## Abstract

Airflow conditions close to the Earth's surface are often complex, posing challenges to flight stability and control for volant taxa. Relatively little is known about how well flying animals can contend with complex, adverse air flows, or about the flight-control mechanisms employed by animals to mitigate wind disturbances. Several recent studies have examined flight in the unsteady von Kármán vortex streets that form behind cylinders, generating flow disturbances that are predictable in space and time; these structures are relatively rare in nature, as they occur only in the immediate, downstream vicinity of an object. In contrast, freestream turbulence is characterized by rapid, unpredictable flow disturbances across a wide range of spatial and temporal scales, and is nearly ubiquitous in natural habitats. Hummingbirds are ideal organisms for studying the influence of freestream turbulence on flight, as they forage in a variety of aerial conditions and are powerful flyers. We filmed ruby-throated hummingbirds (*A. colubris*) maintaining position at a feeder in laminar and strongly turbulent (intensity ~15%) airflow environments within a wind tunnel, and compared their mean head, body, tail and wing kinematics, as well as variability in these parameters. Hummingbirds exhibited remarkably stable head position and orientation in both smooth and turbulent flow while maintaining position at the feeder. However, the hummingbird's body was less stable in turbulent flow and appeared to be most sensitive to disturbances along the mediolateral axis, displaying large lateral accelerations, translations, and rolling motions during flight. The hummingbirds mitigated these disturbances by increasing mean wing stroke amplitude and stroke plane angle, and by varying these parameters asymmetrically between the wings, and from one stroke to the next. They also actively varied the orientation and fan angle of the tail, maintaining a larger mean fan angle when flying in turbulent flow; this may improve their passive stability, but likely incurs an energetic cost due to increased drag. Overall, we observed many of the same kinematic changes noted previously for hummingbirds flying in a von Kármán vortex street, but we also observed kinematic changes associated with high force production, similar to those seen during load-lifting or high-speed flight. These findings suggest that flight may be particularly costly in fully mixed, freestream turbulence, the flow condition that hummingbirds are likely to encounter most frequently in natural habitats.

## 36 **Introduction**

37

38 The Earth's surface directly influences wind profiles within the lowest region of the atmosphere, the  
39 Atmospheric Boundary Layer (ABL). Mean and instantaneous properties of wind within the ABL  
40 depend upon a number of variables, including large-scale meteorological conditions, solar heating  
41 (convective and radiative), and the profile of local terrain (Stull, 1988). The Earth's surface is seldom  
42 flat, but rather heterogeneous at multiple size scales, due to both natural (hills, vegetation, etc.) and  
43 manmade (buildings, poles, etc.) features. These features act as obstacles to steady air flow, and  
44 aerodynamic interactions between the wind and such obstacles lead to unsteady, turbulent flow  
45 (Stull, 1988).

46 Freestream turbulence within the ABL has generally been characterized in terms of its intensity and  
47 integral length scale. Turbulence Intensity (Ti), defined as the ratio between the standard deviation of  
48 wind speed and the mean speed (Stull, 1988), quantifies the turbulent energy within the flow. The  
49 integral length scale provides a measure of the average size of the largest turbulent eddy present  
50 within the flow (Kaimal and Finnigan, 1994). Meteorologists and building engineers have collected  
51 wind measurements over long time-scales, and report turbulence intensities of ~10-20% in urban  
52 terrain and over 50% at lower levels in cities (<10m), while integral length scales range from less than  
53 a meter to many tens of meters. More recently, wind measurements have been made in the ABL with  
54 higher temporal accuracy to gather information for surface vehicles and micro-air vehicles (MAVs).  
55 These measurements have shown that turbulence intensity relative to the moving vehicle varies from  
56 7% (under light winds, < 5m/s) to >20% (under heavy winds > 5m/s), depending on wind, vehicle  
57 speed and terrain (Cooper and Watkins, 2007; Watkins et al., 2006; Wordley, 2009). When high levels  
58 of freestream turbulence are present within the ABL, wind speed and direction can change rapidly  
59 (Watkins et al., 2006), posing considerable challenges in terms of flight stability and control for flying  
60 animals that operate within the ABL.

61 Despite these challenges, many insects, birds and bats seem to be capable of contending with the  
62 adverse effects of freestream turbulence, likely through the use of both active and passive control  
63 strategies (Dickinson et al., 2000). However, our understanding of biological flight in natural flow  
64 conditions is limited, as most experiments on insect, bird and bat flight have been conducted in  
65 smooth flow or still air. Hummingbirds are ideal model organisms for studying the influence of  
66 complex wind environments on flight performance, as they are not only powerful flyers, but are also  
67 behaviorally amenable to performing consistent flights in controlled settings. Moreover, the high  
68 metabolic rate of hummingbirds (Suarez, 1992) makes them relentless foragers in a broad range of  
69 outdoor weather conditions, likely requiring them to utilize a variety of flight control strategies to  
70 contend with the airflow conditions they encounter in natural habitats. Recent studies have analyzed  
71 the dynamics of hummingbird flight in the unsteady von Kármán vortex street that forms behind a  
72 cylinder in flow (Ortega-Jimenez et al., 2013 & 2014). However, this type of flow is likely to be  
73 encountered only rarely in natural habitats (e.g., immediately downstream of an object in strong  
74 flow). In contrast, birds and other flying organisms are likely to encounter freestream turbulence

75 throughout most natural habitats whenever wind is present, making an assessment of their flight  
76 performance in turbulent flow conditions behaviorally and ecologically relevant.

