Received 1 October 2002; revised 10 February 2003; accepted 7 April 2003; published 13 September 2003.

[1] We report the first in situ measurements of hydrogen cyanide (HCN) and methyl cyanide (CH$_3$CN, acetonitrile) from the Pacific troposphere (0–12 km) obtained during the NASA Transport and Chemical Evolution over the Pacific (TRACE-P) airborne mission (February–April 2001). Mean HCN and CH$_3$CN mixing ratios of 243 ± 118 (median 218) ppt and 149 ± 56 (median 138) ppt, respectively, were measured. These in situ observations correspond to a mean tropospheric HCN column of $4.2 \times 10^{15}$ molecules cm$^{-2}$ and a CH$_3$CN column of $2.5 \times 10^{15}$ molecules cm$^{-2}$. This is in good agreement with the 0–12 km HCN column of $4.4 \pm 0.6 \times 10^{15}$ molecules cm$^{-2}$ derived from infrared solar spectroscopic observations over Japan. Mixing ratios of HCN and CH$_3$CN were greatly enhanced in pollution outflow from Asia and were well correlated with each other as well as with known tracers of biomass combustion (e.g., CH$_3$Cl, CO). Volumetric enhancement (or emission) ratios (ERs) relative to CO in free tropospheric plumes, likely originating from fires, were 0.34% for HCN and 0.17% for CH$_3$CN. ERs with respect to CH$_3$Cl and CO in selected biomass burning (BB) plumes in the free troposphere and in boundary layer pollution episodes are used to estimate a global BB source of 0.8 ± 0.4 Tg (N) yr$^{-1}$ for HCN and 0.4 ± 0.1 Tg (N) yr$^{-1}$ for CH$_3$CN.

In comparison, emissions from industry and fossil fuel combustion are quite small (<0.05 Tg (N) yr$^{-1}$). The vertical structure of HCN and CH$_3$CN indicated reduced mixing ratios in the marine boundary layer (MBL). Using a simple box model, the observed gradients across the top of the MBL are used to derive an oceanic loss rate of $8.8 \times 10^{-15}$ g (N) cm$^{-2}$ s$^{-1}$ for HCN and $3.4 \times 10^{-15}$ g (N) cm$^{-2}$ s$^{-1}$ for CH$_3$CN. An air-sea exchange model is used to conclude that this flux can be maintained if the oceans are undersaturated in HCN and CH$_3$CN by 27% and 6%, respectively. These observations also correspond to an open ocean mean deposition velocity ($v_d$) of 0.12 cm s$^{-1}$ for HCN and 0.06 cm s$^{-1}$ for CH$_3$CN. It is inferred that oceanic loss is a dominant sink for these cyanides and that they deposit some 1.4 Tg (N) of nitrogen annually to the oceans. Assuming loss to the oceans and reaction with OH radicals as the major removal processes, a mean atmospheric residence time of 5.0 months for HCN and 6.6 months for CH$_3$CN is calculated. A global budget analysis shows that the sources and sinks of HCN and CH$_3$CN are roughly in balance but large uncertainties remain in part due to a lack of observational data from the atmosphere and the oceans. Pathways leading to the oceanic (and soil) degradation of these cyanides are poorly known but are expected to be biological in nature.

1. Introduction

Hydrogen cyanide (HCN) and methyl cyanide (CH$_3$CN, acetonitrile) are two of the most abundant cyanides present in the global atmosphere. Following the first spectroscopic detection of HCN in the stratosphere [Coffey et al., 1981], a number of ground and space based observations of its total atmospheric column have been made [Mahieu et al., 1995; Rinsland et al., 1998, 1999, 2000; Notholt et al., 2000; Zhao et al., 2000, 2002]. The presence of methyl cyanide was first inferred from the composition of its positive ions in the stratosphere [Arnold et al., 1978]. Limited in situ measurements of HCN and CH$_3$CN have been reported from the lower stratosphere [Schneider et al., 1997]. In the stratosphere, vertical profiles of CH$_3$CN have also been retrieved from satellite data [Livesey et al., 2001]. Sporadic and often conflicting in situ measurements of CH$_3$CN from the surface in urban/rural environments have been published [Becker and Ionescu, 1982; Snider and Dawson, 1984; Hamm and Warneck, 1990]. More recently a proton transfer mass spectrometric technique has been used to measure CH$_3$CN in tropical environments [Crutzen et al., 2000; Reiner et al., 2001; Williams et al., 2001]. There is promise of future space-based tropospheric observations of HCN (and possibly CH$_3$CN) with some vertical resolution [Singh and Jacob, 2000].

Controlled studies of laboratory fires have been used to suggest that biomass burning (BB) results in significant emissions of HCN and CH$_3$CN into the atmosphere [Lobert et al., 1991; Holzinger et al., 1999]. Estimates of their global sources are highly uncertain in part due to extremely limited and often conflicting field observational data [Andreae and Merlet, 2001]. Although large quantities of HCN (≈0.40 Tg (N) yr$^{-1}$) and smaller amounts of CH$_3$CN (≈0.01 Tg (N) yr$^{-1}$) are also manufactured for applications as fumigants and chemical intermediates, their release is stringently controlled due to their known toxicity. Extremely high HCN concentrations (1–2 parts per thousand) have been reported in cigarette smoke [Verschueren, 1996]. These cyanides are expected to be slowly removed from the atmosphere by reaction with OH radicals [Cicerone and Zellner, 1983; Hamm and Warneck, 1990]. It has also been speculated that oceans may provide an important sink for CH$_3$CN [Hamm and Warneck, 1990; Lobert et al., 1990; Bange and Williams, 2000], although no direct evidence of this sink is presently available. A recent modeling study by Li et al. [2000] concludes that the seasonal behavior of the total column of HCN can be reconciled with an exclusive BB source and a relatively short lifetime attributable to an oceanic sink. Measurements of cyanides in the troposphere are extremely sparse, and our present knowledge of their sources, sinks, and role in atmospheric chemistry and biogeochemistry is highly uncertain.

