Abstract

Background
Understanding the patterns of HCV RNA levels during acute hepatitis C virus (HCV) infection provides insights into immunopathogenesis and is important for vaccine design. This study evaluated patterns of HCV RNA levels and associated factors among individuals with acute infection.

Methods
Data were from an international collaboration of nine prospective cohorts of acute HCV (InC³ Study). Participants with well-characterized acute HCV infection (detected within three months post-infection and interval between the peak and subsequent HCV RNA levels ≤120 days) were categorised by a priori-defined patterns of HCV RNA levels: i) spontaneous clearance, ii) partial viral control with persistence (≥1 log IU/mL decline in HCV RNA levels following peak) and iii) viral plateau with persistence (increase or <1 log IU/mL decline in HCV RNA levels following peak). Factors associated with HCV RNA patterns were assessed using multinomial logistic regression.

Results
Among 643 individuals with acute HCV, 162 with well-characterized acute HCV were identified: spontaneous clearance (32%), partial viral control with persistence (27%), and viral plateau with persistence (41%). HCV RNA levels reached a high viraemic phase within two

Data Availability Statement: The data in this study are available upon request. The data cannot be publicly available because they contain confidential and potentially identifying information. Data will be made available to all interested researchers upon request. Data requests should be submitted to InC³ Steering Committee (Professor Kimberly Page, the chair: pagek@salud.um.edu).

Funding: The InC³ Study is supported by the National Institute on Drug Abuse Award Number R01DA031056. The Kirby Institute is funded by the Australian Government Department of Health and Ageing. BH is supported by an Australian
months following infection, with higher levels in the spontaneous clearance and partial viral control groups, compared to the viral plateau group (median: 6.0, 6.2, 5.3 log IU/mL, respectively; P=0.018). In the two groups with persistence, \textit{Interferon lambda 3} (\textit{IFNL3}) CC genotype was independently associated with partial viral control compared to viral plateau (adjusted odds ratio \textit{(AOR)}: 2.75; 95\%CI: 1.08, 7.02). In the two groups with viral control, female sex was independently associated with spontaneous clearance compared to partial viral control (\textit{AOR}: 2.86; 95\%CI: 1.04, 7.83).

Conclusions
Among individuals with acute HCV, a spectrum of HCV RNA patterns is evident. \textit{IFNL3} CC genotype is associated with initial viral control, while female sex is associated with ultimate spontaneous clearance.

Introduction
Initial infection with hepatitis C virus (HCV) is characterized by detection of virus in blood within 2–14 days of exposure, increases in hepatic transaminases, and appearance of detectable HCV-specific antibodies (anti-HCV) within 30–60 days of exposure [1–6]. Understanding of early HCV RNA patterns during acute HCV infection provides insights into immunopathogenesis and is important for vaccine design. However, data in this area remains limited due to the generally asymptomatic nature of initial infection, the highly marginalised nature of at-risk populations, such as people who inject drugs (PWID), and small study populations.

Based on available data, the dynamics of HCV RNA levels following HCV exposure indicate an initial “pre-ramp-up” phase with intermittent low-level viraemia (from exposure to initial quantifiable HCV RNA), followed by a “ramp-up” phase with an exponential increase in HCV RNA levels (8–10 days), and a high viraemic plateau phase (45–68 days) [2]. Among the ~25\% with subsequent spontaneous clearance [7, 8], this plateau phase is followed by a decline in HCV RNA to undetectable levels [9–12]. Among those who subsequently develop persistent HCV infection, patterns of HCV RNA levels are heterogeneous [3, 12–15], but there are limited studies investigated the differential patterns of HCV RNA levels in these individuals. A study of acute HCV infection among HIV co-infected men who have sex with men characterised those who developed persistent infection into two broad patterns: 1) fluctuating levels of HCV RNA (≥1 log IU/mL) corresponding to partial viral control with subsequent persistence; or 2) stable high HCV RNA levels [11, 16].

Factors associated with spontaneous HCV clearance have been well-described and include host (e.g. female sex, \textit{Interferon lambda 3} [\textit{IFNL3}] genotype [formerly called \textit{IL28B}], immune responses) [7, 8, 15, 17–21] and viral factors (e.g. HCV genotype and viral evolution) [8, 11, 22–25]. However, little is known about the host and viral factors associated with partial viral control with persistence when compared to either those who achieve spontaneous HCV clearance or those without partial viral control (high viral plateau with persistence).