77 In this study, we compared the position and orientation of the head, body and tail of ruby-throated  
78 hummingbirds, as well as their wing kinematics, while the hummingbirds maintained position at a  
79 feeder in both laminar and highly turbulent airflow. We created turbulence in a wind tunnel by placing  
80 a symmetric, planar grid at the inlet of the test section, generating flow conditions similar to those  
81 that hummingbirds would experience when foraging in a cluttered environment on a windy day,  
82 where wind passively interacts with obstacles (trees, leaves, etc.) to create freestream turbulence.  
83 The flow conditions generated here are fundamentally different from those utilized in previous  
84 experiments on flight in unsteady flows (Ortega-Jimenez et al., 2013 & 2014; Ravi et al., 2013), in  
85 which bumblebees, hawkmoths and hummingbirds were flown in the unsteady, structured flow  
86 present in the wake of a cylinder, where discrete alternating vortices are shed at a constant  
87 frequency. These structured wakes rapidly break down into the type of freestream turbulence  
88 generated in the present study, which consists of random variations in wind speed and direction that  
89 impose unpredictable perturbations at all frequencies and in all directions.

90 We compared the performance of hummingbirds flying in smooth and turbulent flow to address three  
91 main questions: (1) How does freestream turbulence influence stability of the hummingbird head and  
92 body during flight? (2) Are hummingbirds directionally sensitive to flow disturbances? And (3) What  
93 active and passive control strategies do hummingbirds employ to mitigate the effects of turbulence?

## 94 **Results**

### 95 **Flow conditions**

96

97 In both unimpeded and turbulent flow, a uniform velocity profile was present across the interrogation  
98 volume (< 2% variation in mean flow speed). With unimpeded flow, turbulence intensity in the wind  
99 tunnel test section was less than 1.2%. The integral length scale was not estimated for smooth flow, as  
100 it has limited significance at such low turbulence intensities. There were also no dominant velocity  
101 fluctuations at any particular frequency (Fig 2), indicating that the flow disturbance created by the  
102 small feeder upstream was minimal.

103 With the turbulence-generating grid present at the inlet of the test section, the turbulence intensity  
104 increased to 15% and the longitudinal integral length scale was 0.04 m. The power spectrum of  
105 turbulence showed no peak at any particular frequency and displayed an energy decay with a slope of  
106  $-5/3$  (black line in Fig. 2), which are distinguishing characteristics for fully mixed freestream turbulence  
107 (Pope, 2000). However, the turbulence generated here was not perfectly isotropic, as fluctuations  
108 along the lateral axis were slightly higher than those along the longitudinal and vertical axes (Table  
109 S1). This anisotropy is common for turbulence generated within wind tunnels, and considerable  
110 anisotropy also exists in the freestream turbulence in outdoor environments (Stull, 1988). The

111 integral length scale of the turbulence produced in the wind tunnel was on the order of the wing  
112 dimensions of the hummingbirds, which we hypothesize is likely to produce the greatest instabilities;  
113 disturbances many orders of magnitude greater than the wing dimensions would be experienced as  
114 quasi-steady changes in oncoming flow, and those many orders of magnitude smaller likely average  
115 out across the body to produce minimal disturbance.

116

117

118

## 119 **Head and body stability**

120

121 All hummingbirds were capable of maintaining remarkably constant head position with respect to the  
122 feeder across flow conditions, displaying fluctuations of < 1.5 mm when the mean wind speed was 5  
123 m/s and the turbulence intensity was 15%. Turbulent flow did not appear to diminish the birds' ability  
124 to maintain head position, as there was no significant difference in the mean or standard deviation of  
125 the distance between the head and the feeder in smooth *versus* turbulent conditions (mean distance,  
126  $p = 0.59$ ;  $\sigma$  of distance,  $p = 0.19$ ; Table S2). The head experienced greater translational accelerations  
127 (absolute values) along the lateral axis in turbulence as compared to smooth flow ( $S-T_{lat}$ ,  $p = 0.023$ ),  
128 but no statistically significant difference was noted in the accelerations between the two flow  
129 conditions along the longitudinal and vertical axes ( $S-T_{long}$ ,  $p = 0.62$ ;  $S-T_{vert}$ ,  $p = 0.99$ ; Fig. 3). The  
130 magnitude of head accelerations along each axis during flight in turbulence were not significantly  
131 different ( $T_{long}-T_{lat}$ ,  $p = 0.11$ ;  $T_{long}-T_{vert}$ ,  $p = 0.99$ ;  $T_{lat}-T_{vert}$ ,  $p = 0.07$ ). Roll, pitch and yaw rates (absolute  
132 values) of the head were generally quite small (Fig. 4), with significantly greater yaw rates in turbulent  
133 *versus* smooth flow conditions ( $S-T_{yaw}$ ,  $p = 0.037$ ). However, no significant difference in roll or pitch  
134 rates of the head were observed between flow conditions ( $S-T_{roll}$ ,  $p = 0.70$ ;  $S-T_{pitch}$ ,  $p = 0.06$ ).