The NASA Transport and Chemical Evolution over the Pacific (TRACE-P) airborne experiment was performed in the spring (February–April) of 2001 to study the composition and chemistry of the outflow of pollution from Asia to the Pacific troposphere. This experiment provided a first opportunity to utilize a recently developed technique to perform real time in situ airborne measurements of HCN and CH$_3$CN. Complementing these were measurements of a large number of unique trace chemicals that are helpful in the identification of sources. Further details on the instrument payload, flight patterns, and prevailing meteorology can be found in the overview papers of Jacob et al. [2003] and Fue kterg et al. [2003]. Here we describe the atmospheric distribution of HCN and CH$_3$CN over the Pacific and use the relationship of their observed concentrations with other selected tracers to construct a first picture of their sources and sinks. We also note that these data have been further investigated by Li et al. [2003] with the help of a global 3-D model.

2. Experiments

A gas chromatographic (GC) instrument, previously used to measure PAN and oxygenated organics [Singh et al., 2001, and references therein], was expanded to measure HCN and CH$_3$CN. This instrument was integrated aboard the DC-8 aircraft and all measurements discussed in this paper were performed on this platform. A volume of 5.0 L min$^{-1}$ (0°C, 1 atm) of ambient air was drawn through a heated Teflon-lined sampling probe using a low pressure drop mass flow controller (MKS Model 1559A). An aliquot of 200 mL of air (80 mL min$^{-1}$) was passed through a water dryer held at −35°C, and then cryogenically trapped in a sample loop held at −140°C. Extensive laboratory tests were performed to ensure that the water trap removed moisture without measurable loss of other constituents of interest. After cryogenic concentration, the sample loop was heated to 70°C and switched in line with the GC columns. A 50-m “analytical” and a 15-m “stripper” DB wax (0.85 μm) quartz capillary column of 0.45 mm ID were used for constituent separation. The “stripper column” was used to back flush high boiling constituents from the system. Chemicals were detected with a photo ionization detector (PID) placed in series with a reduction gas detector (RGD). Only the RGD was capable of detecting cyanides while both PID and RGD were suitable for detecting oxygenates. All calibrations were performed using standard addition techniques and in a manner that mimicked ambient air sampling. Primary standards for HCN and CH$_3$CN were referred to a series of permeation tubes held at 30°C and 0°C. A 1-ppm compressed mixture of CH$_3$CN in nitrogen was also used for this purpose. The detector response for CH$_3$CN and HCN was linear over a wide concentration range. A precision of ±5% could be obtained on the ground in dry air. Precision under the highly variable atmospheric conditions during airborne operation was of the order of ±15% in the free troposphere and somewhat poorer in the moist marine boundary layer (MBL). Overall measurement accuracy is expected to be ±25% with a limit of detection of 30 ppt.

A chromatogram showing the separation and detection of HCN and CH$_3$CN from ambient air is shown in Figure 1. The tailing of peaks in Figure 1 occurs in the mercuric oxide bed and is a known difficulty with the RGD detector but is not a source of additional error. This was the first time that this instrument was used to measure ambient HCN and CH$_3$CN. There were some instances, usually in the early stages of sampling, when the sensitivity of the instrument appeared to be poor. This loss of sensitivity could be easily confirmed from the analysis of calibration standards. Although the causes of this loss of sensitivity are not fully understood, we have chosen to disregard data collected under such
The Pacific troposphere was sampled from 0.1 to 12 km over a region that extended from 10 to 45°N latitude and 100°E to 120°W longitude. More details on flight profiles and sampling density are provided by Jacob et al. [2003]. When appropriate, this region has been divided into areas representing the western Pacific (longitude 100°–160°E) and central/eastern Pacific (longitude 160°E–130°W). To relate these data with other key chemicals, which were measured at differing frequencies, merged data files were created. In appropriate, this region has been divided into areas representing density are provided by Jacob et al. [2003]. 3. Results and Discussion

