Received 8 December 2014; revised 16 February 2015; accepted 23 February 2015

Background: Glioblastoma (GBM) is the most common malignant brain cancer occurring in adults, and is associated with dismal outcome and few therapeutic options. GBM has been shown to predominantly disrupt three core pathways through somatic aberrations, rendering it ideal for precision medicine approaches.

Methods: We describe a 35-year-old female patient with recurrent GBM following surgical removal of the primary tumour, adjuvant treatment with temozolomide and a 3-year disease-free period. Rapid whole-genome sequencing (WGS) of three separate tumour regions at recurrence was carried out and interpreted relative to WGS of two regions of the primary tumour.

Results: We found extensive mutational and copy-number heterogeneity within the primary tumour. We identified a TP53 mutation and two focal amplifications involving PDGFRA, KIT and CDK4, on chromosomes 4 and 12. A clonal IDH1 R132H mutation in the primary, a known GBM driver event, was detectable at only very low frequency in the recurrent tumour. After sub-clonal diversification, evidence was found for a whole-genome doubling event and a translocation between the amplified regions of PDGFRA, KIT and CDK4, encoded within a double-minute chromosome also incorporating miR26a-2. The WGS analysis uncovered progressive evolution of the double-minute chromosome converging on the KIT/PDGFRA/PI3K/mTOR axis, superseding the IDH1 mutation in dominance in a mutually exclusive manner at recurrence, consequently the patient was treated with imatinib. Despite rapid sequencing and cancer genome-guided therapy against amplified oncogenes, the disease progressed, and the patient died shortly after.

Conclusion: This case sheds light on the dynamic evolution of a GBM tumour, defining the origins of the lethal subclone, the macro-evolutionary genomic events dominating the disease at recurrence and the loss of a clonal driver. Even in the era of rapid WGS analysis, cases such as this illustrate the significant hurdles for precision medicine success.

Key words: glioblastoma, multi-region sequencing, intra-tumour heterogeneity, double minute chromosome

introduction

Glioblastoma (GBM) is the most common malignant brain cancer occurring in adults and is associated with poor prognosis and a median overall survival of only 15 months [1]. Nearly all
GBM tumours recur after surgery, radiotherapy and chemotherapy, with a median time to recurrence of 7 months [1].

Accumulating evidence suggests that treatment failure in cancer may be driven by intra-tumour heterogeneity (ITH), and branched tumour evolution involving genetically distinct sub-clones [2]. Recent studies have documented widespread ITH in GBM. Sottoriva et al. [3] found that each individual tumour can harbour multiple distinct copy-number profiles and transcriptomic subtypes simultaneously. Johnson et al. [2] revealed spatial and temporal heterogeneity in GBM, confirmed the importance of TP53 and IDH1 as early driver mutations [4, 5], and demonstrated the impact of temozolomide (TMZ) treatment on tumour evolution, with 6 of 10 tumours showing evidence of TMZ-induced hypermutation at recurrence.

In order to fully assess ITH within the life history of a single tumour and attempt to offer the patient a cancer genome-guided therapy, we implemented rapid multi-region whole-genome sequencing (WGS) in a patient with recurrent GBM. This analysis reveals the temporal and spatial evolution of a GBM tumour, defining the origins of the lethal sub-clone from a sub-clone in the primary tumour and the associated macro-evolutionary genomic events dominating the disease at recurrence, confounding treatment success.

**methods**

**ethics**

Written informed consent was obtained from the patient in the HospitauxUniversitaires de Geneve ‘Analyse de la reponse immunologique contre les tumeurs cérébrales’ translational approved protocol IRB 03-126. Tumour material was analysed under the UCL-Cancer Institute and Pathology biobank (UCLHRTB 10/H1306/42). The patient provided written informed consent to tumour sequencing analysis within a compassionate setting. The study was conducted according to the provisions of the Declaration of Helsinki and the Good Clinical Practice Guidelines of the International Conference on Harmonization.

