(Received 13 October 2014; published 3 November 2014)

We demonstrate a method of magnetic resonance imaging with single nuclear-spin sensitivity under ambient conditions. Our method employs isolated electronic-spin quantum bits (qubits) as magnetic resonance “reporters” on the surface of high purity diamond. These spin qubits are localized with nanometer-scale uncertainty, and their quantum state is coherently manipulated and measured optically via a proximal nitrogen-vacancy color center located a few nanometers below the diamond surface. This system is then used for sensing, coherent coupling, and imaging of individual proton spins on the diamond surface with angstrom resolution. Our approach may enable direct structural imaging of complex molecules that cannot be accessed from bulk studies. It realizes a new platform for probing novel materials, monitoring chemical reactions, and manipulation of complex systems on surfaces at a quantum level.

Nuclear magnetic resonance and magnetic resonance imaging are essential tools for both the physical and life sciences [1,2], but have been limited to the detection of large ensembles of spins due to their low sensitivity [3,4], or the macroscopic nature of sensors [5,6]. Over the past decades, significant efforts [7–11] have been directed toward pushing this sensitivity to its ultimate physical limit, the detection of individual nuclear spin signals localized in a small volume. Our approach to magnetic sensing and imaging makes use of electronic spin-1/2 qubits on the surface of a high purity diamond crystal, coupled to a nearby single nitrogen vacancy (NV) color center a few nanometers below the diamond surface [Fig. 1(a)] [12]. Clean (100) diamond surfaces in ambient conditions are known to host stable electron spins with $S = \frac{1}{2}$ and a $g$ factor of 2 [13,14]. These spins have been considered to be deleterious because they are thought to cause decoherence of NV electronic spins within a few nanometers of the diamond surface [15,16]. However, with proper quantum control, the surface electron spins can be turned into a useful resource. They can be coherently manipulated and measured, thereby serving as a network of quantum “reporters” [17,18] that probe and report the local magnetic environment. The key advantage of such surface spins is their proximity to sensing targets in samples placed on or near the diamond surface. As suggested in recent theoretical work [12], surface electron spins coupled to NV centers can also effectively “amplify” small magnetic field signals, allowing for subnanometer localization of individual nuclear spins.

To measure the quantum states of surface electron reporter spins through the NV-reporter magnetic dipole interaction, the nearby shallow NV center is initialized into the $m_s = 0$ sublevel using an optical pumping laser pulse at 532 nm; the spin states of the NV center and of the reporter spins are independently manipulated using pulsed magnetic resonance sequences, and the final quantum state of the NV center is measured using its spin-state-dependent fluorescence [Fig. 1(b)]. The $m_s = 0 \leftrightarrow m_s = -1$ NV spin transition is addressed at the angular frequency $\omega_{\text{NV}} = \Delta - \gamma_e B$, and the $m_s = +1/2 \leftrightarrow m_s = -1/2$ surface reporter spin transition is driven at frequency $\omega_q = \gamma_e B$. Here, $\Delta = 2\pi \times 2.87 \text{ GHz}$ is the NV zero-field splitting, $B$ is the magnitude of the static magnetic field applied along the NV axis, and $\gamma_e = 2\pi \times 2.8 \text{ MHz/G}$ is the electron gyromagnetic ratio [Figs. 1(c) and 1(d)].

The magnetic dipole coupling between the NV center and the surface electron reporter spins is characterized using a generalized spin-echo (double electron-electron resonance or DEER) sequence, shown in Fig. 1(b). Figure 1(e) shows that for one typical shallow NV center (NVA) the measured spin-echo signal decays on a time scale $T_{2}^{\text{NV}} \approx 5 \mu s$ [Fig. 1(e)]. However, when a pulse flips the surface reporter spin population simultaneously with the NV-center pulse, the NV-reporter magnetic dipole interaction causes more rapid NV spin-echo collapse [Fig. 1(e), red circles], with a form that depends on the locations of the surface electron spins around the NV center. Because the magnetic dipole interaction is long range, the NV center can be coupled to multiple surface reporter spins, with the coupling strengths dependent on their positions on the diamond surface. When we treat the diamond with a strongly oxidizing reflux mixture of concentrated nitric, sulfuric, and perchloric acids (see the Supplemental Material [19]), and repeat the DEER experiment on the same NV center,
For the DEER signal is clearly modified [Fig. 1(e), blue triangles], suggesting that this surface treatment "resets" the positions of the electron reporter spins and confirming that they indeed reside on the diamond surface.

To determine the reporter spin positions, we repeat the DEER measurements while changing the direction of the applied magnetic field $B$. The magnetic dipole interaction between the NV center and a surface spin depends on their separation and the angle that the vector between them makes with the vector $B$. By rotating $B$, we change this angle, and thus the strength of this interaction (similar methods have been employed to localize $^{13}$C spins and other NV centers inside the diamond lattice [20,21]). By combining the results of the DEER experiments at 7 different magnetic field angles, we reconstruct the positions of 4 reporter spins, constrained to be on the diamond surface, that are nearby to NV A. The positions of these 4 reporter spins relative to NV A are shown in Fig. 1(f), where the color scale represents the reporter spin position probability density (normalized to unity), corresponding to the best-fit chi-squared statistic, performed with each reporter spin position fixed at the associated map coordinate [19]. In particular, the surface reporter spin closest to the NV center can be localized with nanometer-level uncertainty.