The International Collaboration of Incident HIV and Hepatitis C in Injecting Cohorts (InC\textsuperscript{3}) Study, is a collaborative of pooled data from nine prospective cohorts mainly following PWID [26], consisting of well-characterized participants with acute HCV infection. This current study assessed the dynamics of HCV RNA and alanine aminotransferase (ALT) levels in acute HCV infection among those with spontaneous clearance and persistent infection.
Individuals with persistent infection were further categorized into those with high viral plateau with persistence and partial viral control with persistence.

**Materials & Methods**

**Study population and design**

The InC³ Study is a collaboration of nine prospective cohorts evaluating HIV and HCV infection outcomes [26] All cohorts follow participants at regular intervals using standardized methods, although participants were recruited and followed over different time periods, between 1985 and 2010. The InC³ Study includes both: 1) participants without HCV infection; and 2) participants with acute HCV infection. All participants provided written informed consent and the cohort protocols conform to the ethical guidelines of the 1975 Declaration of Helsinki as reflected in *a priori* approval by the University of California at San Francisco (UCSF) Institutional Review Board. The cohort protocols were also approved by local ethics committees in each site [26].

For the current study, only individuals with acute HCV were included. Acute HCV was defined as either: 1) HCV seroconversion with an anti-HCV negative test followed by either an anti-HCV or HCV RNA positive test within two years of the anti-HCV negative test; or 2) evidence of symptomatic HCV infection. Symptomatic HCV infection was defined as a) a positive anti-HCV/HCV RNA test; b) jaundice or ALT elevation > 400 U/L; and c) detection of HCV RNA or history of high-risk exposure within three months of clinical manifestation of acute HCV.

The estimated date of HCV infection was calculated based on a hierarchy using all serological (anti-HCV), virological (HCV RNA) and clinical (symptoms and liver function tests) data to arrive at the most precise estimate of infection date:

a. Among individuals with HCV RNA positive and anti-HCV negative at acute HCV detection, date of infection was four weeks prior to HCV RNA detection [3, 6].

b. Among individuals with symptomatic acute HCV, date of infection was six weeks prior to its onset (jaundice or ALT > 400 IU/L) [27].

c. Among individuals with a negative anti-HCV test followed by either a positive anti-HCV or HCV RNA test, seroconversion was assumed to occur at the mid-point between the last negative and the first positive test. HCV seroconversion generally occurs about 30–60 days following infection [3, 6, 28]. Date of infection in this group was six weeks prior to estimated seroconversion date if the first positive test was anti-HCV test and four weeks prior to estimated seroconversion date if the first positive test was only HCV RNA test.

Profiles of levels of HCV RNA and ALT in those with spontaneous clearance and persistent infection were assessed in 643 (79%) of the 812 persons with acute HCV infection in the InC³ study (Fig. 1). Of the 812, 143 (18%), individuals with unknown virological outcome were excluded. Individuals treated for HCV within 26 weeks of estimated duration of infection were also excluded (n = 37; 5%) to reduce misclassification bias resulting from uncertainty around subsequent spontaneous clearance in the absence of treatment [8, 21].

Among untreated individuals, all longitudinal HCV RNA and ALT measurements were used to assess the profiles of HCV RNA and ALT levels. Among treated individuals (treatment commencement after 26 weeks following infection), only HCV RNA and ALT data up to and including the date of treatment commencement were included in the analysis. Individuals with documented re-infection episodes after spontaneous clearance were censored at the last undetectable HCV RNA before re-infection [29].
Patterns of HCV RNA levels were then evaluated in a sub-group of people classified as “well-characterized acute HCV infection” (Fig. 1). First, the study population was restricted to individuals with HCV RNA detected within the first three months following estimated date of infection (n = 210). This reduced the likelihood that changes in early HCV RNA levels would be missed due to late detection of initial HCV RNA. Two hundred and ten participants met this criteria including 52 with spontaneous clearance and 158 with persistent infection. Second, for participants with persistent infection to be classified as having “well-characterized acute HCV infection” a second HCV RNA test within four months (120 days) of their peak HCV RNA test was also required. This reduced the likelihood of missing unobserved HCV RNA values among individuals with persistent infection and wide intervals between consecutive HCV RNA tests. One hundred and ten participants with persistent infection met this criteria. As such, 162 participants were classified as “well-characterized acute HCV infection” (Fig. 1).