**WGS data processing and analysis**

WGS was carried out by Illumina, UK. Mutation calling and filtering was carried out using VarScan2 as described [6], annotation of coding mutations were carried out using ANNOVAR [7]. Structural variant (SV) breakpoint mechanism classification was carried out according to the criteria defined in Yang et al. [8]. Reconstruction of the putative double-minute chromosomes was carried out as described in Sanborn et al. [9] and breakpoints mapping to the focal amplifications were validated by PCR and Sanger Sequencing. Copy-number variation (CNV) analysis was carried out on the WGS data. Purity, ploidy and allele-specific copy-number estimates were obtained with Sequenza [10]. Clonal analysis was carried out as described in Bolli et al. [11], estimating the cancer cell fraction (CCF) by integrating variant allele frequency estimates with copy number, purity and ploidy estimates. Single-sample and multi-sample Dirichlet process clustering was carried out using the DPpackage R package [12]. In this work, mutations are referred to as ‘sub-clonal’ if their CCF indicates they are present in only a subset of cancer cells within a given sample (CCF < 1). Mutations present in all cancer cells of a given sample (CCF ∼ 1) are referred to as ‘clonal’. Genome doubling (GD) was determined from the comparison of the sequencing of the grade II and the grade IV regions and by considering the mutations located in the portion of the genome where a clear doubling of the number of alleles was detected, see supplementary Information, available at Annals of Oncology online, for details. All data analysis was carried out in R version 3.0.2, all P values are two sided.

**results**

**clinical case report**

A 35-year-old female presented with partial complex seizures in January 2007, increasing in frequency after the delivery of her second child in September 2007 (Figure 1A). MRI carried out in June 2008, revealed a right temporal mass (6 × 6.7 × 4.5 cm) with slight contrast enhancement. She underwent complete removal of the tumour on 3 July 2008 and the diagnosis of WHO grade IV astrocytoma (GBM) was established (the tumour consisted of a grade II and grade IV histological components). She received concomitant treatment with irradiation (60 Gy in 30 fractions) and TMZ, followed by 6 monthly cycles of TMZ (200 mg/m² D1–D5) until March 2009. She was free of symptoms for 2 years but partial seizures reappeared in early 2011. A further MRI showed a multi-focal recurrence in the right temporal area extending to the thalamus and the corpus callosum. Considering the long disease-free interval (3 years) between first treatment and recurrence, TMZ at a similar dose and schedule was prescribed again.

In March 2012, she presented with acute headache and intracranial hypertension. MRI showed massive progression mainly in the right frontal area with risk of herniation. She underwent partial removal of the tumour on 29 March 2012. The histology confirmed grade IV astrocytoma with MGMT gene promoter methylation. She received bevacizumab and TMZ; after transient clinical improvement, her clinical condition deteriorated and TMZ was replaced by 800 mg imatinib daily, guided by the WGS data, sequenced and reported within 7 days by Illumina, indicating amplification of KIT and PDGFRA. The tumour progressed rapidly on therapy and she died 3 months after the second surgical debulking procedure.

**whole-genome sequencing**

Archival formalin-fixed paraffin-embedded (FFPE) specimens of the grade II and IV primary samples along with three fresh-frozen samples from the recurrence and a germline reference were WGS to a depth of 30× (∼1.3 × 10⁸ paired reads per sample; supplementary Table S1 in supplementary Information, available at Annals of Oncology online). The three recurrence regions were homogeneous at the SNV level indicating limited clonal variation in the recurrence; however, the SNV calling was hampered by stromal contamination (supplementary Table S1, available at Annals of Oncology online). The three recurrent regions, referred to as A1, A2 and A3, respectively, were merged in silico in a single alignment file, termed As, to increase the resolution and improve the capacity to define the evolutionary trajectory of the recurrence specimen. 1271 and 1935 high-confidence somatic silent and non-silent SNVs were identified in the grade II and IV regions, respectively, and 1435 in the recurrence specimen. When comparing the grade II and grade IV to the recurrence, the grade IV shared 338 mutations with the recurrence not found in the grade II region, while the grade II only shared one mutation with the recurrence not found in the grade IV region (Figure 1B, coding mutations only in supplementary Figure S1, available at Annals of Oncology online, for details).
detailed mutation information in supplementary File, available at Annals of Oncology online). Given that the grade II region exhibited fewer private mutations (69/1271, Figure 1B and C), this indicates that it most closely resembles the most recent common ancestor, and that the recurrence specimen evolved from the grade IV region.

