Enhanced HIV-1 immunotherapy by commonly arising antibodies that target virus escape variants

Florian Klein,1 Lilian Nogueira,1 Yoshiaki Nishimura,3 Ganesh Phad,4 Anthony P. West Jr.,5 Ariel Halper-Stromberg,1 Joshua A. Horwitz,1 Anna Gazumyan,1 Cassie Liu,1 Thomas R. Eisenreich,1 Clara Lehmann,7 Gerd Fätkenheuer,7 Constance Williams,8 Masashi Shingai,3 Malcolm A. Martin,3 Pamela J. Bjorkman,3,6 Michael S. Seaman,9 Susan Zolla-Pazner,8,10 Gunilla B. Karlsson Hedestam,4 and Michel C. Nussenzweig1,2

RESULTS AND DISCUSSION
Simultaneous administration of three bNAbs (tri-mix) targeting the CD4-binding site (CD4bs;
To determine whether HIV-1 can escape from all three antibodies when they are administered sequentially, we treated HIV-1YU2-infected mice with bNAbs starting with PG16 alone, and added 3BNC117 after 14 d, and 10–1074 after 28 d (Fig. 1 A). We found a transient reduction (0.18 log10 to 0.78 log10) of the viral load shortly after each antibody was administered, followed by rapid rebound to baseline viremia (day 42; +0.14 log10 compared with day 0; Fig. 1 A). Thus, sequential antibody administration differs from co-administration of the same tri-mix in that sequential therapy fails to control viral replication.

Figure 1. Sequential treatment of HIV-1YU2-infected humanized mice with bNAbs selects for triple-escape mutants. (A) HIV-1YU2-infected mice were sequentially treated with PG16 (orange), PG16, and 3BNC117 (green) and finally with the tri-mix consisting of PG16, 3BNC117, and 10–1074 (blue) as indicated. Graph shows the log10 change in viral RNA copies in plasma plotted on the y-axis and time in days after starting treatment on the x-axis. The red line shows the mean of changes in viral load. Individual mice IDs are listed at the right. (B) gp120 envelope sequence analysis before and after 14, 28, and 42–49 d of treatment revealed the emergence of HIV-1YU2 escape variants at the respective target sites of the bNAbs (i.e., PNGS at position N160 for PG16; 280–282 and 458 for 3BNC117; PNGS at position N332 for 10–1074). Each dotted line represents an independent sequence and changes to gp120YU2 are shown in bold. Red letters and gray highlights indicate regions corresponding to known escape sites as identified in previous monotherapy experiments (Klein et al., 2012; Horwitz et al., 2013). Residues in HIV-1YU2 (top) were numbered according to HXBc2 (bottom). Presented data were obtained from five treated mice in a single experiment, and sequence information was retrieved and analyzed from at least three mice at each indicated time point.
Failure to suppress viremia with sequential tri-mix administration suggested that this form of therapy selects for viral variants that are resistant to all three antibodies (Fig. 1 A). Consistent with this idea, viral envelope sequence analysis at day 0, 14, 28, and 42–49 revealed sequential development of specific antibody-resistant HIV-1<sub>YU2</sub> escape variants (Fig. 1 B). For example, 14 d after starting PG16 therapy, all gp120 sequences analyzed carried mutations at position N160 or T162 that remove the epitope targeted by PG16 (Fig. 1 B). Sequential addition of 3BNC117 and 10–1074 selected for viral escape.

![Figure 2](image_url)

**Figure 2.** Infection of humanized mice with HIV-1<sub>YU2</sub> triple mutant (HIV-1<sub>YU2-TM2</sub>). (A) Viral loads in humanized mice infected with WT HIV-1<sub>YU2</sub> (blue) and HIV-1<sub>YU2-TM2</sub> (green) at day 34 after infection. P-value was determined using a two-sided Mann-Whitney U test. **, P < 0.001. Plot shows data of 30 infected mice of 1 representative experiment of 2 performed. (B) Graph shows viral RNA copies/ml (y-axis) versus days after infection (x-axis) for HIV-1<sub>YU2-TM2</sub>-infected humanized mice. Each black line represents a single mouse, and the red line represents the geometric mean. (C) env sequence analysis of individual mice that are shown in (B). Time of sequence analysis is indicated in days after infection. (D) Tri-mix (PG16, 3BNC117, 10–1074) therapy in mice infected with HIV-1<sub>YU2</sub> (left) and HIV-1<sub>YU2-TM2</sub> (right). Changes in viral load in Δlog<sub>10</sub> (y-axis) plotted against days after infection (x-axis) compared with baseline (day 0). Each black line represents a single mouse and the red line illustrates the mean. Treatment response in mice infected with HIV-1<sub>YU2</sub> or HIV-1<sub>YU2-TM2</sub> was analyzed in parallel in a single experiment and each group consisted of at least five individual mice (D).
variants that carry mutations in all three antibody target sites (Fig. 1 B; Klein et al., 2012; Horwitz et al., 2013). Thus, sequential triple bNAb therapy selects for HIV-1 YU2 variants that are resistant to all three bNAbs.