Study outcomes

Spontaneous clearance was defined by two consecutive undetectable HCV RNA test results ≥4 weeks apart following the estimated date of infection [8]. Individuals with persistent infection...
were categorized into two broad *a priori*-defined groups. Partial viral control with persistence was defined by a $\geq 1$ log IU/mL decline between the peak HCV RNA level during the first 90 days following infection and the subsequent HCV RNA level (within 120 days from peak). This group represented individuals who had an initial $\geq 1$ log IU/mL decline in HCV RNA level and stayed at low levels, or had an initial $\geq 1$ log IU/mL decline in HCV RNA levels and had a re-increase (fluctuation) during follow-up (for representative examples, see S1 Fig. [A, B, C]). High viral plateau with persistence (hereinafter called viral plateau with persistence) was defined by an increase or $< 1$ log IU/mL decline between the peak HCV RNA level during the first 90 days following infection and the subsequent HCV RNA level (within 120 days from peak). This group represented individuals who had an increase in HCV RNA level after the first 90 days following infection, or had relatively stable high HCV RNA levels with $< \log$ IU/mL initial decline (for representative examples, see S1 Fig. [D, E, F]). For participants with more than one HCV RNA level within 120 days after the peak level, both individual values and medians were assessed. As results were similar, results with median values are presented.

Among individuals with any of the above described patterns of HCV RNA levels, those with undetectable HCV RNA followed by detectable HCV RNA during twelve-month follow-up were classified as having intermittent viraemia. Among those with intermittent viraemia, viral genotype/subtype data and viral sequence analysis were used to distinguish three subcategories: reinfection (heterologous virus with no subsequent detection of the original viral strain), intercalation (homologous virus), and indeterminate (viral sequencing unavailable, or heterologous virus with subsequent detection of the original viral strain) [29].

**Laboratory testing**

Choice of qualitative and quantitative HCV RNA testing varied by cohort but was consistent at each site. Qualitative HCV RNA testing was performed using the following assays: Versant TMA [Bayer, Australia; $< 10$ IU/ml], COBAS AmpliPrep/COBAS TaqMan (Roche, Branchburg, NJ, USA; $< 15$ IU/ml), COBAS AMPLICOR HCV Test v2.0 (Roche Diagnostics, Mannheim, Germany; $< 50$ IU/ml) or discriminatory HCV transcription-mediated amplification component of the Procleix HIV-1/HCV (Gen-Probe, San Diego, CA, USA; $< 12$ copies/ml). Quantitative HCV RNA testing was performed using the Versant HCV RNA 3.0 (Bayer, Australia; $< 615$ IU/ml), COBAS AMPLICOR HCV MONITOR 2.0 (Roche Diagnostics, Mannheim, Germany; $< 600$ IU/ml), COBAS AmpliPrep/COBAS TaqMan (Roche, Branchburg, NJ, USA; $< 15$ IU/ml) or an in-house PCR ($< 1000$ IU/ml) [30, 31]. HCV genotype was determined by line-probe assay (Versant LiPa1/LiPa2, Bayer, Australia) or HCV sequencing at acute HCV detection. Among those with undetectable HCV RNA (no genotype) and available samples, Murex HCV serotyping was performed to determine HCV genotype (Murex Biotech Limited, Dartford, UK). *IFNL3* genotyping was determined by sequencing of the rs12979860 single nucleotide polymorphism, as previously described [8, 18, 19, 21].

**Statistical analyses**

Population-average curves describing HCV RNA and ALT profiles were constructed using longitudinal HCV RNA and ALT measurements. The median HCV RNA levels (log IU/mL) and ALT levels (IU/L) among all individuals ($n = 643$) were calculated in monthly intervals for the first 12 months following estimated date of infection. To calculate monthly medians of HCV RNA and ALT levels, all individual measurements recorded during each month were included. Medians of HCV RNA and ALT levels were compared between groups using Wilcoxon-Mann-Whitney test or Kruskal Wallis test. Similar analyses were performed in those with well-characterized acute HCV infection ($n = 162$).
To account for within-individual clustering of data points (repeated measurements) and the natural heterogeneity of the population a random effects linear regression model was fitted for the different patterns of HCV RNA levels. Overall time trends were allowed to vary smoothly using natural cubic splines [32]. The intercept and the slope were allowed to differ per individual via the random effects.

