Received 2 October 1997/Accepted 6 March 1998

Two toluene-degrading strains, T103 and T104, were isolated from rock surface biomass in a freshwater stream contaminated with toluene. The strains exhibit different capacities for degradation of toluene and other aromatic compounds and have characteristics of the genus *Mycobacterium*. Both are aerobic, rod-shaped, gram-positive, nonmotile, and acid-alcohol fast and produce yellow pigments. They have mainly straight-chain saturated and monounsaturated fatty acids with 10 to 20 carbon atoms and large amounts of tuberculostearic acid that are typical of mycobacteria. Fatty acid analyses indicate that T103 and T104 are different mycobacterial strains that are related at the subspecies level. Their identical 16S rDNA sequences are most similar to *Mycobacterium aurum* and *Mycobacterium komossense*, and they constitute a new species of fast-growing mycobacteria. Ecological studies reveal that toluene contamination has enriched for toluene-degrading bacteria in the epilithic microbial community. Strains T103 and T104 play only a small role in toluene degradation in the stream, although they are present in the habitat and can degrade toluene. Other microorganisms are consequently implicated in the biodegradation.

In the United States, toluene is ranked 27th among the top 50 chemical products by production volume, with 931 million gallons (3.5 × 10^9 liters) of toluene manufactured in 1994 (22). Industry uses toluene in refining gasoline; chemical manufacturing; the manufacture of paints, lacquers, and adhesives; and some printing and leather-tanning processes. Toluene is usually disposed of as a used solvent. Toluene is listed as a priority pollutant (46), because contamination of drinking water can pose a potential health hazard. In a 1988 study, toluene was detected in groundwater, surface water, or soil at 29% of the hazardous waste sites surveyed; the average amounts detected were 0.2 μM in groundwater, 0.1 μM in surface water, and 77 μg/kg in soil (46).

Since toluene is ubiquitous in the environment, it is not surprising that microorganisms capable of degrading toluene have been isolated from a variety of environments, including polluted topsoils and oil tanker ballast waters (4, 5, 10, 29, 38, 48, 50). However, little is known about the role these isolates may play in the conversion of toluene in the environment. Therefore, studies that address the response of stream bacteria to effects of anthropogenic chemical impact are important in enhancing our understanding of the ecology of contaminant degradation.

This study describes the isolation and characterization of two closely related toluene-degrading strains of a novel *Mycobacterium* species from rock surface biofilms in a toluene-contaminated reach of a small freshwater stream. Ecological data are also presented to assess the role of these *Mycobacte-

### MATERIALS AND METHODS

**Study site.** The East Drainage Ditch is a small stream in an industrial area of Wilmington and Woburn, Mass. (7, 20), and forms part of the Aberjona Watershed, a 90-km² area 20 km north of Boston. Toluene in the stream arises from subsurface contamination below an 80-m-long culvert (11) located 1,600 m upstream from the confluence of the East Drainage Ditch with Halls Brook. Toluene levels typically range from 0.6 to 4.2 μM in the streamwater near the source (20). Sampling stations are upstream 50 m (U50) and 100 m (U100) and downstream 5 m (D5) and 50 m (D50).

**Isolation of bacterial strains.** Rocks were collected in July 1992 from the streambed at station D5. Rock biomass was scraped with sterile spatulas, serially diluted, and plated onto a mineral salts (MS) agar medium (35) supplemented with trace elements (49). The plates were incubated in a desiccator with a beaker of water (15 ml) previously equilibrated with toluene. The water was replaced every 2 to 3 days. Toluene was supplied by diffusion from the beaker in the desiccator that resulted in theoretical concentrations of approximately 110 μM in the agar based on Henry's law (36), although the actual concentrations might be affected by diffusion kinetics and hydrophobic interactions between toluene and organic constituents of the agar. Plates were monitored over 7 weeks, during which colonies were picked and restreaked on fresh plates. Several colonies grew in the presence of toluene, and four strains, numbered sequentially starting from T101, were selected for further characterization. Strains T103 and T104 possessed traits typical of mycobacteria and are described in this paper.