**extensive mutational variation found between grade II and grade IV regions**

Several clonal mutations were found in both primary lesions suggesting a shared clonal origin. These include a TP53 Y220C mutation, a frame shift mutation in ATRX (K1871fs) and an IDH1 mutation, R132H. These genes have previously been described as driver events for GBM [4, 13], and ATRX mutations has been shown to co-occur with TP53 and IDH1 mutations [2], and to be a driver of alternative telomere lengthening [14]. Clustering the mutation CCFs in the grade II and grade IV regions revealed six distinct clusters (Figure 1D). Most mutations were identified as clonal in both primary lesions and the recurrence specimen (clusters 1, 3 and 6). However, we also found 202 mutations that were clonal in the grade IV but sub-clonal in the grade II (cluster 2), and two clusters of mutations (4 and 5) that were sub-clonal in the grade IV.
and absent in the grade II. The cluster 2 mutations likely represent a persistent sub-clone within the grade II region that gave rise to the grade IV region, while clusters 4 and 5 may have arisen independently in the grade IV, consistent with further sub-clonal evolution occurring during disease progression.

primary tumour shows heterogeneous acquisition of copy-number changes

CNV and SV analyses identified a number of shared events in the primary regions (supplementary Table S2, available at Annals of Oncology online), including copy-neutral loss of heterozygosity on chromosome 17p following TP53 mutation (supplementary Figure S2A and B, available at Annals of Oncology online); CDK6 and MET amplifications via gain of 7q; and two high-level focal amplifications (supplementary Figure S3, available at Annals of Oncology online) of 4q12 (encoding PDGFRα and KIT) and 12q13.3-q14.1 (encoding CDK4, AVIL and miR-26a-2).

ITH was also detected by CNV and SV analyses (supplementary Figure S4, available at Annals of Oncology online): CDKN2A/B loss and other CNVs (gain of 6p, 19p and 20p; loss of 10q, 12q, 13, 16q, 17q and 22) were detected only in the grade IV sample. Furthermore, the 4q12 and 12q13.3–14.1 focal amplifications were linked by numerous translocations in the grade IV but not in the grade II sample (supplementary Figures S5 and S6, available at Annals of Oncology online).

Allele-specific CNV analysis revealed that the grade IV region was predominantly tetraploid, while the grade II region was largely diploid. Mutations in the grade IV region also exhibited a bimodal variant allele frequency distribution consistent with a GD event, exclusively in the grade IV region (supplementary Figure S7, available at Annals of Oncology online). As previously reported [15], GD is permissive for chromosome instability (CIN) and accelerated cancer genome evolution. Consistent with a GD event in the grade IV region followed by chromosome losses due to increasing CIN [15], flow cytometry on the fresh tissue of the three recurrence samples revealed a DNA index of 1.60, 1.58 and 1.55 for each recurrence region (supplementary Figure S8, available at Annals of Oncology online).

chromosome 4 rearrangements and evolution of a double-minute chromosome

Copy-number analysis of the recurrence tumour revealed focal amplifications in 4q12 and 12q13.3-q14.1 detected in the grade IV region, with comparably high copy number and seemingly identical breakpoints (supplementary Figures S2C and D and S6, available at Annals of Oncology online). Although the grade II sample also shared the 12q13.3-q14.1 amplification, the entire 4q-arm was amplified in this sample. SV analysis revealed complex chromosomal re-arrangements linking the 4q12 and 12q13.3-q14.1 focal amplifications in the higher grade samples only. Taken together, these features are reminiscent of a double-minute chromosome (DM), a relatively frequent cytogenetic event in GBM [9, 16].

To investigate this further, we employed a precise amplicon reconstruction method [9]. This involved the identification of breakpoints related to the highly amplified regions, followed by the construction of a breakpoint graph that links the amplified segments and their associated breakpoints, and a final search for an optimal path that completely traverses the graph (supplementary Figure S9, available at Annals of Oncology online). In the final solution, segment traversal number correlates with observed relative copy number of the segment, and circular paths are indicative of a DM.