Factors associated with patterns of HCV RNA levels were assessed among those with well-characterized acute HCV infection (n = 162). Hypothesized factors were determined a priori based on factors known to be associated with spontaneous clearance of HCV infection and included age [33]. Sex [7, 8, 15, 17, 18], ethnicity [34], IFNL3 genotype (SNP rs12979860; CC vs. CT/TT) [8, 19–21], HIV co-infection [34], and HCV genotype (genotype 1 vs. genotype non-1) [8, 11, 22]. Due to the data of higher spontaneous clearance in HCV genotype 1 [8, 11, 22], and the small numbers within some genotype categories (2/4/6/mixed), all HCV genotype non-1 infections were grouped together.

First, the distribution of each hypothesised factor was compared between those with spontaneous clearance, partial viral control with persistence and viral plateau with persistence using chi square for categorical variables and kruskal wallis test for continuous variables. A multinomial logistic regression model was used for multivariate analyses, including factors with an overall P value <0.20 in unadjusted analyses. Two separate models were fitted considering viral plateau with persistence and partial viral control with persistence as the baselines, respectively. Given that peak HCV RNA levels (IU/ml) and log10 transformation (log IU/ml) of these data was not normally distributed, a dichotomised version of this variable was included in the model using a threshold of 400,000 IU/ml (5.6 log IU/ml) [35]. Statistically significant differences were assessed at P < 0.05; p-values were two-sided. All analyses were performed using stata v12.0 (college station, tx, united states).

Results
Participant characteristics
The characteristics of the population with acute HCV infection included in this study (n = 643) are summarized in Table 1. Median age was 26 years, 36% were female, 96% had a history of injecting drug use, and 17% (n = 112) received HCV treatment during follow-up (all treated individuals included started treatment at >26 weeks following infection). Acute HCV infection was documented by HCV seroconversion in 89% (n = 573) of participants; 183 of these were HCV RNA positive and anti-HCV negative at acute HCV detection. During the first 12 months following estimated date of HCV infection, a median of three HCV RNA tests (inter-quartile range [IQR]: 2, 5), with a median of 35 days (IQR: 23, 91) between tests, were included. The median interval from estimated date of infection to the first positive anti-HCV or HCV RNA test was 101 days (IQR: 28, 172). The overall median follow-up time from the estimated date of infection to the last HCV RNA measurement was 19 months (IQR: 9, 36).

HCV RNA and ALT levels during acute infection, by infection outcome
HCV RNA and ALT levels among those with spontaneous clearance and persistent infection were assessed among 643 participants with acute HCV infection (173 with spontaneous clearance and 470 with persistent infection; Fig. 2). Peak median HCV RNA levels occurred at one month following infection in those with spontaneous clearance (5.7 log IU/mL; IQR: 3.0, 7.0) and at months one and two in those with persistent infection (month one: 5.4 log IU/mL; IQR: 3.8, 6.5 and month two: 5.4 log IU/mL; IQR: 3.1, 6.4; P = 0.39 for month one comparison). By month two to four, HCV RNA declines were seen in both groups. At month two, median HCV RNA levels remained comparable

doi:10.1371/journal.pone.0122232.t001
between individuals with persistent infection (5.4 log IU/mL; IQR: 3.1, 6.4) and spontaneous clearance (4.8 log/IU/mL; IQR: 0.0, 6.0; \( P = 0.38 \)). Median HCV RNA levels initially diverged at three months following infection, being 4.8 log/IU/mL (IQR: 3.3, 6.0) in individuals with persistent infection compared to 3.2 log/IU/mL (IQR: 0.0, 6.1) in those with spontaneous clearance (\( P = 0.03 \)). Subsequent marked divergence in median HCV RNA level between the two groups was seen at month four and beyond (Fig. 2A).

Peak HCV RNA preceded peak ALT by approximately one month, with peak ALT levels being observed in month two following infection among individuals with persistent infection (354 IU/L; IQR: 99, 944) and spontaneous clearance (463 IU/L; IQR: 72, 2316; \( P = 0.43 \)). By month four to five following infection, median ALT level had declined sharply in both groups. Among individuals with spontaneous clearance, median ALT returned to normal at month five and remained within the normal range thereafter. In contrast, in those with persistent infection, median ALT levels remained elevated throughout follow-up with intermittent fluctuations (Fig. 2B). Similar results were observed in sensitivity analyses (S2 Fig.) restricted to individuals identified in the so-called sero-silent acute HCV phase (HCV RNA positive and anti-HCV negative) given the well-defined estimated date of infection in this sub-group (\( n = 183 \)).