To determine whether tri-mix resistant HIV-1 YU2 retains infectivity we compared infection with WT HIV-1 YU2 and a variant harboring the N160K, N332K, and G458D mutation (HIV-1 YU2 TM2). 34 d after infection, HIV-1 YU2– and HIV-1 YU2 TM2–infected mice showed geometric mean viral loads of 4.2 log_{10} and 5.42 log_{10}, respectively (P = 0.0003; Fig. 2 A). Viremia was long lasting in HIV-1 YU2 TM2–infected mice (Fig. 2 B) and was more resistant to sequential tri-mix therapy in vivo without measurable loss of infectivity or impaired viral fitness in humanized mice.

To determine whether chronically SHIV AD8–infected NHPs or HIV–1–infected humans harbor antibodies that might neutralize bNAb-resistant variants, we assayed plasma/serum samples for neutralizing activity against escape variants in vitro. Plasma samples from chronically SHIV AD8–infected macaques (Shingai et al., 2012, 2013) were tested against WT SHIV AD8 and SHIV AD8 variants. The SHIV AD8 variants carried either an N332K mutation (SHIV AD8 N332K) that rendered the virus resistant to the bNAb 10–1074 and the G458D mutation (SHIV AD8 G458D) that strongly reduced (200-fold) sensitivity to the bNAb 3BNC117. In addition, we included an SHIV AD8 variant that harbored both mutations (N332K-G458D; SHIV AD8 DM). Although plasma from 16 SHIV AD8–infected macaques showed varying levels of neutralizing activity against the WT virus SHIV AD8 (Fig. 3 A; ID_{50}), a significant increase in neutralizing activity was detected for bNAb-resistant variants that carried the G458D and the double N332K-G458D mutation (Fig. 3 B). Moreover, this effect was not specific for SHIV AD8 since even more striking differences were observed for WT HIV–1 YU2 and HIV–1 YU2 triple bNAb escape mutants TM1 (N160K, N332K, and N280Y) and TM2 (N160K, N332K, and G458D; Fig. 3 A and B). Thus, macaques chronically infected with SHIV AD8 frequently carry antibodies that neutralize the bNAb escape mutants studied.

To determine whether chronically infected humans also have similar antibodies, we tested a collection of 17 serum samples from HIV–1–infected individuals. Similar to macaques, purified IgGs from infected humans showed little or no neutralization against WT HIV–1 YU2, but increased activity against HIV–1 YU2 TM1 (Fig. 4 A; mean percentage of neutralization at 100 µg/ml total IgG: 2.5 vs. 23.9; P = 0.0004, two-sided Mann-Whitney U test). Thus, most humans infected with HIV–1 carry antibodies that have demonstrable in vitro neutralizing activity against the studied bNAb-resistant variants of HIV–1 YU2.

Individuals infected with HIV–1 develop up to 60 different clones of B cells, producing antibodies that have neutralizing activity against easy to neutralize (tier–1) HIV–1 strains but have weak or no activity against more resistant tier–2 primary isolates (Zolla-Pazner, 2005; Scheid et al., 2009). To determine whether these antibodies with limited activity (tier–1 strains only; here termed tier–1 neutralizing antibodies) are active against viruses that carry bNAb escape mutations, we assayed a panel of 34 tier–1 neutralizing mAbs directed against the V2 or the V3 loop, the CD4bs, the CD4–induced site (CD4i), and gp41 (Scheid et al., 2009; Pietzsch et al., 2010; Mouquet et al., 2011). Each of these antibodies was tested against WT HIV–1 YU2 and bNAb-resistant variants of HIV–1 YU2 with mutations that naturally arose in vivo (single mutations: N160K, N332K, and N280Y; HIV–1 YU2 triple mutations: TM1–3; Fig. 4 B; Klein et al., 2012; Horwitz et al., 2013). Only one of the tier–1 neutralizing antibodies showed activity against the WT HIV–1 YU2 at a very high concentration (IC_{50} = 93 µg/ml; Fig. 4 B). In contrast, three V2 loop–, four V3 loop–, two CD4bs–, and one CD4i–directed antibodies showed activity against the HIV–1 YU2 mutant viruses with IC_{50} as low as 0.5 µg/ml (Fig. 4 B). The three V2