Consistent with a DM, the 4q12 and 12q13.3-q14.1 amplifications revealed circular paths, indicating DMs in the grade IV and recurrence samples (Figure 2A and B and supplementary Figure S9A, available at Annals of Oncology online). Two chromosomal intervals (Figure 2A) replete with putative driver genes (PDGFRα, KIT, CDK4, AVIL and miR-26a-2) are re-configured into circular assemblies. Figure 2B illustrates the optimal paths that account for the observed breakpoints and high copy-number amplifications. The absence of this structure in the grade II sample suggests that the 12q13.3-q14.1 focal amplification preceded DM formation, consistent with a breakage-bridge fusion cycle [17]. However, L1 elements flank the 12q13.3-q14.1 amplification (data not shown), precluding further local SV resolution. There are numerous precisely shared breakpoints between the DM models, and all breakpoints tested validated (Figure 2C and supplementary Figure S10, available at Annals of Oncology online), which suggests a common origin of the extra-chromosomal structures. Moreover, the breakpoints exhibit features of non-homologous end-joining [8] which may be indicative of a single chromothric event [18].

To investigate the origin of the DMs, we carried out haplotype analysis in the grade IV and recurrence DMs. This was achieved using allele frequencies of heterozygous SNPs located in the DM locus (supplementary Information, available at Annals of Oncology online). Consistent with a shared origin of the DMs, the allelic composition of the DM haplotypes appears to be identical at the 4q12 and 12q13.3-q14.1 loci (supplementary Figure S11, available at Annals of Oncology online). Moreover, the DM derived from both higher copy-number haplotypes; conversely, the higher copy-number haplotypes on 4q12 were predominantly lost in the segments flanking the DM. Such a pattern is consistent with shattering of a ‘gained’ chromosome 4q followed by ‘rescue’ of oncogenic fragments within the DM and loss of the remainder of the chromosome.

double-minute chromosome is associated with progression

We computed a distance matrix from all the mutations detected in the primary regions and in the three recurrence regions, establishing a phylogenetic relationship between the sequenced regions. This confirmed that the recurrence specimen was most similar to the grade IV region, with the DM likely arising between the grade II and grade IV regions (Figure 3A). The DM carries the putative GBM driver gene AVIL [19], with a mutation restricted to the grade IV/recurrence lineage and linked to the focal amplification via discordant paired-end reads as well as exhibiting a high-variant allele frequency (chr12:58204830; supplementary Figure S2F, available at Annals of Oncology online). Additionally, the DM unifies multiple oncogenic components of the PI3K pathway: PDGFRα, KIT, and a regulator of PTEN (miR-26a-2) as well as CDK4 (Figure 2B). To assess if the grade IV tumour shows increased activation of the PI3K
Figure 2. Evolution of the double minute. (A) The upper panel represents the genomic segments before the DM formation, with genes annotated by horizontal lines. The lower panel contains circular chromosome plots representing the double-minute models for the grade IV (G4) and recurrence samples (A1/A3), with validated (and shared) breakpoints denoted by dark grey (red online) links between segments. Light grey (yellow online) links represent un-validated breakpoints for which de novo contigs could be assembled. Validated breakpoints are illustrated in panels (B and C).
pathway, we carried out immunohistochemistry against PDGFRA, PTEN and cKIT in the grade II and grade IV tumours (Figure 3B). We found increased levels of PDGFRA (215/300 versus 93/300, grade IV versus grade II) and cKIT (222/300 versus 31/300) in the grade IV tumour, but no difference in the PTEN levels (34/300 versus 23/300). This suggests that PTEN is deactivated in both the grade II and grade IV tumours, but that the PI3K pathway is further activated in the grade IV tumour, likely due to amplification of genes encoded within the DM.