**Phenotypic characterization.** Tests for Gram stain, oxidase activity, catalase activity, carbon source utilization, nitrate reduction, and acid fastness (Ziehl-Neelsen method) were performed as previously described (27, 37). Tests for growth on aromatic compounds were conducted in the same manner as with toluene. Substrates were supplied by diffusion from a reservoir in the desiccator resulting in theoretical concentrations in the agar of 10 mg of benzene, o-xylene, m-xylene, p-xylene, phenol, or chlorobenzene per liter. Plates were monitored for 4 weeks, and visible colonies were picked and restreaked on fresh plates that were further incubated in either the presence or absence of the relevant substrate.
Toluene biodegradation kinetics. Rates of toluene degradation were determined by a headspace gas chromatography method (7). Cells were grown in 1,100-ml Teflon-stoppered glass bottles with 600 ml of MS medium initially containing 110 μM toluene. Toluene levels were monitored daily and replenished as needed. After every five toluene feedings, the headspace was flushed with air to replenish the oxygen. Cells were harvested by centrifugation during the exponential phase and resuspended in 100 ml of fresh medium. Kinetic experiments were performed with 60-ml Teflon-stoppered serum bottles (The VWR Co., PhoeniXville, Pa.) with 19 ml of medium and 0.5 ml of concentrated cell suspension (230 μg of protein/ml for strain T103 and 185 μg of protein/ml for strain T104). Toluene was injected at approximately 1.1, 2.2, 5.4, and 10.9 μM (aqueous concentration). Control experiments were performed with autoclaved cell suspensions. Bottles were shaken in the dark at 20°C on a rotary shaker at 150 rpm and assayed hourly for toluene. Initial rates of toluene disappearance were determined to establish Michaelis–Menten kinetic parameters. Protein was measured with the biocinchonic acid protein assay (Pierce, Rockford, Ill.).

Fatty acid analyses. Cells were grown on Middlebrook 7H10 agar (9) for 7 days at 28°C, harvested, and saponified to prepare fatty acid methyl esters (33). The analysis was performed at Microbial ID, Inc. (MDI, Newark, Del.), by using the MIDI microbial Identification System software for identification of fatty acids. Strains T103 and T104, together with the M. komossense type strain (ATCC 33013), were analyzed in duplicate and compared with profiles from the Microbial Identification System (MIS) library (34).

16S rDNA sequencing. Strains T103 and T104 were cultured in nutrient broth (Difco Laboratories, Detroit, Mich.) in Teflon-stoppered serum bottles by shaking at 20°C on a rotary shaker at 150 rpm. Cells were harvested by centrifugation, and genomic DNA was extracted with a miniprep (1). The nearly full-length 16S rDNA was amplified from genomic DNA by PCR with forward primer Eubac27F and reverse primer Universal 1492R (23). All reactions were run in triplicate under PCR conditions as described elsewhere (8), and PCR products were purified with the Wizard PCR Prep (Promega Corp., Madison, Wis.) for automated dye-terminator terminator sequencing at the Michigan State University Sequencing Facility with a 373A DNA sequencing system (Applied Biosystems, Foster City, Calif.). Sequences for oligonucleotides complementary to the conserved regions of the eubacterial 16S rRNA gene were kindly provided by Debra J. Lomont (United States Geological Survey, Reston, Va.). These oligonucleotides were chosen to prime the sequencing reactions. Sequencing reaction mixtures consisted of 12 pmol of sequencing primer and 50 to 250 ng of PCR template in a total volume of 20 μl of sterile H2O. The sequences of approximately 1,425 nucleotide bases, corresponding to the Escherichia coli 16S rDNA sequence from nucleotides 55 to 1501, were obtained in both directions for the two strains.

Phylogenetic analyses. The 16S rDNA secondary structures of strains T103 and T104 were constructed manually with templates published in the Ribosomal Database Project (RDP) (25) to aid in the identification of homologous sequence positions. Sequence alignments were performed manually in the Geneious Data Environment (39). All reference sequences and the basic alignment were obtained from the RDP. Only homologous sites at which the 16S rDNA sequences of strains T103 and T104 could be aligned unambiguously with the reference sequences were included in a final data set of 1,165 nucleotides for further analyses. Distance, parsimony, and maximum likelihood analyses were performed with PHYLP 3.5 (13), PAUP 3.1 (42), and fastDNAML (12, 28), respectively. Descriptions elsewhere (31).