![Figure 3. Increased neutralizing NHP serum activity against bNAb escape variants.](Image)

(A) Table shows serum neutralization (ID_{50}) of NHPs after established infection with SHIV AD8 (days post infection [PI]) as indicated in NHP ID. Neutralizing activity was measured against SHIV AD8 WT (gray), N332K, and G458D single mutants (blue), as well as an SHIV AD8 double mutant (double; N332K and G458D, blue). NHP plasma was also tested against WT HIV–1 YU2 (gray) and HIV–1 YU2 TM1 (N160K, N332K, and N280Y, blue) and HIV–1 YU2 TM2 (TM2; N160K, N332K, G458D, blue). (B) Bars represent the mean and SEM of the respective data shown in A. Statistical analysis was performed using a Friedman test followed by Dunn multiple comparison test. Significant differences compared with WT are indicated by asterisks (*, P < 0.05; **, P < 0.001; ***, P < 0.0001). All neutralizing activities were measured in duplicate. 2364 Common anti–HIV–1 antibodies target viral escape variants | Klein et al.
To determine whether antibodies that neutralize bNAb escape variants can also be elicited by vaccination, we analyzed plasma from NHPs immunized with YU2 gp140-F trimers (Sundling et al., 2010). Although plasma samples from the vaccinated animals showed little or no neutralizing activity against HIV-1\textit{YU2} (WT), HIV-1\textit{YU2\textsuperscript{TM1}} (TM1; N160K, N332K, N280Y), HIV-1\textit{YU2\textsuperscript{TM2}} (TM2; N160K, N332K, G458D), HIV-1\textit{YU2\textsuperscript{TM3}} (TM3; N162, N332K, N279K), HIV-1\textit{YU2\textsuperscript{N160K}} (N160K), HIV-1\textit{YU2\textsuperscript{N332K}} (N332K), and HIV-1\textit{YU2\textsuperscript{N280Y}} (N280Y). The epitopes targeted by the antibodies are indicated on the left and in parentheses.

Values reflect ID\textsubscript{50} neutralization titers against HIV-1\textit{YU2} (WT), HIV-1\textit{YU2\textsuperscript{TM1}} (TM1), and HIV-1\textit{YU2\textsuperscript{TM2}} (TM2) for plasma samples from two macaques (F124, F128) before and after immunization with gp140-F (YU2). D）IC\textsubscript{50} concentrations (µg/ml) against HIV-1\textit{YU2} and HIV-1\textit{YU2\textsuperscript{mutants}} for six randomly selected V3 loop-directed mAbs obtained from gp140-F immunized macaques as described in B. Neutralization activity is color-coded and IC\textsubscript{50}-values of mAbs (B and D) are highlighted in red (<2 µg/ml), orange (2–20 µg/ml), yellow (>20 µg/ml), and white (IC\textsubscript{50} is not reached at concentration tested). ID\textsubscript{50}-titers of plasma are highlighted in red (>400), orange (200–400), yellow (50–200), and white (<50). Neutralizing activities of plasma samples, antibodies, or purified IgGs were measured in duplicate.

D）IC\textsubscript{50} concentrations (µg/ml) against HIV-1\textit{YU2} and HIV-1\textit{YU2\textsuperscript{mutants}} for six randomly selected V3 loop-directed mAbs obtained from gp140-F immunized macaques as described in B. Neutralization activity is color-coded and IC\textsubscript{50}-values of mAbs (B and D) are highlighted in red (<2 µg/ml), orange (2–20 µg/ml), yellow (>20 µg/ml), and white (IC\textsubscript{50} is not reached at concentration tested). ID\textsubscript{50}-titers of plasma are highlighted in red (>400), orange (200–400), yellow (50–200), and white (<50). Neutralizing activities of plasma samples, antibodies, or purified IgGs were measured in duplicate.
in neutralizing activity against the HIV-1<sub>YU2</sub> triple mutants (HIV-1<sub>YU2-TM1</sub>, HIV-1<sub>YU2-TM2</sub>; Fig. 4 C). To determine whether macaque antibodies recognizing the V3 loop might account for this activity, we tested 6 different anti-V3 mAbs isolated from these immunized macaques against WT HIV-1<sub>YU2</sub>, HIV-1<sub>YU2-N280Y</sub>, HIV-1<sub>YU2-N160K</sub>, HIV-1<sub>YU2-N332K</sub>, and two HIV-1<sub>YU2-TM</sub> (Fig. 4 D). 2 of the 6 antibodies had low levels of activity against HIV-1<sub>YU2</sub> (WT; IC<sub>50</sub> of 33.8 and 49.6 µg/ml), whereas the other four did not reach an IC<sub>50</sub> when measured up to a concentration of 50 µg/ml. In contrast, 5 out of these 6 V3 loop-directed antibodies showed activity against the HIV-1<sub>YU2</sub> single mutants. Moreover, neutralization activity was strongly increased against both HIV-1<sub>YU2-TM</sub> as reflected by IC<sub>50</sub> in the range of 1 µg/ml (Fig. 4 D). Thus, although tier-1 neutralizing human and macaque anti–HIV-1 antibodies do not neutralize WT HIV-1<sub>YU2</sub>, they are active against bNAb escape variants in TZM-bl assays in vitro.