135 In smooth flow, body accelerations were higher than those of the head along the lateral axis ( $S_{lat\_body}-$   
136  $S_{lat\_head}$ ,  $p = 0.014$ ), but head and body accelerations along the other axes were not significantly  
137 different ( $S_{long\_body}-S_{long\_head}$ ,  $p = 0.94$ ;  $S_{vert\_body}-S_{vert\_head}$ ,  $p = 0.26$ ). In contrast, turbulent flow resulted in  
138 body accelerations that were significantly greater than head accelerations along all three axes  
139 ( $T_{lat\_body}-T_{lat\_head}$ ,  $p = 0.03$ ;  $T_{long\_body}-T_{long\_head}$ ,  $p = 0.04$ ;  $T_{vert\_body}-T_{vert\_head}$ ,  $p = 0.005$ ; Fig. 3). In addition,  
140 body accelerations along the lateral axis were significantly greater than those along the longitudinal or  
141 vertical axes during flight in turbulence ( $T_{lat}-T_{long}$ ,  $p = 0.040$ ;  $T_{lat}-T_{vert}$ ,  $p = 0.08$ ;  $T_{long}-T_{vert}$ ,  $p = 0.002$ ).  
142 Across flow conditions, body accelerations were significantly greater along all axes in turbulent flow as  
143 compared to smooth flow ( $S-T_{lat}$ ,  $p = 0.03$ ,  $S-T_{long}$ ,  $p = 0.027$  &  $S-T_{vert}$ ,  $p = 0.042$ ).

144 In turbulent flow, absolute rotation rates of the body along all three axes were significantly higher  
145 than those of the head ( $T_{roll\_body}-T_{roll\_head}$ ,  $T_{pitch\_body}-T_{pitch\_head}$  &  $T_{yaw\_body}-T_{yaw\_head}$ ,  $p < 0.008$ ), and body  
146 rotation rates were significantly higher in turbulence as compared to smooth flow ( $S-T_{roll}$ ,  $p = 0.0054$ ,  
147  $S-T_{pitch}$ ,  $p = 0.048$  &  $S-T_{yaw}$ ,  $p = 0.019$ ; Fig. 4). In addition, roll rates of the body were significantly

148 greater than pitch or yaw rates during flight in turbulent conditions ( $T_{roll}-T_{pitch}$ ,  $p = 0.001$ ;  $T_{roll}-T_{yaw}$ ,  $p =$   
149  $0.007$ ;  $T_{pitch}-T_{yaw}$ ,  $p = 0.21$ ).

## 150 **Tail kinematics and body forces**

151 Tail kinematics data show that the tail does not move significantly more than the body in smooth flow,  
152 with no significant difference in roll, pitch or yaw rates between the tail and body ( $S_{roll\_tail}-S_{roll\_body}$ ,  $p =$   
153  $0.47$ ;  $S_{pitch\_tail}-S_{pitch\_body}$ ,  $p = 0.15$ ;  $S_{yaw\_tail}-S_{yaw\_body}$ ,  $p = 0.15$ ; Fig. 4). However, in turbulent flow, pitch  
154 rates of the tail were significantly higher than those of the body ( $T_{pitch\_tail}-T_{pitch\_body}$ ,  $p = 0.065$ ), whereas  
155 roll and yaw rates were not significantly different ( $T_{roll\_tail}-T_{roll\_body}$ ,  $p = 0.13$ ;  $T_{yaw\_tail}-T_{yaw\_body}$ ,  $p = 0.18$ ).  
156 Tail rotation rates in turbulence were significantly higher than tail rotation rates in smooth flow ( $S-T_{roll}$ ,  
157  $p = 0.02$ ,  $S-T_{pitch}$ ,  $p = 0.03$  &  $S-T_{yaw}$ ,  $p = 0.02$ ), and did not differ significantly between the three axes  
158 ( $T_{roll}-T_{pitch}$ ,  $p = 0.65$ ;  $T_{roll}-T_{yaw}$ ,  $p = 0.13$ ;  $T_{pitch}-T_{yaw}$ ,  $p = 0.40$ ; Fig. 4). Hummingbirds also increased the  
159 mean fan angle of their tails significantly when flying in turbulence ( $p = 0.04$ ; Fig. 5a), and fan angle  
160 was significantly more variable in turbulent *versus* smooth flow ( $p = 0.007$ ; Fig. 5b).

161 Force measurements performed on a static hummingbird body in smooth flow revealed that  
162 variations in tail position and fan angle affect the lift and drag produced by the body. For both body  
163 angles investigated here ( $0^\circ$  &  $20^\circ$ ), increasing the tail fan angle and depressing the tail (i.e. increasing  
164 tail pitch angle relative to the body), as was observed during flight in turbulence, increased both lift  
165 and drag generated by the body (Fig. 6). For both body angles, more lift was generated by fanning the  
166 tail (with or without changing its pitch) than by depressing the tail without fanning. Lift was enhanced  
167 more at the higher body angle ( $20^\circ$ ). Conversely, more drag was generated by depressing the tail (with  
168 or without fanning) than by fanning it with no change in pitch angle. Drag increased more at the lower  
169 body angle ( $0^\circ$ ). Tail fanning always resulted in an increase in lift and drag but its influence was more  
170 pronounced at lower body angles. Maximum lift and drag, therefore, occurred with the tail depressed  
171 and the tail feathers fanned out.