In the following sections we provide an analysis of the observations of HCN and CH$_3$CN during TRACE-P (25 February to 10 April 2001). All measurements discussed in this paper were performed aboard the NASA DC-8 aircraft. The Pacific troposphere was sampled from 0.1 to 12 km over a region that extended from 10 to 45°N latitude and 100°E to 120°W longitude. More details on flight profiles and sampling density are provided by Jacob et al. [2003]. When appropriate, this region has been divided into areas representing the western Pacific (longitude 100°–160°E) and central/eastern Pacific (longitude 160°E–130°W). To relate these data with other key chemicals, which were measured at differing frequencies, merged data files were created. In much of the analysis that follows, a 5-min merged data set has been used. Unless noted otherwise, only data from the troposphere are considered. A convenient filter ($O_3 > 100$ ppb and $z > 10$ km or $CO < 50$ ppb) was used to remove stratospheric influences. We used methyl chloride and potassium as tracers of biomass combustion, and CO as a more generic tracer of pollution. Although CH$_3$Cl is known to have a diffuse oceanic and possibly biogenic source [Butler, 2000], it was possible to use it as a tracer of biomass/biofuel combustion in air masses downwind of its terrestrial sources. Tetrachloroethylene (C$_2$Cl$_4$), a synthetic organic chemical, was employed as a tracer of urban pollution. When appropriate, a pollution filter was used to mitigate the effect of pollution ($CO < 120$ ppb; $C_2Cl_4 < 10$ ppt). This filter resulted in mixing ratios of 96(±15) ppb/CO and 3(±1) ppt/C$_2$Cl$_4$, and is assumed to represent near-background conditions. Utilizing meteorological and tracer information, we are able to draw important conclusions about the sources and sinks of HCN and CH$_3$CN.

3.1. Atmospheric Distribution

Figure 2 shows the vertical distribution of HCN and CH$_3$CN in the troposphere based on all TRACE-P data. Superimposed on the data are mean (±σ) mixing ratios based on 2-km bins. Mean concentrations of these and key tracer species are presented in Table 1. It is evident that substantial concentrations of cyanides are present throughout the atmosphere and that there is significant variability. These mixing ratios correspond to a 0–12 km grand average of 243 ± 118 ppt (median 218 ppt) HCN and 149 ± 56 ppt (median 138 ppt) CH$_3$CN. Comparable in situ HCN data from the troposphere are not available. However, our measured values in the upper troposphere (UT) are not inconsistent with the 164 (±25%) ppt lower stratospheric mixing ratios reported by Schneider et al. [1997] for February 1995. Unlike HCN, a more extensive tropospheric database for CH$_3$CN has become available. Following the TRACE-P deployment, Pacific region measurements of CH$_3$CN were made at the Mauna Loa observatory (April 2001) and over the eastern Pacific (April–May 2002). These studies report mixing ratios in the vicinity of 100–200 ppt in good agreement with our results [Karl et al., 2003; De Gouw et al., 2003]. Background CH$_3$CN mixing ratios reported from the Indian Ocean and Surinam [Crutzen et al., 2000; Lelieveld et al., 2000; Reiner et al., 2001; Wisthaler et al., 2002] were generally in the range of 100–300 ppt. It is noted that strong seasonal variations in the atmospheric abundance of HCN (and likely CH$_3$CN) are present [Zhao et al., 2002], and any comparison of observations must take this factor into account.

The variability in the mixing ratios of cyanides is substantial and largely associated with the outflow of pollution from the Asian continent. Maximum concentrations of 1610 ppt and 320 ppt were measured for HCN and CH$_3$CN, respectively. It is instructive to normalize these data with respect to a common tracer of pollution to minimize the observed scatter. Figure 3 shows the altitude profile when the mixing ratios of HCN and CH$_3$CN are normalized with respect to CO. An evident feature is that relative to CO, the mixing ratios of HCN and CH$_3$CN decline rapidly toward the surface of the ocean. A nearly identical vertical structure can also be seen when mixing ratios are normalized to a more specific tracer of BB such as CH$_3$Cl. This behavior is also seen directly in the vertical structure of HCN and CH$_3$CN (Table 2) when the data are further filtered for relatively clean atmospheric conditions ($CO < 120$ ppb; $C_2Cl_4 < 10$ ppt). As we show in section 3.5, these reduced lower tropospheric concentrations are a first indication of their surface sink.
On limited occasions and at midlatitudes, it was possible to penetrate the lowermost part of the stratosphere. Ozone concentrations as large as 600 ppb were measured during these episodes. Figure 4 shows the distribution of CH$_3$CN plotted as a function of O$_3$. The decline in CH$_3$CN concentrations above the tropopause is very similar to that observed by Schneider et al. [1997]. It was not possible to collect sufficient HCN data in the stratosphere due to an instrument artifact.

### 3.2. Atmospheric Columns

For the sampled latitudes and season, our in situ measurements (Table 1) correspond to a 0–12 km tropospheric HCN column of 3.7–4.2 $\times 10^{15}$ molecules cm$^{-2}$ and a CH$_3$CN column of 2.4–2.5 $\times 10^{15}$ molecules cm$^{-2}$. The lower end of this range is based on median mixing ratios while the upper end is based on means. This result can be best compared with the Japanese ground-based infrared solar spectroscopic observations of the column of HCN over Tsukuba (36.2°N), Rikubetsu (43.5°N), and Moshiri (44.4°N) during the TRACE-P period. Mean 0–12 km column densities (in units of $10^{15}$ molecules cm$^{-2}$) of 4.8 ± 0.7, 4.1 ± 0.4, 4.4 ± 0.6 respectively, were derived. The daily HCN columns from these sites are shown in Figure 5. These mean column densities of 4.1–4.8 $\times 10^{15}$ molecules cm$^{-2}$ are in reasonably good agreement with the derived mean HCN column of $4.2 \times 10^{15}$ molecules cm$^{-2}$ deduced from in situ measurements (Figure 5). Although there can be substantial year to year variability, typical spring time column densities of $4-5 \times 10^{15}$ molecules cm$^{-2}$ have been reported from 1996 to 2000 over Japan [Zhao et al., 2000, 2002].