Of the tested human tier-1 neutralizing antibodies, 10–188 and 1–79 demonstrated the best neutralizing activity against the triple mutated HIV-1<sub>YU2</sub> (Fig. 4 B). Both antibodies recognize the crown of the V3 loop. Notably, 10–188 and 1–79 bind to different regions of the V3 loop: 1–79 targets the hydrophobic V3 core at aa 307, 309, and 317 (CRA-DLE-type; Burke et al., 2009; Almond et al., 2010; Jiang et al., 2010; and unpublished data) and 10–188 targets the V3 β-turn at aa 312–314 (LADLE-type; Burke et al., 2009). To determine, whether similar antibodies are present in NHPs chronically infected with SHIV<sub>AΔK</sub>, we measured reactivity of plasma samples against selected peptides by ELISA (Fig. 5; Totrov et al., 2010). All tested NHP sera showed activity against both peptides, demonstrating the presence of CRA-DLE- and LADLE-type antibodies in SHIV<sub>AΔK</sub>-infected NHPs (Fig. 5).

To examine the possibility that HIV-1–directed tier-1 neutralizing antibodies can actively suppress viremia in vivo, we infected humanized mice with HIV-1<sub>YU2</sub> (WT) or with HIV-1<sub>YU2-TM2</sub>. Infected mice were treated with either of the tier-1 neutralizing human V3 loop–directed antibodies 10–188 or 1–79. Although only a small effect on the viral load was detected in HIV-1<sub>YU2</sub>-infected mice (Fig. 6 A, left), a reduction in viremia was observed in mice infected with the mutant virus HIV-1<sub>YU2-TM2</sub> (Fig. 6 A, middle and right). We conclude that the tier-1 neutralizing anti-V3 loop antibodies 10–188 and 1–79 do not alter the viral load in HIV-1<sub>YU2</sub>-infected mice, but can suppress HIV-1<sub>YU2-TM2</sub> infection in vivo.

To determine whether 10–188 and 1–79 exerted selective pressure on HIV-1<sub>YU2</sub> and/or HIV-1<sub>YU2-TM2</sub>, we cloned and sequenced cDNA encoding gp120 from HIV-1<sub>YU2</sub>– and HIV-1<sub>YU2-TM2</sub>–infected mice treated with these antibodies. Although 10–188 showed little activity against HIV-1<sub>YU2</sub> in vitro (IC<sub>50</sub> 93 µg/ml) and had no measurable effect on the viral load in HIV-1<sub>YU2</sub>–infected mice, 2 out of the 4 mice showed mutations in the β-turn of the V3 loop, which is the epitope targeted by 10–188 (Zolla-Pazner and Cardozo, 2010; Mouquet et al., 2011; Fig. 6 B, top). In addition, all gp120 sequences analyzed from HIV-1<sub>YU2-TM2</sub>–infected mice (2 animals) carried mutations in the same region (Fig. 6 B, bottom). In the case of HIV-1<sub>YU2</sub>–infected mice treated with 1–79, we also detected mutations in the V3 crown in some but not all of the sequences in the 3 animals we analyzed, indicating incomplete selection (Fig. 6 C). In contrast, all sequences obtained from HIV-1<sub>YU2-TM2</sub>–infected mice treated with 1–79 harbored the same K305R mutation (Fig. 6 C).

HIV-1<sub>YU2-TM2</sub> is an engineered virus that carries bNAb escape mutations that naturally occurred in mice treated with single antibodies (Klein et al., 2012; Horwitz et al., 2013). However, it is not a naturally arising strain that might also contain compensatory mutations as part of a heterogeneous swarm. To determine whether combination immunotherapy with a bNAb and a tier-1 neutralizing antibody can delay or suppress emergence of resistant HIV-1 variants during an established infection with a naturally arising strain, we infected humanized mice with HIV-1<sub>YU2</sub> (WT) and treated them with the bNAb 10–1074 alone (Fig. 7 A) or in combination with one of the tier-1 neutralizing antibodies 10–188 (Fig. 7 B) or 1–79 (Fig. 7 C). Notably, the humanized mice used in our experiments are unable to make a significant humoral immune response to the HIV-1 envelope, and therefore lack any autologous neutralizing antibodies (Baenziger et al., 2006; Klein et al., 2012; Horwitz et al., 2013).

