics and associated inhibition of transferrin uptake.

Osmotic shock
Cells were subjected to a brief, 10-min incubation with iso-osmotic, hypo-osmotic, or hyper-osmotic medium, followed by acquisition in the same medium of a 200-s time series using spinning-disk confocal microscopy consisting of 200 frames acquired every second. Hypo-osmotic medium was prepared by mixing one volume of MEMx without phenol red (Gibco) containing 1% FBS with water also containing 1% FBS. Hyper-osmotic medium was made by dis-
solving sucrose to 0.25 M in MEMx without phenol red containing 1% FBS.

Live-cell imaging and fluorescence calibration
Spinning-disk confocal fluorescence microscopy and TIRF micros-
copy were done using Marianas-based systems (Intelligent Imaging Innovations, Denver, CO). Both systems were controlled with Slide-
Book V5.0 (Intelligent Imaging) operating under Windows 7 on a computer with 12 GB of RAM (Dell, Round Rock, TX). The spinning-
disk confocal microscopy system was based on a fully enclosed, en-
vironmentally temperature controlled Axiovert 200M microscope equipped with a 100×/1.4 numerical aperture objective (Carl Zeiss Microimaging, Thornwood, NY), a CSU-22 spinning-disk confocal head (Yokogawa Electric, Tokyo, Japan) modified with a photon ex-

pansion Borealis upgrade (Andor, Belfast, UK), and computer-con-
trolled piezo-Z stage equipped with a linear X&Y encoder (Applied Scientific Instruments, Eugene, OR). A 1.5x magnification lens placed in front of the cooled electron multiplication charge-coupled device (CCD) camera (QuantEM 512SC, Photometrics, Tucson, AZ) provided a final pixel size corresponding to 100 nm of image. The excitation was provided by solid-state lasers operating at
The total expected distribution of EGFPs as a weighted sum of bi-ent in the step (e.g., as (dimer, tetramer, etc.) is calculated by taking into account the extent of substitution estimated by the Wester blot data, $n_i$ is the maximum number of fluorophores for each value of $i$, and $M$ is the maximum number of molecules included in the model for that step. From this distribution, the corresponding cumulative intensity distribution is calculated as

$$f(k) = \sum_{i=1}^{M} a_i \left( \frac{n_i}{k} \right)^{q^i(1-q)^{n-i}}$$

where $q$ (98%) is the substitution probability derived from the Western blot data, $n_i$ is the maximum number of fluorophores for each value of $i$, and $M$ is the maximum number of molecules included in the model. The corresponding cumulative intensity distribution is calculated as

$$F(x) = \sum_{i=1}^{n_{max}} f(n_i) \int 1 + \text{erf} \left( \frac{x-(\mu)n}{\sigma \sqrt{2n}} \right)$$

where $n_{max}$ is the maximum number of fluorophores in $f(k)$ and $\mu$ and $\sigma$ are the mean and SD of the intensity of a single molecule, respectively; the values of $\mu$ and $\sigma$ were obtained from the single-molecule dynamin2-EGFP calibration. During the fit of $F$ to the measured cumulative intensity distributions, the parameter $a_i$ was estimated for a given configuration of the assembly unit of dynamin (e.g., monomer, dimer, tetramer, hexamer, and octamer). Different models were created by the iterative addition of components to the simplest possible initial description (e.g., one monomer is recruited during each step, or monomer is the only oligomeric state present in the cytosol). Selection of the best combination of models was based on the BIC used to prevent overfitting of the data (Jaqaman and Danuser, 2006). The BIC with the lowest value was the best descriptor of the data; it defines an optimal trade-off between the likelihood of a model and the number of parameters used in the model description. Its value decreased with the model likelihood and increased with the number of model parameters used to fit the data.

Independent confirmation for the extent of substitution determined by Western blot analysis from SUM-Dyn2 cell extracts was obtained by comparing mathematical models of different dynamin2 assembly units (monomer, dimer, tetramer, combinations of dimers and tetramers, etc.) and variable substitution with the experimental data from the SUM-Dyn2 cells used to determine the preferential assembly unit of dynamin; the BIC was then used to search for the model that would best fit the experimental data.

The amount of dynamin recruited to coated pits was determined in SUM-Dyn2 and hCLAT2/DNM2 cells from data obtained by spinning-disk confocal fluorescence microscopy using the cmeAnalysis software with clathrin as the "master" and dynamin as the "slave" (Aguet et al., 2013). Parameters used for the detector were Sigma, 1.1, and Alpha, 0.05; valid tracking was constrained to objects containing less than two gap lengths, at least five frames in length, and with <3-pixel shift between consecutive frames. Clathrin traces >25 s in duration were binned as valid coated pits, whereas shorter ones were classified as abortive pits. Clathrin traces present during the full duration of the time series were classified as persistent coated plaques. Not included in the analysis were objects rapidly appearing or disappearing and objects whose dynamics were truncated by the initiation of end of the time series. All objects reported in this study were validated by visual inspection; this verification was necessary because the fluorescence signal elicited by mCherry-LCa or by LCa-RFP was not strong enough for reliable automatic selection.

The number of dynamin2-EGFPs recruited to a coated-pit spot was obtained from the fluorescence intensity of dynamin2-EGFP on the diffraction-limited spot calibrated by the mean intensity of single dynamin2-EGFP obtained by the single-step photobleaching determination. The number of recruited dynamin2 molecules was then calculated by taking into account the extent of substitution estimated by Western blot analysis (98% in SUM-Dyn2 cells, 50% in