## 172 **Wing kinematics**

173 Large variations in flapping frequency, stroke amplitude and stroke plane angle from one wingbeat to  
174 the next were observed when hummingbirds flew in turbulent conditions (Fig. 7g-h, supplementary  
175 video 1&2). Mean flapping frequency was higher in turbulent flow ( $p = 0.0065$ ; Table S2), but the  
176 increase in frequency was only marginal compared to smooth flow, the flapping frequency was also  
177 significantly more variable (higher  $\sigma$ ) in turbulent *versus* smooth flow ( $p = 0.008$ ; Table S2). Mean  
178 stroke amplitude was significantly higher in turbulent *versus* smooth flow ( $p = 0.046$ ; Fig. 7a), and  
179 significantly more variable ( $p = 0.042$ ; Fig. 7b). Birds flying in turbulent air adopted a higher mean  
180 stroke plane angle relative to their body angle ( $p = 0.046$ ; Fig. 7d), which was more variable from one  
181 stroke to the next in turbulent *versus* smooth flow ( $p = 0.02$ ; Fig. 7e). In addition to varying their  
182 kinematics from one stroke to the next, hummingbirds flying in turbulent flow increased the  
183 asymmetry of their wing strokes, with larger left-right differences in stroke amplitude ( $p = 0.034$ ; Fig.  
184 7c) and stroke plane angle ( $p = 0.025$ ; Figs. 7f) compared to smooth flow.

185 The birds' maximal capacity to vary left *versus* right wing kinematics (stroke plane angle and stroke  
186 amplitude) is reported in Table S2 as the maximum bilateral difference in each kinematic variable. The

187 birds were able to render large bilaterally asymmetric changes in both variables, with greater left:right  
188 asymmetries occurring during flight in turbulent flow. The asymmetric variations in left *versus* right  
189 wing stroke plane angle and stroke amplitude did not occur in phase, as the standard deviations of  
190 bilateral asymmetry in these variables were greater than the standard deviations observed for either  
191 left *versus* right wing individually (Table S2).

192

## 193 **Discussion**

### 194 **Effects of unsteady flow on flight stability**

195

196 Unsteady wind is ubiquitous in natural habitats, and its complex and unsteady properties can render  
197 the aerial environment challenging for flying organisms. In the highly turbulent flow environment  
198 generated here, the hummingbirds' heads were likely subjected to translational and rotational  
199 disturbances induced by both the unsteady wind and by disturbances propagated from the body to  
200 the head, through the neck. Given these imposed perturbations, the hummingbirds maintained  
201 remarkably stable head position and orientation, displaying <1.5 mm fluctuations in head position  
202 while flying in relative turbulence intensities that would ground most current Micro-Air Vehicles  
203 (Abdulrahim et al., 2010; Watkins et al., 2009), see supplementary video 1&2. Accelerations of the  
204 head were nearly two orders of magnitude lower than those present in the oncoming flow (see Fig. 3),  
205 and head rotation rates were minimal, typically <0.5 revolutions/sec. The head stability of birds, in  
206 steady flight or while maneuvering, has been studied and reported in previous investigations (Erichsen  
207 et al., 1989; Land, 1999; Warrick et al., 2002; Ros and Biewener 2015, in review), and birds have been  
208 shown to rely upon their ocular and vestibular reflexes to maintain a stable head orientation as their  
209 body undergoes rotations and translations (Erichsen et al., 1989; Warrick et al., 2002; Ros, 2013). The  
210 translational and rotational disturbances induced by the turbulent flow interacting directly with the  
211 hummingbird's head were likely small, due to the relatively small size and streamlined profile of the  
212 head. The limited variations in the head position and orientation observed here could also be due to  
213 the birds' desire to continue feeding and thus higher variations may be present when foraging at a  
214 distance from food sources. However, the hummingbird's body does experience considerably larger  
215 fluctuations in position and orientation, and the bird's neck appears to effectively attenuate and damp  
216 these variations (Figs 3, 4a-b), as has been observed when hummingbirds track artificial visual  
217 surrounds (Ros, 2013; Ros and Biewener 2015, in review).

218 When flying in turbulent conditions, the hummingbird's body undergoes accelerations and rotations  
219 that are nearly twice as large as those observed in the head (Figs. 3, 4), with the greatest translational  
220 disturbances occurring along their mediolateral axis and the greatest rotational disturbances about  
221 their roll axis (Figs. 3, 4), see supplementary video 1&2. Similar results have been obtained for  
222 hummingbirds and bumblebees flying in unsteady vortex streets (Ortega-Jimenez et al., 2014; Ravi et  
223 al., 2013), whereas hawkmoths flying in vortex streets display greater instability in yaw than in roll

224 (Ortega-Jimenez et al., 2013). Instantaneous variations in position and orientation of the body are  
225 likely due to a complex combination of drag-based interactions with the unsteady airflow, force and  
226 moment imbalances on the wings and tail due to the heterogeneous flow environment, and active  
227 reorientation performed by the birds to compensate for perturbations.