---

**Table 1.** Presence of V3-specific antibodies in plasma of SHIV<sub>Δen</sub>-infected NHPs. Values reflect OD<sub>405</sub> measurements (values >0.3 were considered positive). PI, post infection (days); mAbs were measured at 10 µg/ml. Plasma samples were measured at a titer of 1:100. ID<sub>50</sub> titers of plasma are highlighted in red (>2.5), orange (1–2.5), and yellow (0.3–1).

Figure 5. Presence of V3-specific antibodies in plasma of SHIV<sub>Δen</sub>-infected NHPs. Values reflect OD<sub>405</sub> measurements (values >0.3 were considered positive). PI, post infection (days); mAbs were measured at 10 µg/ml. Plasma samples were measured at a titer of 1:100. ID<sub>50</sub> titers of plasma are highlighted in red (>2.5), orange (1–2.5), and yellow (0.3–1).
Figure 6. Suppression of HIV-1<sub>YU2</sub><sup>TM2</sup> but not HIV-1<sub>YU2</sub> viremia by V3-loop antibodies 10–188 and 1–79. (A, left and middle) Graphs show changes in viral load in response to 10–188 or 1–79 treatment in Δlog<sub>10</sub> (y-axis) plotted against days after infection (x-axis) compared with baseline (day 0) for mice infected with HIV-1<sub>YU2</sub> or HIV-1<sub>YU2</sub><sup>TM2</sup>. Each black line represents a single mouse, and the red line illustrates the mean. Blue colored symbols indicate a viral load measurement below 200 copies/ml. (A, right) Statistical analysis to determine group differences between HIV-1<sub>YU2</sub> (green) and HIV-1<sub>YU2</sub><sup>TM2</sup> (orange) using repeated measures ANOVA; 10–188, P = 0.003; 1–79, P = 0.032. (B and, C) gp120 sequences obtained from HIV-1<sub>YU2</sub>- or HIV-1<sub>YU2</sub><sup>TM2</sup>-infected mice treated with 10–188 (B) or 1–79 (C) between days 14 and 28. Residues in HIV-1<sub>YU2</sub> (top) were numbered according to HXBc2 (bottom). Treatment response of 10–188 and 1–79 in mice infected with HIV-1<sub>YU2</sub> or HIV-1<sub>YU2</sub><sup>TM2</sup> was analyzed in a single experiment in which each group consisted of at least four individual mice and sequence data were obtained from at least two mice per group.
Common anti–HIV-1 antibodies target viral escape variants | Klein et al.

Most individuals infected with HIV-1 develop antibodies that neutralize autologous but not primary heterologous viral strains (Doria-Rose et al., 2009; Simek et al., 2009). As a result of the rapid rate of viral evolution in the host, the effect of these antibodies on effectively controlling viremia is limited (Schmitz et al., 2003; Miller et al., 2007; Gaufin et al., 2009a,b; Huang et al., 2010). Nevertheless, these antibodies put selective pressure on HIV-1 as indicated by the emergence of antibody-resistant escape variants (Wei et al., 2003). Escape from tier-1 neutralizing antibodies frequently involves changes that indirectly conceal the epitope (Ly and Stamatatos, 2000; Wei et al., 2003; Pinter et al., 2004; Blish et al., 2008; Bunnik et al., 2008; et al., 2012). In contrast to monotherapy with any of the three antibodies alone (Figs. 6A and 7A), both combinations produced a prolonged and sustained drop in viremia (Fig. 7, B–D). Moreover, the combination of 10–1074 and 1–79 continued to suppress viremia below the limit of detection, with no viral escape during 6 wk of therapy (Fig. 7 C). Escape from 10–1074 monotherapy was associated with N332K/S in 6 out of 6 mice analyzed (Fig. 7 E). When rebound occurred with the combination of 10–1074 and 10–188, it was associated with selection of mutations in both the 10–1074 and 10–188 target sites at position 332 and the β-turn of the V3 crown (position 312–315), respectively (Fig. 7 F).

We conclude that tier-1 neutralizing antibodies with little demonstrable activity against primary isolates in vitro can make significant contributions to control HIV-1 infection when combined with potent bNAbs in vivo.
Serum samples from HIV-1–infected individuals were collected under informed consent and in accordance with institutional guidelines of the Swedish Board of Agriculture. Isolation of mAbs from NHPs was performed essentially as previously described (Sundling et al., 2012a) but by sorting for total Env–specific memory B cells and using optimized primers for amplification of NHP VDJ sequences (Sundling et al., 2012b). For antibody expression, equal amounts of heavy- and light-chain plasmid DNAs were transfected into Freestyle 293F cells and the secreted IgGs were purified by protein A–Sepharose columns (GE Healthcare). The specificities of these V3 loop–directed antibodies were determined by ELISA binding analyses using a set of different YU2 Env probes.