Patterns of HCV RNA levels among individuals with well-characterized acute HCV infection

To further characterise the different patterns of HCV RNA levels, longitudinal HCV RNA levels were assessed among individuals with well-characterized acute HCV infection (\( n = 162 \)). Compared to those not included in this analysis (\( n = 481 \)), included individuals were younger, were less likely to be Caucasians, and more likely to have symptomatic acute infection (S1 Table).

Individuals with well-characterized acute HCV infection (\( n = 162 \)) had a median of 4.5 HCV RNA tests (IQR: 3, 8), with a median of 33 days (IQR: 27, 68) between tests during the first 12 months following estimated date of HCV infection. Median interval from estimated date of infection to the first positive anti-HCV or HCV RNA test was 28 days (IQR: 28, 49). Spontaneous clearance was observed in 52 individuals. Among those with persistent infection (\( n = 110 \)), 44 individuals demonstrated partial viral control with persistence (defined by \( \geq 1 \) log IU/mL decline between the peak and the subsequent HCV RNA levels) and 66 individuals demonstrated viral plateau with persistence (defined by increase or \(< 1 \) log IU/mL decline between the peak and the subsequent HCV RNA levels). HCV RNA levels among individuals with these three HCV RNA patterns are illustrated in Fig. 3.

Among 66 individuals with viral plateau and persistence, consistently high HCV RNA levels with irregular fluctuations were observed throughout follow-up. Representative examples of HCV RNA levels among individual cases are shown in S1 Fig. (D, E, F). Intermittent viraemia was observed in four participants in this group during twelve-months of follow-up, including one case of intercalation, three indeterminate cases, and no re-infections.

Among 44 individuals with partial control and persistence, HCV RNA levels declined after the peak and rebounded following months 4–5. Representative examples of HCV RNA levels among individual cases are shown in S1 Figs. (A, B, C). The decline in median HCV RNA levels between month two and five was 3.7 log IU/mL. HCV RNA levels observed after viral rebound were lower than the initial values. The patterns of HCV RNA levels were relatively similar between individuals with partial control and those with viral plateau after months 8–10 following infection. Intermittent viraemia was observed in 10 participants with partial
Fig 2. Monthly medians of HCV RNA and ALT levels in individuals with acute HCV infection in the InC3 study (total n = 643). doi:10.1371/journal.pone.0122232.g003
control and persistence during twelve months of follow-up, including six cases of intercalation, four indeterminate cases, and no re-infections.

Median (IQR) HCV RNA levels at month one following infection were 6.0 log IU/mL (4.3, 7.1), 6.2 log IU/mL (5.2, 7.1), and 5.3 log IU/mL (4.1, 6.0) in individuals with spontaneous clearance, partial viral control with persistence, and viral plateau with persistence, respectively ($P = 0.02$). Compared to those with viral plateau with persistence, median HCV RNA levels was significantly higher in participants with spontaneous clearance ($P = 0.03$) and partial viral control with persistence ($P < 0.01$). However, median HCV RNA levels did not significantly differ between participants with partial viral control compared to those with clearance ($P = 0.68$).

Factors associated with patterns of HCV RNA levels

Among individuals with well-characterized acute HCV, key baseline characteristics were compared among those with viral plateau with persistence (n = 66), partial viral control with persistence (n = 44) and spontaneous clearance (n = 52; Table 2, Fig. 4). Between the three groups, there was a significant difference in the proportion with IFNL3 CC genotype (29% vs. 51% vs. 63%, respectively; $P < 0.01$), median peak HCV RNA level (5.3 log IU/mL vs. 6.0 log IU/mL vs. 6.5 log IU/mL, respectively; $P < 0.01$) and the proportion with peak HCV RNA $\geq$ 5.6 log IU/mL (39% vs. 61% vs. 67%, respectively; $P < 0.01$). There was also a trend towards a significant difference in sex across the three groups, with 54% of individuals with spontaneous HCV clearance being female, as compared to 37% in those with partial viral control with persistence and 35% in those with viral plateau with persistence ($P = 0.09$).