HCN columns have also been derived from spectra collected at high altitude observatories located at Mauna Loa, Hawaii (19.5°N, 3.4 km altitude) and Jungfraujoch, Switzerland (46.6°N; 3.6 km altitude) [Rinsland et al., 1999, 2000]. Mean springtime HCN columns from these locations are found to be in the range of 2–3 $\times 10^{15}$ molecules cm$^{-2}$. Once again, this is in reasonable agreement with the 3.5–12 km mean column density of 2.4 $\times 10^{15}$ molecules cm$^{-2}$ derived from the present in situ measurements (Table 1). We note that the ground-based spectroscopic observations do not have sufficient vertical resolution to determine the boundary layer HCN column. Long-term spectroscopic observations are inconclusive about any possible trend in the atmospheric HCN [Mahieu et al., 1997; Rinsland et al., 2001]. Similar spectroscopic data for CH$_3$CN are not available possibly because its strongest absorption in the 6-μm region is obscured by water vapor.

### 3.3. Tracer Relationships

Despite a high degree of variability, mixing ratios of HCN and CH$_3$CN are related suggesting common sources. Figure 6 shows this relationship in the free troposphere (>2.5 km) over the entire Pacific. A linear relationship

provides a reasonable fit to these data \((R = 0.70)\) which is somewhat improved with a second order best fit \((R = 0.77)\). The latter suggests that under certain conditions emissions of HCN increase more rapidly than CH₃CN. While there is insufficient data to draw firm conclusions, there is an indication that these mixing ratios are nonlinearly related. A likely cause is that emission factors of HCN and CH₃CN vary differently with the nature of fuel and combustion temperature. There is insufficient knowledge about the pyrogenic formation mechanisms of cyanides to quantitatively understand the nonlinear behavior. There exists a linear relation between CH₃Cl, a tracer of biomass combustion, and HCN, CH₃CN, and CO in the free troposphere over the western Pacific as well as the central/eastern Pacific regions (Figure 7). These linear relationships are maintained over the entire Pacific troposphere. Figure 8 demonstrates the persistence of this linear relationship between cyanides and tracer (CO and CH₃Cl) mixing ratios in the UT (8–12 km). The somewhat improved linear correlations over the central/eastern Pacific as well as the UT are attributable to the greater homogeneity of the air masses farther away from their sources. In their entirety, these relationships provide broad support for the view that the atmospheric burden of cyanides is strongly associated with BB sources. Nonvolatile aerosols also behaved in a manner similar to gas phase tracers such as CO.

The linear relationships typically observed in the free troposphere frequently broke down in the boundary layer in part due to the high complexity of the Asian anthropogenic sources and the proximity of the oceanic sink. We sampled two distinct outflow events when low level outflow (<1 km) of pollution was encountered in the Taiwan Straits (Mission 12) and the Yellow Sea (Mission 13). Trajectory analysis showed that the Taiwan Straits episode was impacted by source regions from the Fujian province of China, while the Yellow Sea episode was a direct outflow from the Shanghai urban complex. Figure 9 shows the relationship of CH₃Cl with cyanides and CO for these missions. Extremely large concentrations of CH₃Cl were associated with virtually no elevation in CH₃CN and only a modest increase in HCN. A very large fraction \((\approx 30\%)\) of fuel consumed in China is from the use of biofuels/coal. We interpret the boundary layer outflow data to infer that such fuels are inefficient producers of cyanides. A low fuel nitrogen content and a high halogen content is implied.

### 3.4. Source Estimates of HCN and CH₃CN From Biomass Burning

[14] To assess the sources of cyanides, we investigated their atmospheric behavior relative to known tracers of combustion and urban pollution. As a first step, we looked

at the enhancement ratios (ERs) of HCN and CH$_3$CN relative to CH$_3$Cl and CO in 12 plumes sampled in the free troposphere (>3 km) and in episodes of pollution outflow in the MBL (0–1 km). These data are summarized in Table 3. All these chemicals are long-lived (several months), and the plumes are sufficiently fresh (<5 days), so that chemical changes during transport should have a negligible effect on these ERs. Therefore these enhancement ratios are effectively the same as emission ratios defined by Andreae and Merlet [2001]. Five-day back trajectory analysis [Fuelberg et al., 2003], indicated that the free tropospheric plumes generally originated over regions of southern China, Southeast Asia, and northern Africa. Satellite observations showed that fires were prevalent in these regions. It is common knowledge that BB air masses are easily advected into the free troposphere. All of the relevant tracers of biomass combustion (e.g., HCN, CH$_3$CN, CO, CH$_3$Cl, and potassium) were significantly elevated in these plumes. Additionally, the elevation in C$_2$Cl$_4$ (Table 3) was quite small (0–10 ppt). In contrast, trajectories associated with the 9 boundary layer pollution episodes (Table 3) showed that nearly all of them had crossed the eastern China coastal areas at relatively low altitudes within the last two days. These episodes were also associated with high concentrations of C$_2$Cl$_4$ and other anthropogenic tracers.