**Humanized mice.** NOD.Rag1<sup>−/−</sup> IL2R<sup>γc</sup>KO<sup>U2</sup> mice were humanized with hematopoietic stem cells (HSCs), as previously described (Klein et al., 2012). In brief, human fetal livers were procured from Advanced Bioscience Resources, Inc. and HSCs were isolated using a CD34<sup>+</sup> isolation kit (Stem Cell Technologies, Inc.). Mice (NOD.Cg-Rag1<sup>−/−</sup>Il2rg<sup>−/−</sup>Il2r<sup>γc</sup>Mtm1Bkk/Sg) were obtained from The Jackson Laboratory and bred and maintained at the Comparative Bioscience Center of The Rockefeller University. Between 1–5-d-old mice were irradiated with 100 cGy and injected with 2 × 10<sup>6</sup> human HSCs. HSCs used to reconstitute the mice were obtained from human fetal liver tissues of 12 different donors. In the experiments shown, up to 12 humanized mice shared the same donor. Engraftment was evaluated by FACS analysis of the peripheral blood as previously described (Klein et al., 2012) and mice with successful reconstitution of human lymphocytes were challenged with HIV-1<sub>YU2</sub> or HIV-1<sub>TM2</sub>. All experiments were performed under approval of the Institutional Review Board and the Institutional Animal Care and Use Committee of The Rockefeller University.

**HIV-1 infection.** HIV-1<sub>VU2</sub> and HIV-1<sub>TM2</sub> were produced by transient transfecting HEK 293T/17 cells using a construct consisting of HIV-1<sub>NL4-3</sub> backbone carrying the HIV-1<sub>VU2</sub> envelope (Zhang et al., 2002). HIV-1<sub>TM2</sub> harbors the mutations N160K, N332K, and G458D that were introduced by site-directed mutagenesis using the QuikChange Site-Directed Mutagenesis kit (Agilent Technologies). The concentration of the virus was determined by measuring p24 using the Alliance HIV-1 p24 Antigen ELISA kit (Perkin-Elmer). Humanized mice were infected by intraperitoneal injection of HIV-1<sub>VU2</sub> or HIV-1<sub>TM2</sub> viral supernatant containing 110 ng of p24.

**Production and administration of mAbs.** For mouse treatment experiments we used the following mAbs: PG16 (V1/V2; Weller et al., 2009), 10–1074 (V3-stem; Mouquet et al., 2012), 2BNC117 (CD4bs; Scheid et al., 2011), 10–188 (V3-crown; Mouquet et al., 2011), and 1–79 (V3-crown; Scheid et al., 2009). With the exception of 3BNC117, all antibodies were produced by transiently transfected HEK 293–6E cells with equal amounts of immunoglobulin heavy and light chain expression vectors. After 7 d, the supernatant was harvested and antibodies were concentrated by ammonium sulfate precipitation. IgG was purified with Protein G–Sepharose 4 Fast Flow (GE Healthcare). Sterile filtration and buffer exchange to PBS was performed for all IgGs before testing for neutralizing activity.

**Materials and Methods.**

*Human samples.* Serum samples from HIV-1–infected individuals were collected under informed consent and in accordance with institutional guidelines of the Swedish Board of Agriculture. All experiments were performed according to NIAID animal protocol LMM32, approved by the Institutional Animal Care and Use Committees of NIAID/NIH. The animals used for immunizations were housed at the AAALAC-accredited Astrid Fagraeus Laboratory animal facility in Stockholm in compliance with the guidelines of the Swedish Board of Agriculture. Isolation of mAbs from NHPs was performed essentially as previously described (Sundling et al., 2012a) but by sorting for total Env–specific memory B cells and using optimized primers for amplification of NHP VDJ sequences (Sundling et al., 2012b). For antibody expression, equal amounts of heavy- and light-chain plasmid DNAs were transfected into Freestyle 293F cells and the secreted IgGs were purified by protein A–Sepharose columns (GE Healthcare). The specificities of these V3 loop–directed antibodies were determined by ELISA binding analyses using a set of different YU2 Env probes.