Bacterial counts. Rock samples were collected from stations U100, U50, D5, and D50 along the East Drainage Ditch on 7 September 1993. Biomass was measured as described previously (7). Colonies growing on the highest-dilution plates were picked, transferred to new plates, and incubated in both the presence and absence of toluene to confirm the abilities of these isolates to grow with toluene as an energy source.

Toluene levels in the stream. Duplicate water samples were collected at stations U100, U50, D5, and D50 along the East Drainage Ditch on 7 September 1993. Samples were filtered with hollow screw caps and Teflon-coated silicone septa. Mercuric chloride was added to the samples to a final concentration of 15 mg/liter. Toluene was determined as described elsewhere (7).

Enrichment and isolation. Two mycobacterial toluene-degrading strains, T103 and T104, were independently isolated from two yellow colonies, 1 to 2 mm in diameter, that appeared between 3 and 8 days on toluene-incubated MS plates inoculated with 10^5 cells/g of biomass, indicating that these strains were present in the rock surface biomass at a density of 10^6 cells/g of biomass. Biomass slurries averaged 0.018 g (fresh weight) cm^-2 of rock surface. Both strains grew slowly (relative to other nonmycobacterial toluene-degrading strains similarly isolated) on solid media when inoculated with toluene. Mycobacterial colonies were not detected on plates inoculated with higher dilutions of biomass.

Morphological and phenotypic characteristics. Strains T103 and T104 had morphologically similar rod-shaped cells when grown on solid media. Cells were nonmotile, and flagella were not observed under scanning electron microscopy (data not shown). The strains were aerobic, gram positive, and acid-alcohol fast (Table 1), which is characteristic of the mycobacteria (47). Strain T104 differed physiologically from strain T103 in that T104 could grow on xylene (Table 1).

To evaluate toluene biodegradation kinetics, strains T103 and T104 had maximal toluene consumption rates (Fmax) of 1.0 ± 0.1 and 6.0 ± 1.3 μmol of toluene/mg of protein per h, respectively; their half-saturation constants (Km) were 0.6 ± 0.4 and 3.8 ± 1.9 μM, respectively.
Fatty acid analyses. Strains T103 and T104 were made up of mainly straight-chain saturated and monounsaturated fatty acids, as well as substantial amounts of tuberculostearic acid (Table 2) that are typical of mycobacteria (16). Fatty acid analyses (34) indicated that T103 and T104 were different strains of a novel *Mycobacterium* sp. that was most closely related to *M. aurum* (similarity indices of 0.31 and 0.24 with strains T103 and T104, respectively).

16S rDNA sequence analyses. Strains T103 and T104 possessed identical 16S rDNA sequences. The secondary structures of the sequences of T103 and T104 and other fast-growing mycobacteria were identical, and they contained the shortened stem structure bounded by positions 455 to 477 (*E. coli* numbering) that typically distinguishes the fast-growing from the slow-growing mycobacteria (41). The levels of identity between the T103/T104 sequence and the sequences of the fast-growing mycobacteria, slow-growing mycobacteria, and other nonmycobacterial nocardioform bacteria ranged from 96.9 to 99.0%, 96.1 to 97.3%, and 93.0 to 95.7%, respectively. The T103/T104 sequence was most identical to the sequences of *M. aurum* (identity, 99.0%) and *M. komossense* (identity, 98.9%).

Distance and bootstrap analyses confirmed that strains T103 and T104 clustered with fast-growing mycobacteria (Fig. 1). The mycobacteria fell into a closely related, coherent group, distinct from the other high-G+C gram-positive bacteria examined. Within the genus, the slow-growing mycobacteria defined a distinct line of evolutionary descent, while the precise relationships among the fast-growing species remained unresolved because of low bootstrap values. Parsimony and maximum likelihood analyses also showed that strains T103 and T104 belonged with the fast-growing mycobacteria (data not shown).