**IDH1 driver mutation is lost at recurrence**

Trunk events including the TP53 and ATRX mutations and PDGFRA/KIT, CDK4/miR-26a-2 focal amplifications along with the grade IV private mutation detected in AVIL were identified at high frequency in the recurrence samples. Surprisingly, the *IDH1* R132H mutation was not detected in the recurrence samples despite being clonal in the grade II and IV lesions. To validate this observation, we carried out digital PCR (dPCR) on *IDH1* and TP53 (using TP53 as a control). We confirmed that the R132H mutation was indeed clonal in the grade II and grade IV specimens (found in ~42%–44% of DNA molecules, supplementary File, available at *Annals of Oncology* online), but essentially undetected in the recurrence samples, with between 0.01% and 0.1% of DNA molecules showing the mutation by dPCR. Conversely, TP53 was found in between 8% and 12% of the DNA molecules (supplementary File, available at *Annals of Oncology* online), consistent with clonal presence in the low-purity recurrence biopsies (estimated at 10%–15% purity, supplementary Information, available at *Annals of Oncology* online). It is therefore likely that the recurrence has experienced loss of the mutated *IDH1* allele and retention of the wild-type allele.

A recent report indicates mutual exclusivity between activation of the PI3K pathway and *IDH1* activity [20]. As the recurrence demonstrated increased levels of PDGFRA and KIT amplification encoded on the DM, activators of the PI3K pathway, we carried out immunohistochemistry against PDGFRA, PTEN and cKIT in the grade II and grade IV tumours (Figure 3B). We found increased levels of PDGFRA (215/300 versus 93/300, grade IV versus grade II) and cKIT (222/300 versus 31/300) in the grade IV tumour, but no difference in the PTEN levels (34/300 versus 23/300). This suggests that PTEN is deactivated in both the grade II and grade IV tumours, but that the PI3K pathway is further activated in the grade IV tumour, likely due to amplification of genes encoded within the DM.

**IDH1 driver mutation is lost at recurrence**

Trunk events including the TP53 and ATRX mutations and PDGFRA/KIT, CDK4/miR-26a-2 focal amplifications along with the grade IV private mutation detected in AVIL were identified at high frequency in the recurrence samples. Surprisingly, the *IDH1* R132H mutation was not detected in the recurrence samples despite being clonal in the grade II and IV lesions. To validate this observation, we carried out digital PCR (dPCR) on *IDH1* and TP53 (using TP53 as a control). We confirmed that the R132H mutation was indeed clonal in the grade II and grade IV specimens (found in ~42%–44% of DNA molecules, supplementary File, available at *Annals of Oncology* online), but essentially undetected in the recurrence samples, with between 0.01% and 0.1% of DNA molecules showing the mutation by dPCR. Conversely, TP53 was found in between 8% and 12% of the DNA molecules (supplementary File, available at *Annals of Oncology* online), consistent with clonal presence in the low-purity recurrence biopsies (estimated at 10%–15% purity, supplementary Information, available at *Annals of Oncology* online). It is therefore likely that the recurrence has experienced loss of the mutated *IDH1* allele and retention of the wild-type allele.

A recent report indicates mutual exclusivity between activation of the PI3K pathway and *IDH1* activity [20]. As the recurrence demonstrated increased levels of PDGFRA and KIT amplification encoded on the DM, activators of the PI3K pathway, we carried out immunohistochemistry against PDGFRA, PTEN and cKIT in the grade II and grade IV tumours (Figure 3B). We found increased levels of PDGFRA (215/300 versus 93/300, grade IV versus grade II) and cKIT (222/300 versus 31/300) in the grade IV tumour, but no difference in the PTEN levels (34/300 versus 23/300). This suggests that PTEN is deactivated in both the grade II and grade IV tumours, but that the PI3K pathway is further activated in the grade IV tumour, likely due to amplification of genes encoded within the DM.
pathway, we addressed whether the GBM data from The Cancer Genome Atlas (TCGA) [16] supports mutual exclusivity between IDH1 R132H mutation and PDGFRA and/or KIT amplification. IDH1 and TP53 mutations are enriched in the proneural subtype [21]. Using the cBio portal [22], we identified 137 TCGA GBM cases classified as proneural in Brennan et al. [16], with both sequence and copy-number data. Of these, 12 showed the R132H mutation, 25 showed dual KIT and PDGFRA amplification and 10 showed PDGFRA amplification only. No overlap between cases with the IDH1 R132H mutation and KIT and/or PDGFRA amplification was observed indicating mutual exclusivity between these oncogenic events (P = 0.036, Fisher’s exact test). This also suggests that the IDH1 R132H mutation was indeed an early driver event that was subsequently lost during recurrence, as a more potent poly-oncogene–oncomir cluster was selected for in the DM.