**Humanized mice.** NOD.Rag1<sup>−/−</sup> IL2R<sup>γc</sup>KO<sup>U2</sup> mice were humanized with hematopoietic stem cells (HSCs), as previously described (Klein et al., 2012). In brief, human fetal livers were procured from Advanced Bioscience Resources, Inc. and HSCs were isolated using a CD34<sup>+</sup> isolation kit (Stem Cell Technologies, Inc.). Mice (NOD.Cg-Rag1<sup>−/−</sup>Il2rg<sup>−/−</sup>Il2r<sup>γc</sup>Mtm1Bkk/Sg) were obtained from The Jackson Laboratory and bred and maintained at the Comparative Bioscience Center of The Rockefeller University. Between 1–5-d-old mice were irradiated with 100 cGy and injected with 2 × 10<sup>6</sup> human HSCs. HSCs used to reconstitute the mice were obtained from human fetal liver tissues of 12 different donors. In the experiments shown, up to 12 humanized mice shared the same donor. Engraftment was evaluated by FACS analysis of the peripheral blood as previously described (Klein et al., 2012) and mice with successful reconstitution of human lymphocytes were challenged with HIV-1<sub>VU2</sub> or HIV-1<sub>TM2</sub>. All experiments were performed under approval of the Institutional Review Board and the Institutional Animal Care and Use Committee of The Rockefeller University.

**HIV-1 infection.** HIV-1<sub>VU2</sub> and HIV-1<sub>TM2</sub> were produced by transient transfecting HEK 293T/17 cells using a construct consisting of HIV-1<sub>NL4-3</sub> backbone carrying the HIV-1<sub>VU2</sub> envelope (Zhang et al., 2002). HIV-1<sub>TM2</sub> harbors the mutations N160K, N332K, and G458D that were introduced by site-directed mutagenesis using the QuikChange Site-Directed Mutagenesis kit (Agilent Technologies). The concentration of the virus was determined by measuring p24 using the Alliance HIV-1 p24 Antigen ELISA kit (Perkin-Elmer). Humanized mice were infected by intraperitoneal injection of HIV-1<sub>VU2</sub> or HIV-1<sub>TM2</sub> viral supernatant containing 110 ng of p24.

**Production and administration of mAbs.** For mouse treatment experiments we used the following mAbs: PG16 (V1/V2; Weller et al., 2009), 10–1074 (V3-stem; Mouquet et al., 2012), 2BNC117 (CD4bs; Scheid et al., 2011), 10–188 (V3-crown; Mouquet et al., 2011), and 1–79 (V3-crown; Scheid et al., 2009). With the exception of 3BNC117, all antibodies were produced by transiently transfected HEK 293–6E cells with equal amounts of immunoglobulin heavy and light chain expression vectors. After 7 d, the supernatant was harvested and antibodies were concentrated by ammonium sulfate precipitation. IgG was purified with Protein G–Sepharose 4 Fast Flow (GE Healthcare). Sterile filtration and buffer exchange to PBS was performed for all IgGs before testing for neutralizing activity.

**Nonhuman primate samples.** Plasma samples were obtained from nonhuman primates (NHPs; *Macaca mulatta*) 90–198 wk after infection with SHIV<sub>AD8</sub> (Shingai et al., 2012, 2013) or from uninfected NHPs (*Macaca mulatta*) before and after immunization with soluble YU2 gp140-F trimers (Yang et al., 2002), as previously described (Sundling et al., 2010). SHIV<sub>AD8</sub>-infected macaques were housed in biosafety level 2 National Institute of Allergy and Infectious Disease (NIAID) facility and cared for in accordance with guidelines of the American Association for Accreditation of Laboratory Animal Care (AAALAC) in AAALAC-accredited facilities. All animal procedures were performed according to NIAID animal protocol LMM32, approved by the Institutional Animal Care and Use Committees of NIAID/NIH. The animals used for immunizations were housed at the AAALAC-accredited Astrid Fagraeus Laboratory animal facility in Stockholm in compliance with the guidelines of the Swedish Board of Agriculture. Isolation of mAbs from NHPs was performed essentially as previously described (Sundling et al., 2012a) but by sorting for total Env–specific memory B cells and using optimized primers for amplification of NHP VDJ sequences (Sundling et al., 2012b). For antibody expression, equal amounts of heavy- and light-chain plasmid DNAs were transfected into Freestyle 293F cells and the secreted IgGs were purified by protein A–Sepharose columns (GE Healthcare). The specificities of these V3 loop–directed antibodies were determined by ELISA binding analyses using a set of different YU2 Env probes.