**Bacterial counts and toluene levels.** No toluene was detected at station U100, although very low levels of toluene (0.04 μM) were found at station U50. Downstream stations D5 and D50 had high toluene concentrations of 2.6 and 1.7 μM, respectively, in September 1993 (Fig. 2). The total heterotrophic bacterial plate counts at these stations ranged from 2 × 10^7 to 7.7 × 10^8 cells/g of biomass. Toluene-degrading bacteria were not detected for station U100, where no toluene was present. The counts of toluene-degrading bacteria for the other three stations increased with increasing toluene concent-

m

n

mycobacteria that have the capacity to degrade the aromatic polycyclic aromatic hydrocarbons (15) and groundwater-

form a variety of xenobiotic compounds and pollutants, includ-

ering degrade toluene and have major characteristics of the

genus Mycobacterium, they exhibit some differences in physi-

ology. Unlike strain T103, strain T104 is able to grow on the

xylene. Also, their fatty acid profiles are sufficiently different

for them to be considered different strains of a novel species

of fast-growing mycobacteria. Compared to the slow-growing my-

cobacteria, many of which are human and animal pathogens,

most of the fast-growing mycobacteria are common sapro-

phytes in natural habitats (18). They have been isolated from a
diverse array of habitats, are able to survive and multiply under a wide range of environmental conditions, and can biotrans-

form a variety of xenobiotic compounds and pollutants, including polycyclic aromatic hydrocarbons (15) and groundwater-
pollutant mixtures (4). There is a long history of isolation of mycobacteria that have the capacity to degrade the aromatic fraction of the oil in contaminated soils (44, 45).

The closest known relative of strains T103 and T104, M. aurum, is a fast-growing species commonly isolated from soils (47) that is able to metabolize morpholine (6, 26) and vinyl chloride (17). The other closely related species, M. komossense, is a fast-growing nonpathogenic species isolated from Sphag-

num vegetation of moors in south Sweden and the Atlantic coastal area of Norway (19). It is unable to utilize benzoate and benzamide; it is not known if it possesses the ability to utilize other aromatic hydrocarbons or xenobiotic compounds. Other closely related species have been found to degrade a range of aromatic hydrocarbons. M. vaccae is the only other Mycobac-
terium species known to grow on toluene. It also grows on acetone and can degrade acetone, cyclohexane, styrene, benzene, ethylbenzene, propylbenzene, dioxane, and 1,2-dichloro-
ethylene (4). A Mycobacterium sp. that was closely related to M. gladus (14) was isolated from the soil of a former coal gasification site and is able to degrade the polycyclic aromatic hydrocarbons phenanthrene, pyrene, and fluoranthene (2). Overall, their physiological versatility suggests that the fast-growing mycobacteria should be important in pollutant biodegradation, and our results point to the possibility that mycobacteria may be useful in the bioremediation of contaminated environments.

**DISCUSSION**

**Taxonomy and phylogeny.** Although strains T103 and T104 both degrade toluene and have major characteristics of the genus Mycobacterium, they exhibit some differences in physiology. Unlike strain T103, strain T104 is able to grow on the xylene. Also, their fatty acid profiles are sufficiently different for them to be considered different strains of a novel species of fast-growing mycobacteria. Compared to the slow-growing mycobacteria, many of which are human and animal pathogens, most of the fast-growing mycobacteria are common saprophytes in natural habitats (18). They have been isolated from a diverse array of habitats, are able to survive and multiply under a wide range of environmental conditions, and can biotransform a variety of xenobiotic compounds and pollutants, including polycyclic aromatic hydrocarbons (15) and groundwater-pollutant mixtures (4). There is a long history of isolation of mycobacteria that have the capacity to degrade the aromatic fraction of the oil in contaminated soils (44, 45).

The closest known relative of strains T103 and T104, M. aurum, is a fast-growing species commonly isolated from soils (47) that is able to metabolize morpholine (6, 26) and vinyl chloride (17). The other closely related species, M. komossense, is a fast-growing nonpathogenic species isolated from Sphagnum vegetation of moors in south Sweden and the Atlantic coastal area of Norway (19). It is unable to utilize benzoate and benzamide; it is not known if it possesses the ability to utilize other aromatic hydrocarbons or xenobiotic compounds. Other closely related species have been found to degrade a range of aromatic hydrocarbons. M. vaccae is the only other Mycobacterium species known to grow on toluene. It also grows on acetone and can degrade acetone, cyclohexane, styrene, benzene, ethylbenzene, propylbenzene, dioxane, and 1,2-dichloroethylene (4). A Mycobacterium sp. that was closely related to M. gladus (14) was isolated from the soil of a former coal gasification site and is able to degrade the polycyclic aromatic hydrocarbons phenanthrene, pyrene, and fluoranthene (2). Overall, their physiological versatility suggests that the fast-growing mycobacteria should be important in pollutant biodegradation, and our results point to the possibility that mycobacteria may be useful in the bioremediation of contaminated environments.