As female sex may have a role in modifying the association of IFNL3 genotype with HCV viral control [8, 18], the proportion of IFNL3 CC genotype was assessed stratified by sex. As shown in Fig. 4E, the difference in the proportion of IFNL3 CC genotype was more pronounced among females compared to males when comparing those with partial viral control with persistence and spontaneous clearance.

Table 3 presents multinomial logistic regression models of factors associated with viral plateau with persistence, partial viral control with persistence and spontaneous clearance. IFNL3 genotype, sex, HCV genotype and peak HCV RNA levels, were included in subsequent models, given the associations observed in unadjusted analyses ($P < 0.20$). In the two groups with viral persistence, the only factor independently associated with partial viral control (compared to viral plateau) was IFNL3 CC genotype (adjusted odds ratio [AOR]: 2.75; 95% CI: 1.08, 7.02; $P = 0.03$). In the two groups with viral control, the only factor independently associated with spontaneous clearance (compared to partial viral control with persistence) was female sex (AOR: 2.86; 95% CI: 1.04, 7.83; $P = 0.04$). Lastly, female sex (AOR: 3.10; 95% CI: 1.18, 8.17; $P = 0.02$), IFNL3 CC genotype (AOR: 5.00; 95% CI: 1.85, 13.51; $P < 0.01$), HCV genotype 1 (AOR: 3.50; 95% CI: 1.24, 9.87; $P = 0.02$), and peak HCV RNA level $\geq$ 5.6 log IU/mL (AOR: 3.77; 95% CI: 1.38, 10.28; $P = 0.01$) were all independently associated with spontaneous clearance compared to viral plateau with persistence.

Discussion

This study has characterized the patterns of HCV RNA and ALT levels in a large population with well-defined acute HCV infection, the majority of whom were PWID. Following acute HCV infection, HCV RNA levels reached a high viraemic phase followed by either spontaneous clearance or persistent infection, with the divergence of HCV RNA levels occurring at approximately three months following infection. Two broad patterns of HCV RNA levels were designated a priori among individuals with persistent infection in this study, including viral plateau with persistence and partial viral control with persistence. IFNL3 CC genotype and
female sex emerged as the most predictive factors for viraemia patterns. Among individuals who develop viral persistence (viral plateau and partial viral control), IFNL3 CC genotype appears to be the most predictive factor of initial viral control. Furthermore, among those who exhibit some degree of viral control (clearance or partial viral control with persistence), female sex is particularly important for determining whether someone will ultimately spontaneously clear the infection.

Differential patterns of HCV RNA levels may reflect a spectrum of immunological viral control during acute infection. Partial viral control with persistence is indicative of a complex pattern of virus–host interaction and can represent loss of immunological control of viral
Fig 4. Distribution of sex, HCV genotype, IFNL3 genotype and peak HCV RNA levels by patterns of HCV RNA levels in individuals with acute HCV infection in the InC3 study. (A) Sex, $P = 0.09$; (B) HCV genotype, $P = 0.18$; (C) IFNL3 genotype, $P < 0.01$; (D) Peak HCV RNA levels, $P < 0.01$; (E) IFNL3 genotype stratified by sex, male $P = 0.03$, female $P = 0.02$.

replication due to virological escape from initial innate responses or a failure in the kinetics, magnitude or breadth of HCV-specific adaptive immune responses (reviewed in [16, 36]). Rapid viral evolution occurs during acute HCV infection, with a higher genetic diversity observed among those with ultimate persistence as compared to clearance [11, 25]. Reductions in HCV RNA levels and genetic diversity have been identified within 100 days of infection (a “bottleneck” effect) irrespective of infection outcome, with subsequent increased HCV RNA levels and diversity in those with persistent infection [37]. The pattern of HCV RNA levels in those with partial viral control and persistence observed in the current study is consistent with these data, given this control was observed largely between months 3–5 (90–150 days).

Vigorous but late onset HCV-specific T-cell responses have been also identified in individuals with transient viral control in acute HCV infection, while ultimately loss of HCV-specific T-cell responses has led to recurrent HCV viraemia and persistent infection (reviewed in [36, 38]). Although two broad patterns of HCV RNA levels were defined among individuals with persistent infection in this study, heterogeneity in individual HCV RNA patterns is still evident in these two groups [3, 12–15].