An analysis of TCGA GBM data from 264 tumours with whole-exome sequencing processed by Sanborn et al. [9] to infer DM structures, identified four samples, of these three proneural, with amplifications of both PDGFRA and CDK4, possibly encoded in double-minute chromosomes. These data suggest that at least 1.5% (4/264) of GBM tumours overall, and 8% (22/264) of the proneural subtype, are driven by the acquisition of such a macro-evolutionary event typified by PDGRA/CDK4/miR-26a-2 DMs.

**discussion**

This study is one of the first reports of a multi-region longitudinal WGS of a GBM from diagnosis to death, carried out specifically with the intention to improve patient outcome by the application of tailored therapy. Unfortunately, despite identifying multiple amplified targetable oncogenes and applying targeted therapy, disease control was not achieved, and the patient died following disease progression.

To our knowledge, this is the first description of a loss of a tier 1 clonal driver event (IDH1, R132H) during disease progression, and may reflect complex epistatic relationships between tumour somatic events and the selection pressure of therapy. We cannot formally exclude the possibility that the IDH1 mutation in the primary samples was a sub clonal event at diagnosis; we have documented in NSCLC and ccRCC that drivers can appear clonally dominant within one region only to find that further tumour sampling reveals the sub clonal nature of the event. However, this would require extensive parallel evolution since the majority of somatic aberrations were shared between relapse and the grade IV region. Rather, the progressive enrichment of the DMs from the grade IV to recurrence suggests increased oncogenic potential based on the PI3K pathway. With the waning of the driver IDH1 event, this indicates a macro-evolutionary switch from the dominance of the IDH1-mutated tumour to a DM-driven tumour in a mutually exclusive context. An analysis of the TCGA data also revealed no overlap between IDH1 R132H mutations and PDGFRA/KIT amplification, suggesting that high-level PDGFRA/KIT amplification would not be favourable with an existent IDH1 R132H mutation.

These findings have important implications for precision medicine, suggesting a targetable clonal driver event can be selectively lost during the disease course, and replaced in its entirety by an initially low-frequency event in the primary tumour. The clonal dominance of IDH1 driver events might need to be considered within the context of low-frequency oncogenic drivers when examining the efficacy of therapeutics targeting IDH1 in this disease [23]. Furthermore, despite rapid WGS at recurrence and cancer genome-directed therapy, imatinib was unable to control the disease. Following radiotherapy and two surgical debulking procedures, it is unlikely that the blood–brain barrier was intact, preventing drug penetration into the central nervous system. It is more likely that treatment failure was a consequence of the evolution of the poly-oncogene/oncomir DM targeting the PI3K axis at multiple nodal points.

Moreover, our results emphasize the profound effects of cancer cell GD, resulting in accelerated cancer genome evolution, characterised by a tolerance of CIN and propagation of aneuploid progeny [15]. The accelerated CIN permitted following the GD event in the grade IV region of the primary tumour, and possibly a chromothripsis event on chromosome 4, resulted in the formation and subsequent selection of a highly poly-oncogene–oncomir DM encoding miR-26a-2, PDGFRA, KIT and CDK4.

MicroRNA miR-26a-2 effectively targets PTEN [24]. Immunohistochemistry demonstrated that PTEN expression was weak or absent relative to stromal cells in both the grade II and grade IV regions, although no genomic aberrations were detected at the PTEN locus. It is likely therefore, that amplification of CDK4/miR-26a-2 region, either encoded within the DM in the grade IV region and recurrent tumour or simply due to amplification as observed in the grade II specimen, directly contributed to loss of PTEN protein expression.

Taken together, these observations emphasise the complexity of signal transduction cascades activated within individual tumours. However, it is apparent that the oncogenic drivers involved in GBM pathogenesis are highly constrained and the combination of these events involved in DMS may be finite. There is an unmet need to enrol patients within longitudinal cohort studies to define these genetic constraints in order to accelerate our understanding of GBM evolution throughout the disease course and optimise therapeutic opportunities in this disease.