Fossil fuel combustion is not a known source of either CH$_3$Cl or cyanides. Because of this specificity, we will first use ERs with respect to CH$_3$Cl to assess BB emissions of HCN and CH$_3$CN. In large east Asian cities, most of the BB emissions are due to biofuels [Streets and Waldhoff, 1998; Yevich and Logan, 2003], and thus boundary layer ERs provide an indicator of cyanide emissions from this source. In the following analysis we use both free tropospheric and MBL ERs to estimate the total BB source of HCN and CH$_3$CN. The former represents relative emissions from plumes due to fires, and the latter indicates biofuel/coal emissions. We adopt a global BB CH$_3$Cl source of 0.9 Tg yr$^{-1}$ (87% biomass fires; 13% biofuels/charcoal) based on the most recent evaluations [Lobert et al., 1999; Andreae and Merlet, 2001]. To obtain global BB source of HCN and CH$_3$CN ($S_{HCN,CH_3CN}$, Tg (N) yr$^{-1}$), we scale ERs in Table 1 (ppt/ppt) according to

$$S_{HCN,CH_3CN} = 0.9 \times (14/50.5) \times (0.87ER_{ft} + 0.13ER_{bl})_{CH_3Cl},$$

where ER$_{ft}$ and ER$_{bl}$ are the respective ERs (ppt/ppt) with respect to CH$_3$Cl in the free troposphere and the MBL.
To minimize errors due to urban influences, only ER\textsubscript{ft} associated with minimal C\textsubscript{2}Cl\textsubscript{4} enhancements (<5 ppt) are used in these calculations. Using equation (1), we calculate a global BB source of 0.8 ± 0.4 Tg (N) yr\textsuperscript{-1} for HCN and 0.4 ± 0.1 Tg (N) yr\textsuperscript{-1} for CH\textsubscript{3}CN. Equation (1) also leads to the conclusion that most of these emissions are due to fires (first term) and biofuels/charcoal (second term) contribute only a small fraction (10% HCN and 5% of CH\textsubscript{3}CN) to the total BB source of cyanides.

A similar analysis was also carried out by using ERs with respect to CO. The presence of non-BB sources of CO may make these estimates somewhat less reliable. However, by using ER\textsubscript{a} values (ppt/ppb) associated with minimal C\textsubscript{2}Cl\textsubscript{4} enhancements (<5 ppt), it is possible to obtain a reasonable estimate by using

\[
\frac{[\text{HCN}]}{[\text{CH}_3\text{CN}]}_{\text{CO}} = \frac{600}{\text{CO}} \times \left(\frac{14}{28}\right) \times 10^{-3} \left(0.74\text{ER}_a + 0.26\text{ER}_b/f\right)_{\text{CO}}.
\]

For this purpose, we adopted a global BB CO source of 600 Tg yr\textsuperscript{-1} (74% biomass fires; 26% biofuels/charcoal), based on the most recent evaluations of BB sources [Duncan et al., 2003; Yevich and Logan, 2003]. The factor f is the CO

Figure 7. Relationships between the mixing ratios of methyl chloride with CH\textsubscript{3}CN, HCN, and CO in the free troposphere over the (a) western Pacific and (b) eastern/central Pacific. For the entire ensemble of data, best fit slopes are ΔHCN/ΔCH\textsubscript{3}Cl -1.80; ΔCH\textsubscript{3}CN/ΔCH\textsubscript{3}Cl -1.19; and ΔCO/ΔCH\textsubscript{3}Cl -1.00.

Figure 8. Relationship of HCN and CH\textsubscript{3}CN with select tracers in the upper troposphere (8–12 km).
fraction from biofuel/charcoal use in regions of eastern Asia and attempts to correct for the impact of fossil fuel CO sources on the MBL. On the basis of the inventory developed by Streets et al. [2003], a value of 0.55 is adopted for \( f \). As we have seen from equation (1), the biofuel component of HCN/CH\(_3\)CN emissions is small (<10%), so errors due to uncertainty in \( f \) are relatively modest. Using equation 2 and ERs with respect to CO from Table 1 results in a BB source estimate of 0.9 ± 0.4 Tg (N) yr\(^{-1}\) for HCN and 0.4 ± 0.1 Tg (N) yr\(^{-1}\) for CH\(_3\)CN, in good agreement with results from equation (1). We caution that these estimates are relative and would be directly affected by the uncertainties in the global BB emissions of CO and CH\(_3\)Cl [Andreae and Merlet, 2001; Yevich and Logan, 2003].

In Table 4, we summarize BB source estimates of HCN and CH\(_3\)CN from published laboratory and field studies. Nearly all these estimates have been derived from measured ERs with respect to CO in controlled laboratory fires, in prescribed burns, and in real forest and savanna fires. In some instances [e.g., Lobert et al., 1991], emission factors relative to fuel nitrogen have been employed. These derived estimates typically lie in the range of 0.5–1.5 Tg (N) yr\(^{-1}\) for HCN and 0.3–0.6 Tg (N) yr\(^{-1}\) for CH\(_3\)CN. Recent measurements of comparatively large HCN ERs relative to CO in African fires by Yokelson et al. [2003] suggest that the HCN global BB source may be near the upper limit of this range (R. Yokelson, private communication, 2003). Our ERs, based on direct atmospheric measurements, and BB source estimates (Tables 3 and 4) are within the broad ranges that have been previously reported.

The source of variability in individual ERs in Table 3 is likely due to the dependence of ERs on the type of fuel burned and its nitrogen content. The outflow of Asian pollution represents an extremely complex mixture resulting from the heterogeneity of the fuel sources [Kato, 1996; Streets and Waldhoff, 1998]. There were instances when CO was elevated but cyanides as well as CH\(_3\)Cl were not, as may be expected from a typical industrialized urban source. There were also instances when a large elevation in CH\(_3\)Cl coexisted with little increase in CH\(_3\)CN. In a study involving a variety of burns, Yokelson et al. [1997] find that relative to CO organic fuels produce the largest HCN, grasses less so, and woody fuels produce the least.