**Biodegradation kinetics.** Toluene contamination of the East Drainage Ditch appears to selectively enrich for toluene-degrading bacteria within the epilithic microbial community. Maximal velocities are somewhat higher than those reported for other aerobic toluene-degrading bacteria; strain T104 also has a larger $K_s$ (3.8 $\mu$M) than those reported for other toluene-degrading bacterial strains. *Pseudomonas* sp. strain T2 had a maximal velocity of 0.30 $\mu$mol of toluene/mg of protein per h (assuming that 50% of a typical cell’s dry weight is protein) and a $K_s$ of 0.48 $\mu$M (32). Corresponding values for a terrestrial strain of *Pseudomonas putida*, PpF1, were 0.43 $\mu$mol of toluene/mg of protein per h and 0.68 $\mu$M, respectively (32). That $K_s$ values for strains T103 and T104 lie within the range of toluene concentrations observed in the stream suggests that these strains are adapted to the ambient level of toluene contamination in the stream. Noncarbon nutrients are unlikely to be limiting in this case, because these are present in the stream at high levels (43).

In order to assess the role that strains T103 and T104 may play in toluene biodegradation in intact biofilms, toluene biodegradation rates for the pure cultures were compared with rates obtained in the laboratory for rock biofilms from a previous study (7). For East Drainage Ditch rocks with their natural biofilms under summer conditions, the rate was observed to be first order for toluene concentrations up to 2.2 $\mu$M and approached zero order for concentrations greater than 4.3 $\mu$M; the $V_{max}$ was 2.0 nmol/cm$^2$ of rock surface per h (7). Assuming that mass transport is not limiting, the potential contributions of strains T103 and T104 to toluene biodegradation on the rock biofilm were estimated according to their cell densities (CD) on the rock surfaces and their individual kinetic parameters. The CD of $1.8 \times 10^5$ cells/cm$^2$ of rock surface was estimated from plate counts of the mycobacterial isolates ($10^6$ cells/cm$^2$ of rock surface). Since the biofilm data were most reliable for toluene concentrations greater than 4.3 $\mu$M (7), comparisons were performed for toluene concentrations greater than or equal to 4.3 $\mu$M. Assuming a typical cell protein weight of 0.2 pg (24) and a uniform distribution of mycobacteria in the biofilm, the relative contributions of strains T103 and T104 to toluene biodegradation by the biofilm can be estimated as follows:

\[
(\text{CD} \times \text{cell protein weight} \times k_{\text{strain T103 or T104}} \times 100\%)/V_{\text{max}, \text{biofilm}}
\]

where

\[
k_{\text{strain T103 or T104}} = V_{\text{max}, \text{strain T103/T104}} \times S/(K_s \text{ strain T103/T104} + S),
\]

and $S$ is the toluene concentration.

At a toluene concentration of 4.3 $\mu$M, strains T103 and T104 are estimated to account for 0.2 and 0.6%, respectively, of the toluene biodegradation that occurs on the rock surfaces. These numbers should be interpreted as upper bounds on the relative
contributions of the pure cultures to toluene degradation in the biofilms; to the extent that diffusion limitation occurs, these numbers may be lower, especially in the case of T104. Strain T103, having a $K_c$ much lower than 4.3 $\mu$M, would be less affected. The low relative contributions suggest that other bacterial species play a larger role than strains T103 and T104 in toluene biodegradation on the rock surfaces. Cohen et al. (7) showed that constantly shaken flasks provided a reasonable microcosm simulation of the fast-flowing stream. In addition, mass transport of the substrate to the biofilm surface is not calculated to be a limiting factor in the turbulent flow regime of this stream, although biofilms themselves are not always free of transport limitation (21). We therefore expect that the results from laboratory microcosms offer a reasonable estimate of the importance of T103 and T104 to toluene degradation in the East Drainage Ditch itself.