228 Some attenuation of the disturbances induced by unsteady airflow is expected due to the bird's own  
229 inertia, which would reduce translational motions equally in all directions, but inhibit pitch and yaw  
230 rotations more effectively than roll rotations (due to the lower moment of inertia around this axis),  
231 However, hummingbirds undoubtedly also responded actively to the aerial perturbations via changes  
232 in wing and tail kinematics, including both dynamic adjustments (reflected by increased variability)  
233 and fixed shifts (reflected by altered mean values). We were not able to estimate the relative  
234 contributions of external airflow perturbations *versus* active compensatory responses to the observed  
235 body motions in this study, due to the lack of information on instantaneous wind profile, activation of  
236 muscles involved in flight control, and instantaneous forces generated by the wings and body.  
237 Visualizing the wind profile around a freely flying bird in unpredictable, turbulent flow is challenging  
238 and would require instantaneous 3D particle image velocimetry. Assessing time-varying forces  
239 produced by the wings and body through active muscle control would be equally challenging. The  
240 future development of techniques to perform these types of measurements would improve our  
241 understanding of the physical and neuromuscular processes underlying hummingbirds' remarkable  
242 flight stability in unsteady flows.

243

### 244 **Compensatory turbulence mitigation strategies**

245 Our results suggest that hummingbirds flying in turbulent flow compensate for aerial perturbations by  
246 employing instantaneous adjustments (reflected by increased stroke to stroke variability and bilateral  
247 asymmetry; Fig. 7), as well as longer-term, fixed changes in kinematic parameters (reflected by altered  
248 mean values; Figs. 7a, d), which may improve passive stability and reduce the need for instantaneous  
249 compensation. Wing beat frequency increased slightly in turbulence (~3% increase, though this trend  
250 was not statistically significant), and became significantly more variable from beat to beat. Previous  
251 studies have shown that hummingbirds display statistically significant but modest increases in flapping  
252 frequency to increase force production during hovering (~4-10% increase in reduced air density or up  
253 to 19% with added loads - Chai and Dudley, 1995; Altshuler and Dudley, 2003) and while flying in the  
254 unsteady wake behind a cylinder (~10% increase, Ortega-Jimenez et al., 2014), but display no  
255 significant change in frequency with increased flight speeds in smooth flow (Tobalske et al., 2007).  
256 Hummingbirds flying in unsteady vortex streets also display increased variability in flapping frequency  
257 (Ortega-Jimenez et al., 2014), as in our study.

258 When flying in turbulent flow, the hummingbirds also displayed a significant, but fairly modest (~7%)  
259 increase in mean stroke amplitude, as well as greater stroke-to-stroke variability and bilateral  
260 asymmetry. Previous studies have shown that hummingbirds increase stroke amplitude to maximize  
261 force production when hovering with loads or in variable-density gases (~19-24% - Chai and Dudley,  
262 1995; Altshuler and Dudley, 2003), and at higher flight speeds (e.g., ~25% increase from 8 to 12 m/s;

263 Tobalske et al., 2007). When flying in the unsteady wake behind a cylinder, hummingbirds do not  
264 increase mean stroke amplitude, but variability and bilateral asymmetry in amplitude increase  
265 significantly (Ortega-Jimenez et al., 2014). Thus, our data show that hummingbirds flying in fully  
266 mixed, freestream turbulence display some of the same kinematic adjustments in stroke amplitude as  
267 those seen during flight in unsteady vortex streets (increased variability and bilateral asymmetry), as  
268 well as those seen when hummingbirds increase force production during hovering or forward flight  
269 (increased mean amplitude).

270 Anatomical stroke plane angle (stroke plane relative to the body) increased significantly and became  
271 more variable in turbulent airflow. Hummingbirds flying in laminar flow have previously been shown  
272 to maintain a fixed anatomical stroke plane angle while decreasing body angle as flight speed  
273 increases from hovering to 6 m/s, but to increase anatomical stroke plane angle at flight speeds  
274 greater than 8 m/s (Tobalske et al., 2007). Here, we found an approximately 20% increase in  
275 anatomical stroke plane angle during flight in turbulent *versus* smooth flow at 5 m/s, comparable in  
276 magnitude to the change in anatomical stroke plane angle from 6 to 12 m/s in laminar flow (Tobalske  
277 et al., 2007). We also found an increase in bilateral asymmetry of stroke plane angle during flight in  
278 turbulent air.

279 The aerodynamic role of the tail in avian flight has been the subject of much debate, with various  
280 hypotheses proposed concerning the underlying aerodynamic mechanisms of force production by the  
281 tail (Evans et al., 2002; Maybury et al., 2001; Thomas, 1993). Our findings suggest that the tail of the  
282 hummingbird likely plays an important role in improving flight stability in complex aerial  
283 environments. The large pitch and yaw rotation rates of the tail in turbulent airflow almost certainly  
284 reflect a combination of passive interactions with the imposed airflow and active compensatory  
285 rotations produced by the hummingbirds to correct for perturbations. Consistent with this  
286 interpretation, tail pitch angle has previously been shown to be more variable during flight in vortex  
287 streets as well (Ortega-Jimenez et al., 2014).