### 3.5. Air-Sea Exchange and Oceanic Sink

It is evident from Figure 3 that the atmospheric mixing ratios of HCN and CH\(_3\)CN declined toward the surface over open oceans. This is easily seen in Table 3, where statistical distributions of data filtered to remove pollution episodes (CO < 120 ppb; C\(_2\)Cl\(_4\) < 10 ppt) are summarized. All other indicators of pollution (CO, C\(_2\)H\(_6\), C\(_2\)H\(_2\), etc.) show the opposite behavior with increasing mixing ratios near the surface. We have assessed the significance of these reduced boundary layer mixing ratios using a simple steady state box model [Singh et al., 1996]. In this model the marine boundary layer (MBL) mixing ratios are maintained by entrainment from the free troposphere, loss due to reaction with OH radicals, and exchange with the ocean. As we shall see later, soils are not a likely important sink for cyanides and this gradient is mainly due to the oceanic sink.

The total flux into the MBL (\( F_t \)) was calculated by using a mean entrainment velocity (\( V_e \)) of 0.4 cm s\(^{-1}\) [Kawa and Pearson, 1989; Paluch et al., 1994; Singh et al., 1996; I. Faloona et al., Observations of entrainment in eastern Pacific marine stratocumulus using three conserved scalars, submitted to Journal of Atmospheric Science, 2003] and a concentration gradient (\( \Delta C \)) across the top of the MBL derived from measurements filtered for clean atmospheric conditions (Table 3):

\[
F_t = V_e \Delta C. \tag{3}
\]
### Table 3. Enhancement Ratios (ERs) of HCN and CH$_3$CN With Respect to CO and CH$_3$Cl in Selected Plumes in the Free Troposphere (3–12 km; ER$_{ft}$) and in Pollution Episodes in the Marine Boundary Layer (0–1 km; ER$_{bl}$)

To avoid biases due to scatter in the data, ΔC was determined by using median concentration differences between the free troposphere above the MBL (2–4 km) and within the MBL (0–2 km). A median gradient of 47 ppt for HCN and 20 ppt for CH₃CN from Table 2 is employed to determine Fₜ. A second method that normalized mixing ratios to CO was also used with comparable results. The loss in the MBL due to OH reaction (F_OH) was estimated by using an OH concentration of 1.5 × 10⁶ molecules cm⁻³ and an MBL depth of 2 km, consistent with historic knowledge and actual observations during TRACE-P. Losses due to other radical reactions (Cl, NO₃ etc.) are small and are presently neglected. Choice of a somewhat lower MBL depth (1.5 km) did not perceptibly change results. The CH₃CN + OH rate constant (k_OH-CH₃CN = 7.8 × 10⁻¹³ e⁻¹⁵⁰⁰/T cm³ molecule⁻¹ s⁻¹) was based on the recommendation of DeMore et al. [1997]. The HCN + OH rate constant (k_OH-HCN = 1.0 × 10⁻¹³ e⁻⁹⁷³/T cm³ molecule⁻¹ s⁻¹ at 600 torr) was from the recent study of Wine et al. [2002], who find this rate to be substantially slower than the DeMore et al. [1997] recommendation. Although this reaction is pressure-dependent, this effect is small under tropospheric conditions. A net oceanic deposition flux (F_o = Fₜ - F_OH) of 8.8 × 10⁻¹⁵ g (N) cm⁻² s⁻¹ and 3.4 × 10⁻¹⁵ g (N) cm⁻² s⁻¹ could be calculated for HCN and CH₃CN, respectively (Table 5). The air-sea exchange model of Liss and Slater [1974], with newly recommended parameters [Liss and Merlivat, 1986; Nightingale et al., 2000; Donelan and Wanninkhof, 2001], was adapted to derive the undersaturation (S) necessary to maintain the oceanic deposition flux, F_o:

\[
F_o = F_t - F_{OH} = K_1(C_g/H - C_t)
\]

[4]

\[
K_1 = \left[1/k_l + 1/H_{kg}\right]^{-1}
\]

[5]

\[
S = 1 - HC_1/C_g = H F_0/K_1 C_g
\]

[6]

\[
v_d = F_o/C_g = SK_1/H
\]

[7]

where C_t and C_g are concentrations in the bulk liquid and gas phases, respectively, and H(C_g/C_t) is the dimensionless Henry’s law constant, k_l and k_g are transfer constants for liquid and gas phases, and \(v_d\) is the corresponding deposition velocity. The temperature-dependent Henry’s law constants for HCN and CH₃CN have been measured in water and best values of 3.4 × 10⁻³³ (ΔH₂₉₈ = 40.0 kJ mol⁻¹) and 7.5 × 10⁻³⁴ (ΔH₂₉₈ = 50.0 kJ mol⁻¹), respectively, were
adopted for 295°K (R. Sander, Compilation of Henry’s law constants for inorganic and organic species of potential importance in environmental chemistry, version 3, 1999, available at http://www.mpch-mainz.mpg.de/~sander/res/henry.html). These were increased by 20% to correct for the salting out effect of seawater which reduces solubility [Donelan and Wanninkhof, 2001]. A liquid phase transfer constant (\(k_l\)) of 11 cm h\(^{-1}\) and a gas phase transfer constant (\(k_g\)) of 6912 (18/MW)\(^{1/2}\) cm h\(^{-1}\) were used based on recommended values for a mean surface wind speed of 6 m s\(^{-1}\) [Asher, 1997; Donelan and Wanninkhof, 2001]. HCN and CH\(_3\)CN are moderately soluble in water and both liquid phase (1/k\(_l\)) and gas phase (1/k\(_g\)) resistances are important in controlling their air-sea flux. Using the parameters described above along with equations (4)–(6), we determine that HCN and CH\(_3\)CN are undersaturated in the oceans by 27% and 6%, respectively (Table 5). An uncertainty of the order of \(\pm20\%\) can be placed on the calculated mean oceanic flux and undersaturation due solely to the choice of entrainment velocity.