**Humanized mice.** NOD.Rag1<sup>−/−</sup> IL2R<sup>γc</sup>KO<sup>U2</sup> mice were humanized with hematopoietic stem cells (HSCs), as previously described (Klein et al., 2012). In brief, human fetal livers were procured from Advanced Bioscience Resources, Inc. and HSCs were isolated using a CD34<sup>+</sup> isolation kit (Stem Cell Technologies, Inc.). Mice (NOD.Cg-Rag1<sup>−/−</sup>Il2rg<sup>−/−</sup>Il2r<sup>γc</sup>Mtm1Bkk/Sg) were obtained from The Jackson Laboratory and bred and maintained at the Comparative Bioscience Center of The Rockefeller University. Between 1–5-d-old mice were irradiated with 100 cGy and injected with 2 × 10<sup>6</sup> human HSCs. HSCs used to reconstitute the mice were obtained from human fetal liver tissues of 12 different donors. In the experiments shown, up to 12 humanized mice shared the same donor. Engraftment was evaluated by FACS analysis of the peripheral blood as previously described (Klein et al., 2012) and mice with successful reconstitution of human lymphocytes were challenged with HIV-1<sub>VU2</sub> or HIV-1<sub>TM2</sub>. All experiments were performed under approval of the Institutional Review Board and the Institutional Animal Care and Use Committee of The Rockefeller University.
and reverse transcribed using SuperScript III Reverse transcription (Invitrogen). For cDNA synthesis, the primer was either 5′-TAGCAATAGTTGGTGGACC-3′ and Rev_5′-ATTGTTGGCTGTTGCACCATA-3′, and for second round PCR, FW_5′-AGAAGAGCAAGACATGTCGG-3′ and Rev_5′-TACCCTGATCGTTAGG-3′. Cycling parameters in first and second PCR were 92°C, 2 min; 92°C, 20 s; 57°C, 30 s; and 68°C, 1.40 min over 35 cycles with an additional 20 s/cycle elongation time (starting after cycle 15) followed by 10 min at 68°C after the second round of PCR.

Neutralization. Neutralizing activities of NHP plasma samples, purified IgGs, and mAbs were determined in a TZM.bl neutralization assay (Li et al., 2005; Seaman et al., 2010). Mutations in HIV-1 and SHIV envelope glycoprotein sequences were produced using the QuickChange Site-Directed Mutagenesis kit (Agilent Technologies) according to the manufacturer’s instructions and used for pseudovirus production. SHIV and HIV-1 pseudo-virus mutants included the single mutations SHIVw10 (N332K), SHIVw10 (G458D), HIV-1_YU2 (N160K), HIV-1_AD8 (N332K), and HIV-1_VLX (N280K), as well as the double and triple mutations SHIVw10 (N160K, N332K), HIV-1_YU2 (N160K, N332K, N280Y), HIV-1_VLX (N160K, N332K, N280Y), and HIV-1_VLX (N160K, N332K, N279K).

Statistics. Statistical significance between IgG neutralizing activity against HIV-1_YU2 and HIV-1_YU2M (Fig. 4A), and differences in viral load between HIV-1_YU2 and HIV-1_YU2M-infected mice (Fig. 2A) was determined by performing a two-sided Mann-Whitney U test in which P < 0.05 was considered significant. Statistical analysis for comparing neutralizing activity of NHP sera against SHIV and HIV-1 variants was performed by Friedman test followed by Dunn multiple comparison. Significant differences in log_{10} viral load of mice treated with 10–1074 + 1–79, as well as HIV-1_YU2 and HIV-1_YU2M-infected mice treated with 10–188 or 1–79 were determined by using repeated measures ANOVA with a Bonferroni post-hoc test considering P < 0.05 significant. Sample size of humanized mice in antibody treatment experiments was estimated based on previous results testing single antibodies in HIV-1–infected humanized mice (Horwitz et al., 2013; Klein et al., 2012). All analyses were performed using GraphPad Prism version 5.0b for Mac OS X, GraphPad Software.

Peptide ELISA. ELISA plates (StreptaWell; Roche) were coated at 37°C for 1.5 h with 1 µg/ml biotinylated peptides (Clade B CRADLE peptide, Cyclic Biotin-RCRIHIGPGRAFYACG-OH; Clade B LADLE peptide, Cyclic Biotin-ACQAFYASSPRKSIHGACA-OH). Plates were washed 6 times with PBS containing 0.05% Tween-20, pH 7.4, and incubated for 1.5 h (37°C) with water that was diluted 1:100 in RPMI-1640 (Sigma-Aldrich) containing 15% fetal bovine serum. After washing plates (six times) alkaline phosphatase-conjugated goat anti-human IgG (1:2,000) was added for 1.5 h (37°C). Plates were washed and 10% diethanolamine substrate was added for 30 min followed by analyzing at 405 nm. All reagents were added in a volume of 100 µl/well and each sample was run in duplicate.