**Microbial ecology.** Toluene levels in the stream do not appear to have a significant effect on total heterotrophic bacterial counts. On the other hand, counts of toluene-degrading bacteria in samples from the contaminated stations are about an order of magnitude higher than those from pristine stations, which suggests that toluene in the contaminated reaches of the stream has caused the epilithic bacterial communities to adapt by selectively enriching for toluene-degrading bacteria. Other studies of freshwater environments (30, 40) also reported viable heterotrophic counts to be unaffected by the presence of a xenobiotic contaminant, while the numbers of organisms capable of degrading the contaminant of interest increased by between 2 and 3 orders of magnitude. The increased counts in contaminated reaches versus uncontaminated reaches of the East Drainage Ditch are not as high as observed in these other studies, possibly because of greatly reduced microbial activity at lower temperatures (30). The East Drainage Ditch study was conducted in the fall when stream temperatures averaged 11°C. In the other studies, temperatures averaged 18°C (40) or ranged from 19 to 30°C (30).

Although strains T103 and T104 were isolated from rock biofilms collected in July 1992, a 16S rDNA clone with a $K_c$ much lower than 4.3 $\mu$M was not found from the pristine station D5, suggesting a greater abundance of this species in the contaminated reaches versus uncontaminated reaches of the East Drainage Ditch itself. At-station T103, having a $K_c$ much lower than 4.3 $\mu$M, numbers may be lower, especially in the case of T104. Strain T103, having a $K_c$ much lower than 4.3 $\mu$M, would be less affected. The low relative contributions suggest that other bacterial species play a larger role than strains T103 and T104 in toluene biodegradation on the rock surfaces. Cohen et al. (7) showed that constantly shaken flasks provided a reasonable microcosm simulation of the fast-flowing stream. In addition, mass transport of the substrate to the biofilm surface is not calculated to be a limiting factor in the turbulent flow regime of this stream, although biofilms themselves are not always free of transport limitation (21). We therefore expect that the results from laboratory microcosms offer a reasonable estimate of the importance of T103 and T104 to toluene degradation in the East Drainage Ditch itself.

**Microbial ecology.** Toluene levels in the stream do not appear to have a significant effect on total heterotrophic bacterial counts. On the other hand, counts of toluene-degrading bacteria in samples from the contaminated stations are about an order of magnitude higher than those from pristine stations, which suggests that toluene in the contaminated reaches of the stream has caused the epilithic bacterial communities to adapt by selectively enriching for toluene-degrading bacteria. Other studies of freshwater environments (30, 40) also reported viable heterotrophic counts to be unaffected by the presence of a xenobiotic contaminant, while the numbers of organisms capable of degrading the contaminant of interest increased by between 2 and 3 orders of magnitude. The increased counts in contaminated reaches versus uncontaminated reaches of the East Drainage Ditch are not as high as observed in these other studies, possibly because of greatly reduced microbial activity at lower temperatures (30). The East Drainage Ditch study was conducted in the fall when stream temperatures averaged 11°C. In the other studies, temperatures averaged 18°C (40) or ranged from 19 to 30°C (30).

Although strains T103 and T104 were isolated from rock biofilms collected in July 1992, a 16S rDNA clone with a $K_c$ much lower than 4.3 $\mu$M was not found from the pristine station D5, suggesting a greater abundance of this species in the contaminated reaches versus uncontaminated reaches of the East Drainage Ditch itself. At-station T103, having a $K_c$ much lower than 4.3 $\mu$M, numbers may be lower, especially in the case of T104. Strain T103, having a $K_c$ much lower than 4.3 $\mu$M, would be less affected. The low relative contributions suggest that other bacterial species play a larger role than strains T103 and T104 in toluene biodegradation on the rock surfaces. Cohen et al. (7) showed that constantly shaken flasks provided a reasonable microcosm simulation of the fast-flowing stream. In addition, mass transport of the substrate to the biofilm surface is not calculated to be a limiting factor in the turbulent flow regime of this stream, although biofilms themselves are not always free of transport limitation (21). We therefore expect that the results from laboratory microcosms offer a reasonable estimate of the importance of T103 and T104 to toluene degradation in the East Drainage Ditch itself.