[22] On the basis of the present observations, a deposition velocity (\(v_d\)) of 0.12 cm s\(^{-1}\) for HCN and 0.06 cm s\(^{-1}\) for CH\(_3\)CN is calculated from equation (7). These values are appropriate for deposition over open oceans. Using a different set of assumptions, Li et al [2003] find that a \(v_d\) of 0.13 cm s\(^{-1}\) for both HCN and CH\(_3\)CN provides a reasonable fit to the present data. We were unable to uncover independent studies of HCN dry deposition. However, several estimates of CH\(_3\)CN deposition velocity have been made [de Laat et al., 2001; de Gouw et al., 2003; Karl et al., 2003]. These estimates have been typically in the range of 0.01 to 0.2 cm s\(^{-1}\). In a recent study performed in the upwelling south Atlantic regions off of the Namibian and Angolan coasts, Jost et al. [2003] find that a much higher dry deposition velocity of the order of 0.4 cm s\(^{-1}\) best fits their observations. It is possible that deposition velocities over coastal regions are larger than over open oceans. Clearly, additional HCN and CH\(_3\)CN studies are needed for an accurate assessment of the oceanic sink.

[25] For seawater undersaturation to persist, a removal mechanism within the oceans is necessary. Chemical reaction pathways for HCN and CH\(_3\)CN degradation (e.g., hydrolysis, Cl\(^-\)) are too slow to be a significant process. In polluted streams, bioremediation of HCN has been a common industrial practice. Enzymatic reactions in aerobic conditions can relatively quickly deplete HCN to ammonia \(\text{HCN} + 1/2\text{O}_2 \rightarrow \text{HOCN} + \text{H}_2\text{O} \rightarrow \text{NH}_3 + \text{CO}_2\). Similar removal is also known to occur for CH\(_3\)CN. In one study of river streams, unaided biodegradation was sufficient to remove these cyanides with a half-life of about two weeks [Environmental Protection Agency (EPA), 1985, 1992]. By analogy, we believe that oceanic removal via biological degradation is a likely possibility. Although bacteria present in soils could also destroy cyanides, there is no evidence to support that this is an important loss mechanism, in part because cyanides are rapidly and preferentially exchanged to the air medium. It should be noted that the presence of a net sink does not imply that there are no additional oceanic sources. These sources, if present, could be masked by the oceanic degradation. We were unable to find any direct seawater observations to confirm the hypothesis of undersaturation or to ascertain the rate of loss of HCN and CH\(_3\)CN.

### 3.6. Atmospheric Lifetimes and Global Budgets

[24] Development of an accurate global budget for HCN and CH\(_3\)CN requires far more extensive observational data than are currently available. As a first step, we attempt to use our measurements over the Pacific for this purpose by relying on reasonable extrapolations and assumptions. We extrapolate the TRACE-P observations of HCN and CH\(_3\)CN in time and space by scaling them to the seasonal and latitudinal profile of the column of HCN which has been extensively derived from spectroscopic observations and also modeled [Zhao et al., 2000, 2002; Notholt et al., 2000; Li et al., 2000; Rinsland et al., 2001, 2002]. In the absence of direct observations and given the presumed commonality of sources, we consider this extrapolation to be a reasonable first step for both HCN and CH\(_3\)CN. The seasonal cycle of HCN reported by Zhao et al. [2000] over Japan indicated that the average annual mixing ratios at midlatitudes are 1.08 times those in spring. Latitudinal extrapolation to the globe, based on the work by Notholt et al. [2000] and Rinsland et al. [2002], resulted in a scaling factor of 0.92. Fortuitously, these two factors (seasonal and latitudinal) result in a net scaling factor of 1.0. Thus the springtime midlatitude measurements of HCN made during TRACE-P closely resemble the global annual average. For extrapolation to global scales, median concentrations under relatively clean conditions (Table 2) are utilized. We also assume that the oceanic fluxes estimated for the TRACE-P region are representative of global oceans.