288 Apart from rapidly changing the orientation of the tail, our data also show that hummingbirds increase  
289 the mean fan angle of their tails and display higher variability in fan angle during flight in turbulence.  
290 Limited information exists on the aerodynamic function of tail fanning or on its role in flight  
291 stabilization. The observed increase in mean fan angle may improve passive stability by increasing the  
292 surface area of the tail, enhancing passive damping of aerial disturbances. Su et al. (2012) reported  
293 that passerines fan their tail to recover from downward pitching moments experienced during the  
294 downstroke; however a similar relationship with the stroke cycle was not noted here. An increased tail  
295 fan angle also leads to greater lift production (Fig. 6; Maybury et al., 2001), which would reduce the  
296 aerodynamic demands on the wings, potentially providing birds with higher control authority to  
297 employ in turbulence mitigation. The increased variability in tail fan angle also suggests that tail  
298 fanning may be used to perform or enhance rapid corrective maneuvers. Consistent with this  
299 interpretation, we observed several instances of rapid changes in tail fanning angle that were  
300 correlated with large changes in body orientation, Fig. S8.

301 Overall, our results show that hummingbirds employ both dynamic and fixed changes in several  
302 kinematic variables during flight in turbulent *versus* smooth flow. Increases in mean stroke amplitude,  
303 anatomical stroke plane angle and tail fanning angle may all serve to increase aerodynamic force  
304 production and/or improve passive stability. The hummingbirds also displayed increased stroke to  
305 stroke variability in nearly every kinematic parameter measured when flying under highly turbulent  
306 conditions – including increased variability of flapping frequency, stroke amplitude, anatomical stroke  
307 plane angle, tail rotation rates, and tail fanning angle. Finally, the hummingbirds also displayed  
308 increased bilateral asymmetry in stroke amplitude and stroke plane angle. Taken together, these  
309 changes suggest that hummingbirds actively respond to compensate for aerial perturbations imposed  
310 by turbulent flow via a variety of mechanisms.

### 311 **Energetic considerations for flight in turbulence**

312 Although hummingbirds are clearly capable of contending with high levels of turbulence by employing  
313 a variety of kinematic mechanisms, the feasibility and likelihood of wild hummingbirds actually flying  
314 in adverse wind conditions is likely influenced by the metabolic costs associated with these  
315 adjustments. Body force measurements taken at different tail configurations indicate that the  
316 increased fan angle maintained by ruby-throated hummingbirds while flying in turbulence incurs a  
317 drag penalty (Fig. 6). The hummingbirds also displayed modest increases in both flapping frequency  
318 and stroke amplitude, which suggest an increased energetic cost. However, when flying in the  
319 unsteady wake behind a cylinder, Anna's hummingbirds (*C. anna*) display no change in metabolic rate  
320 as compared to flight in smooth flow, until flight speeds reach 9 m/s (Ortega-Jimenez et al., 2014),  
321 suggesting that Anna's hummingbirds, and perhaps also ruby-throated hummingbirds, have high  
322 tolerance to variations in the aerial environment without significant energetic penalty. However,  
323 whereas some of the kinematic changes we observed in ruby-throated hummingbirds flying in  
324 turbulence are similar to those seen in Anna's hummingbirds flying in the wake of a cylinder (e.g.,  
325 modest increases in flapping frequency and increased variability in frequency and amplitude), we also  
326 observed kinematic changes that are associated with high speed flight (e.g., increased mean stroke  
327 amplitude and increased anatomical stroke plane angle). Both high speed and maneuvering flight are  
328 associated with changes in wing kinematic variables, such as an increase in stroke amplitude, which  
329 have been shown to incur greater energetic costs (Clark and Dudley, 2010). Our finding that many of  
330 these kinematic changes also occur during flight in turbulent flow, whereas they are absent during  
331 flight behind a vortex street, suggests that flying in fully mixed turbulence may be more energetically  
332 demanding than flying in the unsteady, structured wakes of objects. Future studies involving  
333 respirometry measurements of hummingbirds flying in turbulent *versus* smooth flow and  
334 measurements of top flight speeds in these flow conditions would provide more direct information  
335 about the energetic costs and limits of hummingbird flight in freestream turbulence, the flow  
336 condition that hummingbirds are likely to encounter most frequently in natural habitats.

## 337 **Materials and Methods**

### 338 **Animals and flight tests**

339

340 Four female ruby-throated (*Archilochus colubris*) hummingbirds were caught in Bedford, MA and  
341 maintained at the Concord Field Station for up to one week prior to experiments. Birds were housed  
342 in 0.5 x 0.5 x 0.5 m husbandry flight chambers where they were provided *ad libitum* access to fortified  
343 nectar solution (Nektar Plus, Nekton USA) in a hummingbird feeder. Experiments were conducted  
344 once birds were sufficiently acclimatized to their captive environment. Immediately prior to  
345 experiments, each bird was held gently while markers were placed on the head, beak, torso and  
346 wings. The markers on the head consisted of two small black dots separated by 10 mm; markers on the  
347 torso consisted of three black points representing the vertices of an isosceles triangle (measuring 2.7 x  
348 2.3 mm). All markers were set upon a white background (Fig. 1), and were affixed using cyanoacrylate  
349 glue. Small dots of reflective white paint were placed on the beak and on the leading edge of each  
350 wing, around the midpoint of the span (Fig 1).