Among individuals with well-characterized acute HCV infection who eventually developed viral persistence, a notable proportion (40%) initially experienced at least one log IU/mL decline in their HCV RNA levels. This finding has clinical implications suggesting that spontaneous clearance cannot be predicted solely based on initial decline in HCV RNA levels.

Among individuals with persistent infection, IFNL3 CC genotype was independently associated with partial viral control (either a decrease or fluctuation in HCV RNA). Previous studies have demonstrated that genetic variation in the IFNL3 gene region is associated with both spontaneous and treatment-induced HCV clearance (reviewed in [4, 23]). Our findings suggest that even among individuals who develop persistent infection, IFNL3 CC genotype plays a role

in initial viral control. Some other studies also demonstrated an association between \textit{IFNL3} CC genotype and higher HCV RNA levels in acute infection, regardless of acute HCV outcome \cite{10, 39}, and also in chronic infection \cite{40–42}. Although the mechanisms and role of \textit{IFNL3} genotype in viral control and outcome of HCV infection are not fully understood, there is evidence that \textit{IFNL3} regulates the interferon stimulated genes (ISGs), required for initial control of viral infection (reviewed in \cite{43}). Another study demonstrated a superior innate immune function, particularly of natural killer cells, to interferon-based therapy in individuals with \textit{IFNL3} CC genotype, resulting in improved treatment induced viral control \cite{44}. More evidence is needed to show if there is the same association between \textit{IFNL3} genotype and natural killer cells function in acute HCV infection although the existing evidence supports the essential role of natural killer cells in viral control in acute HCV through inducing T-cell responses (reviewed in \cite{45}).

Among individuals with viral control, female sex was independently associated with spontaneous clearance, consistent with the increasing literature demonstrating that females exhibit more successful responses to HCV \cite{7, 8, 15, 17, 18}. However, it is interesting that among those with any level of viral control (partial control or clearance), female sex is particularly important for determining HCV clearance outcome. Unfortunately, data on sex-based differences in immunological profiles in individuals with HCV infection are sparse. However, there is evidence of a lower rate of HCV clearance in men compared to women \cite{7, 8, 15, 17, 18} and also in postmenopausal women compared to premenopausal women \cite{46, 47} implicating female hormones, such as estrogens and progesterone, in viral control.

Female sex, \textit{IFNL3} CC genotype, HCV genotype 1, and higher peak HCV RNA levels were significantly associated with spontaneous clearance when compared to participants with viral plateau and persistence. These findings are consistent with previous data demonstrating the association of female sex \cite{7, 8, 15, 17, 18}, \textit{IFNL3} CC genotype \cite{8, 19–21}, HCV genotype 1 \cite{8, 11, 22} and peak HCV RNA levels \cite{10} with spontaneous HCV clearance following acute infection.

The current study did not show any significant association between age and the patterns of HCV RNA levels, although previous studies identified higher spontaneous clearance rate in younger individuals \cite{33}. InC$^3$ participants are generally young, given HCV transmission among PWID generally occurs in young age. However, this study may not able to explore the potential association of age with HCV RNA patterns due to a narrow age range.

While the current study is unique given the large sample size and well-defined nature of acute HCV infection, there are several limitations. Participating cohorts bring a range of data types and structures presenting issues surrounding both inconsistent measurement and biological data testing protocols (e.g. HCV RNA assays differed across cohorts with different sensitivity, specificity and lower limit of detection). It is important to note that the definition of partial viral control in this study included either a decrease or fluctuation in HCV RNA, so the HCV RNA curves for partial controllers represent the average curve. There was also heterogeneity in HCV RNA and ALT monitoring schedules across cohorts. We were not able to explore the potential association of individual genotypes with HCV RNA patterns, due to the relatively small numbers of some HCV genotypes. Individuals with well-characterised acute HCV infection were not representative of entire InC$^3$ participants given significant difference in distribution of some background characteristics between this group and the rest of InC$^3$ participants (e.g. age, ethnicity, and symptomatic acute infection).

In conclusion, this study identified factors associated with three broad patterns of HCV RNA levels during acute HCV infection. These findings have important implications for understanding the immunological and genetic features important for the control of HCV infection, and have implications for HCV vaccine research. Further research is required to better
understand the mechanisms behind the association of IFNL3 genotype on early viral control and the mechanisms explaining the sex-based immune response to HCV infection.