[25] Table 5 summarizes the global budget of HCN and CH\(_3\)CN based on the present observations and noted assumption. The calculated oceanic deposition flux is equivalent to a deposition of 1.0 Tg (N) yr\(^{-1}\) of HCN and 0.4 Tg (N) yr\(^{-1}\) of CH\(_3\)CN to the global oceans. This nitrogen deposition of 1.4 Tg (N) yr\(^{-1}\) is only a small fraction of the total nitrogen deposition into the oceans of 30 Tg (N) yr\(^{-1}\) [Duce, 1998]. However, this nearly uniform global nutrient source may still play an important role in remote oceans. The total annual tropospheric burden of HCN and CH\(_3\)CN is determined to be 0.44 Tg (N) and 0.30 Tg (N), respectively. The oceanic removal rate thus corresponds to an atmospheric residence time of 5.3 months for HCN and 9.2 months for CH\(_3\)CN. Using the OH reaction rates (in units of cm\(^3\) molecule\(^{-1}\) s\(^{-1}\)) noted earlier \(k_{\text{OH-CH}_3\text{CN}} = 7.8 \times 10^{-13} \text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}\); \(k_{\text{OH-CH}_3\text{CN}} = 1.4 \times 10^{-13} \text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}\) and a CH\(_3\)CCl\(_3\) lifetime of 5 years corresponds to a global mean OH of \(\sim1 \times 10^7\) molecules cm\(^{-3}\) [Montzka et al., 2000], we derive a mean residence time of 63 months for HCN and 23 months for CH\(_3\)CN due to removal by reaction with OH radicals. We note that this HCN residence time is nearly 4 times longer than that inferred from the DeMore et al. [1997] recommendation. Clearly, there is much uncertainty associated with these OH rate constants. Given the extremely low solubility of these cyanides, we expect removal by processes such as rain out and wash out to be unimportant in comparison [Crutzen and Lawrence, 2000]. Loss due to reactions with Cl, O\(_3\)(D), and NO\(_3\) radicals is calculated to be negligibly small. Although soil bacteria could destroy cyanides,
limited studies have shown that cyanides are quickly released after deposition to soil and this sink [EPA, 1985, 1992], although poorly studied, is expected to be minor. The mean atmospheric residence time, based on OH and oceanic loss, is 5.0 months for HCN and 6.6 months for CH3CN (Table 5). The calculated burden and residence times imply that a global source of some 1.1 Tg (N) yr^{-1} for HCN and 0.5 Tg (N) yr^{-1} for CH3CN is present. The 5 month mean lifetime of HCN can be compared with a range of 2–4 months derived by Li et al. [2000]. Similarly, the 7 month lifetime of CH3CN can be compared with estimates of 3–11 months by Hamm and Warneck [1990], 1 month by Bange and Williams [2000], and ~5 months by Karl et al. [2003].

[26] It is evident from Tables 4 and 5 that our estimates of the BB sources can account for most of the needed source for HCN and CH3CN. Nevertheless, the possibility of additional sources is not ruled out. According to the Toxics Release Inventory of U.S. EPA (http://www.epa.gov/tri), the 1999 total U.S. emissions for HCN and CH3CN were 1.6 × 10^9 g (N) yr^{-1} (55% air discharge) and 3.2 × 10^9 g (N) yr^{-1} (5% air discharge), respectively. Thus direct industrial releases of HCN and CH3CN are extremely small (<0.02 Tg (N) yr^{-1}). Measurements over urban Los Angeles during TRACE-P (Mission 20 and test flights) along with the direct measurements of CH3CN in automobile exhaust by Holzinger et al. [2001] are consistent with the view that fossil fuel combustion is a miniscule source (<0.02 Tg (N) yr^{-1}). We note here that cyanides are easily formed during processes of high temperature fuel combustion (CH + N₂ → HCN + N) but are instantly converted to NO resulting in nearly zero net emissions. There is also the possibility that biogenic sources of HCN (and CH3CN) may be present. In several studies cut leaves are found to have significant levels of HCN (1 mg g^{-1} dry weight). High amounts of cyanogenic glycosides (1–30 mg kg^{-1}), which are quickly converted to HCN upon maceration, are found in common foods such as almonds and lima beans. A mechanism for the formation and release of HCN from linamarin (a cyanogenic glycoside) has been discussed by Fall et al. [2001]. Tyndall et al. [2001] also suggest that CH3CN oxidation by OH could also yield some HCN. The possibility that biogenic sources may be present. [27] The budget presented in Table 5 must be considered a somewhat rough estimate in large part because of the extreme paucity of available data. Many of the assumptions and extrapolations (e.g., uniform oceanic loss) have not yet been tested in varied geographical locations and seasons. We should expect losses in coastal, open, and upwelling oceanic regions to vary. Detailed studies of soil deposition and loss have also not been performed. At the present time, there are insufficient data to quantify the uncertainties associated with estimates in Table 5. Substantial additional atmospheric and oceanic data are required to refine these estimates.

4. Conclusions

[28] In situ measurements of HCN and CH3CN are consistent with the view that biomass burning is the largest source and oceanic loss the largest sink. The global budget of these cyanides is in rough balance but the possibility of small additional sources and sinks is not ruled out. While these chemicals are convenient tracers of biomass burning pollution, their atmospheric and biogeochemical cycles are poorly understood. There are few in situ data currently available on the atmospheric distribution of cyanides from the Northern Hemisphere and virtually none from the Southern Hemisphere. The paucity of oceanic data is even more glaring. While bacterial loss in the oceans is postulated as the main loss process, no chemical or biological data from the oceans are currently available. The assumption that soils are a minor sink is poorly validated. There is a need to better quantify the global budget of cyanides, including a better mechanistic understanding of combustion sources and biological sinks. The potential of upcoming satellite instruments to measure of HCN and possibly CH3CN in the troposphere hold great promise.

[29] Acknowledgments. This research was funded by the NASA Global Tropospheric Experiment. We thank all TRACE-P participants for their support. Comments and suggestions by R. Yokelson of the University of Montana are much appreciated.