351 Each bird was then released into the test section of the wind tunnel, which contained a small 1 ml  
352 tuberculin syringe filled with sucrose solution located 800 mm from the inlet of the test section, as  
353 well as a perch in the downstream end. All birds began feeding within a minute of being released in  
354 the wind tunnel. Once birds were sufficiently calm and began feeding consistently, wind speed in the  
355 tunnel was increased. During flight trials, birds maintained position while feeding from the tuberculin  
356 syringe (sustaining a forward flight speed of ~5 m/s), and were filmed using two Photron SA3 high-  
357 speed cameras sampling at 1000 Hz, placed above the wind tunnel at approximately 30° from the  
358 vertical. A static calibration cube that filled the volume of interest was used for spatial calibration via  
359 direct linear transformation (Hedrick, 2008).

360 Experiments were conducted in a 6 m long, suction-type, open-return wind tunnel with a 1.5 L x 0.5 W  
361 x 0.5 H m working section. Wind-speed was set to ~5 m/s, which represents an intermediate cruising  
362 velocity for hummingbirds (Tobalske et al., 2007). To generate fully mixed freestream turbulence, a  
363 symmetric planar grid was introduced at the inlet of the test section. The grid consisted of panels of  
364 40 mm width and 40 mm inter-panel spacing (Fig. 2). These dimensions were chosen because they  
365 resulted in the highest level of fully mixed turbulence intensity within the wind tunnel. The interaction  
366 between airflow and the grid results in the formation of discrete vortices immediately downstream of  
367 the panel (Comte-Bellot and Corrsin, 1966), which advect downstream and eventually break down to  
368 form fully mixed freestream turbulence (Batchelor and Townsend, 1948) due to viscosity and  
369 interactions between vortices. The region of interest in these experiments was located approximately  
370 20 panel widths downstream from the grid, which is the distance generally required for discrete  
371 vortices to break down to fully mixed turbulence (Mohamed and Larue, 1990; Gad-El-Hak and Corrsin,  
372 1974). Fluctuations in flow velocity within the wind tunnel were quantified using a three component  
373 hot-wire anemometer (55P91 probe, Dantec Dynamics, Sweden) sampling at 1kHz, calibrated against  
374 a standard pitot-static tube.

375 We characterized the level of turbulence generated by calculating the turbulence intensity (standard  
376 deviation of wind speed/mean wind speed) and the integral length scale. In this study, the auto-  
377 correlation method was used to estimate the integral length scale along the longitudinal axis (see Ravi,  
378 2011 for further details).

379

## 380 **Kinematics reconstruction and analysis**

381

382 Recorded flight sequences were digitized using an open-source MATLAB-based routine, DLTdv5  
383 (Hedrick, 2008). In addition to digitizing all markers, the shoulder joints (where the wings attach to the  
384 thorax), base of the tail (midline of where the tail meets the body), and extremities of the tail (tips of  
385 the outermost tail feathers) were also digitized (Fig. 2, blue dots), for a total of 12 points digitized over  
386 0.5 s of flight (20-22 wingbeats) for each bird. Subsequent kinematic analyses were performed in  
387 MATLAB.

388 Digitization error in localizing the centroids of marker points was estimated to be approximately 1-2  
389 pixels, which was much smaller than the mean number of pixels separating the markers (~50). This  
390 error is expected to manifest only at higher frequencies, on the order of the Nyquist frequency. To  
391 remove any higher frequency errors due to the digitization process, position data were passed  
392 through a 4<sup>th</sup> order, low-pass Butterworth filter with a cutoff frequency of 400 Hz, which is lower than  
393 the Nyquist frequency (500 Hz) but higher than the flapping frequency of the birds (~45 Hz). To  
394 examine motions that occur over timescales greater than one wingbeat, we further filtered calculated  
395 accelerations and rotations of the head, body and tail with a 30 Hz low-pass filter (4<sup>th</sup> order  
396 Butterworth) to remove motions due to the flapping wings. Reconstructed wing kinematics were  
397 passed through a 4<sup>th</sup> order, low-pass Butterworth filter with a cutoff frequency of 200 Hz to further  
398 smooth the wing trajectories.

399 Instantaneous velocities and accelerations of the head and body were calculated by taking time  
400 derivatives of the positions. Translational accelerations of the head and body were calculated in a  
401 global coordinate system based on the wind tunnel's working section (longitudinal = long axis of the  
402 wind tunnel/direction of mean flow, lateral and vertical span the cross-section in the horizontal and  
403 vertical directions, respectively). For calculating roll, pitch and yaw of the head and body, a local plane  
404 was constructed based on the three marker points present on each body segment (triangular marker  
405 for torso and two head markers + beak marker for head). Assuming rigid body dynamics, the  
406 instantaneous orientation and rotation rates of these planes were calculated using the method  
407 detailed previously (Ravi et al., 2013). The instantaneous orientation of the head was calculated with  
408 respect to the global coordinate system, while the orientation of the torso was calculated with respect  
409 to the local coordinate system of the head. The orientation of the tail was determined by constructing  
410 a local tail plane, formed by the base and extremities of the tail, and calculating the orientation of this  
411 plane with respect to the local coordinate system of the torso (using the method described in Ravi et  
412 al., 2013). The fan angle of the tail was calculated as the angle between the vectors connecting the

413 extremities of the tail to the tail base. The fan angle was measured at each frame for the entire flight  
414 sequence recorded, the mean and standard deviation of the same over the flight was measured and  
415 compared in smooth and turbulent wind conditions.

416 Because a constant and stable head position is assumed to improve feeding efficiency, feeding  
417 performance was assessed by measuring the distance between the beak and the feeder over the  
418 course of each flight trial. The magnitude of fluctuations (standard deviation) in this distance was  
419 compared across smooth and turbulent flow conditions. Mean absolute values of translational  
420 accelerations and rotation rates of the head were calculated with respect to the global coordinate  
421 system and compared across flow conditions. A similar analysis was performed to assess stability of  
422 the torso in laminar and turbulent flow, whereby the mean absolute value of translational  
423 accelerations and rotation rates along each axis of the body were compared. To assess tail  
424 deployment as a potential flight control mechanism, roll, pitch and yaw angles of the tail were  
425 calculated with respect to the local coordinate system of the torso, and mean absolute rotation rates  
426 of the tail were compared between the two flow conditions. In addition, the use of tail fanning as a  
427 potential control mechanism was investigated by calculating the mean and standard deviation of fan  
428 angle during flight in laminar *versus* turbulent flow.

429 Wing kinematics were derived from the digitized positions of the shoulder joints and the leading edge  
430 markers on each wing. For each stroke, the flapping frequency was calculated as the inverse of the  
431 wing beat period, which was independently measured on the left and right wing and then averaged.  
432 The wingbeat frequency at each stroke was subsequently averaged over the recorded sequence to  
433 estimate the mean flapping frequency in smooth and turbulent wind. The standard deviation of the  
434 flapping frequency over the recording was compared between the two flow conditions. Stroke  
435 amplitude was measured as the angle swept by the leading edge with respect to the wing base  
436 between the top of the upstroke and bottom of the downstroke, and was calculated for the left and  
437 right wings separately during each stroke. The mean and standard deviation of the stroke amplitude  
438 of the birds in the two wind conditions over entire recording was compared. The anatomical stroke  
439 plane angle was calculated for each wingbeat by estimating the pitch angle between the body and a  
440 2D regression line of the position of the leading edge throughout a stroke projected onto the x-y  
441 plane; this procedure was conducted separately for each wing. The mean and standard deviation of  
442 the anatomical stroke-plane angle was also taken over the entire sequence and compared between  
443 smooth and turbulent wind conditions. Stroke plane amplitude and anatomical stroke plane angle  
444 were independently measured for the left and right wings to examine how mean values and stroke-to-  
445 stroke bilateral variability differed between smooth and turbulent flow. To assess bilateral asymmetry  
446 in these variables, the difference between the left and right wing was calculated for each stroke.  
447 Subsequently the standard deviation of the stroke-resolve bilateral asymmetry in amplitude and  
448 stroke-plane angle was calculated over the entire sequence.

449 Statistical significance of results was analyzed by performing a parametric repeated measures ANOVA  
450 test ( $n = 4$  individuals in all cases) between experimental conditions (smooth flow [S], turbulent [T]), or  
451 between pairs of translational (Long.-Lat., Long.-Vert. & Lat.-Vert.) or rotational axes (Roll-Pitch, Roll-  
452 Yaw & Pitch-Yaw) in MATLAB.

## 453 **Body force measurements**

454 To test the effects of observed changes in body and tail orientation, we measured the forces  
455 generated by a static hummingbird body in various configurations, placed in the wind tunnel with  
456 laminar flow. The wings of a euthanized hummingbird were removed and the body was attached to an  
457 ATI Nano17 force balance (ATI Industrial Automation, Apex NC) via a thin carbon fiber rod. The rod  
458 was placed near the estimated location of the center of gravity of the body (posterior and ventral to  
459 the wing hinge). Because the rod was small, its influence on airflow and the resulting forces was  
460 judged to be negligible. Lift and drag forces were assumed to act perpendicular and parallel to the  
461 mean wind direction, respectively. A wire support placed on the along the longitudinal axis of the  
462 body was used to vary the pitch of the body and tail. Different tail fan angles were set using a wire  
463 support glued laterally across the basal part of the tail. Forces generated by the hummingbird body  
464 were measured at 0° and 20° body pitch angle with respect to the oncoming wind, which were typical  
465 orientations within the range maintained by the birds in free flight. Tail pitch and fan angles were  
466 altered to examine force production at the extreme values of these variables measured in free flight.  
467 Thus, for each body angle, forces were measured with a tail pitch of 0° or 20° (tail down) with respect  
468 to the body, and for each body and tail orientation, tail fan angle was set to 53° (unfanned) or 104°  
469 (fanned).