The DEER pulse sequence is a useful tool for characterizing the surface reporter spins on the diamond surface, but it is limited by the decoherence time of the shallow NV center $T_{2}^{(NV)}$, which is usually on the order of several microseconds. In order to manipulate and probe the reporter spins on time scales longer than $T_{2}^{(NV)}$, we implement a new “reporter pulse sequence,” shown in Fig. 2(a), inset. This protocol, inspired by Ramsey interferometry in atomic physics [22], consists of two "probe" segments, in which the NV center probes the quantum state of the reporter spin network, separated by an "evolution" segment, in which this state can be manipulated. In essence, this protocol enables the comparison of the reporter-spin quantum states before and after the evolution segment. Importantly, the duration of the evolution segment is limited by the NV center $T_{1}^{(NV)}$ time (typically milliseconds), rather than its $T_{2}^{(NV)}$, thereby extending the evolution time scale by orders of magnitude [23]. In the measurements described below, the duration of the probe segments is kept short ($\approx 0.9 \mu s$) to ensure that the NV readout signal is dominated by the coupling to the proximal (most strongly coupled) reporter spin [19].

To demonstrate coherent control of the surface reporter spins, we vary the length of the radio frequency (rf) pulse applied at the reporter spin resonance frequency, as shown in Fig. 2(a). We observe Rabi oscillations with decay time of $\approx 1 \mu s$, which is much longer than the reporter-spin Rabi period, indicating that the pulses can be used for coherent control of the reporter spins. Next, the population relaxation time $T_{1}^{(s)}$ of the surface spin network is measured by varying the delay time $t_{p}$ between the two probe segments in the pulse sequence, Fig. 2(b). The extracted value of $T_{1}^{(s)} = (29.4 \pm 2.3) \mu$s can be used to place a lower limit of $\approx 5$ nm on the mean separation between surface reporter spins: if they were closer together, their mutual magnetic dipole flip-flop interaction would give rise to a shorter population relaxation time (see the Supplemental Material [19]). Note that this observation is consistent with the reconstructed spin locations shown in Fig. 1(f).

We next use the reporter electron spins to perform measurements of the magnetic fields on the diamond surface.
surface, using the rf pulse sequence shown in Fig. 3(a). The
time-varying magnetic field at the site of a reporter spin
gives rise to a phase shift during its spin-echo precession
time $t_s$, which is converted to a change in its spin state
population, and is then detected by the NV center. By
varying the time $t_s$, we implement a frequency filter, whereby the measurement is sensitive to magnetic-field
Fourier components at angular frequencies $\omega$ on the order
of $2\pi t_s/\omega_n$, which show up as reporter spin echo collapses
at delay times $t_s = 2\pi k/\omega$, where $k = 1, 3, \ldots$ [9]. The
experimental data exhibit collapses and revivals character-
istic of a time-varying magnetic field created by nuclear
spins on the diamond surface, precessing in the applied
magnetic field $B$ with Larmor frequency $\omega_n = \gamma_n B$, where
$\gamma_n$ is the nuclear spin gyromagnetic ratio. Figure 3(a) shows
example results for a particular NV center (NV A), and the
data are consistent with the reporter spin coupled to an
oscillating magnetic field created by surface protons with
root-mean-squared amplitude of $B_p = 0.3$ G and angular
frequency of $\omega_p = 10.6$ $\mu$s$^{-1}$. In order to determine the
nature of these nuclear spins, we repeat the measurements
and analysis at several magnetic fields, and find that the
reporter spin-echo modulation frequency scales with the
applied magnetic field in agreement with the proton gyro-
magnetic ratio of $2\pi \times 4.26$ kHz/G [Fig. 3(b), blue points].

Remarkably, however, this simple scaling is not
observed at all values of the magnetic field. For example,
the data taken with NV A at the magnetic field of 619 G
show modulation at frequencies very different from the
Larmor frequency expected for the coupling of the reporter
spin with a semiclassical proton spin bath [Fig. 3(b), red
points]. This high-frequency modulation, seen in the data
plotted in Fig. 4(a), indicates the presence of coherent
dynamics between the reporter and proximal proton spins. In order to reproduce and further explore this
coherent coupling, another NV center (NV B) is studied
at a similar magnetic field. The experimental points, shown
in Fig. 4(b), again display strong modulation, crossing the
abscissa axis. This signals coherent population transfer
between the proton spin states, mediated by the interaction
with a single reporter spin, which cannot occur in the
absence of reporter-proton entanglement.

To understand these observations, we analyze the coher-
ent dynamics of a reporter electron spin interacting with
proximal proton spins on the diamond surface. The hyper-
fine interaction between them can be described by the
Hamiltonian $H = h a J_z I_z + h b J_z I_x$, where $J$ is the spin
operator of the reporter spin, $I$ is the nuclear spin operator,
and the $z$ axis is along the applied magnetic field
[19,24]. This Hamiltonian can be interpreted as an effective
hyperfine field, created by the reporter spin at the site of
the proton spin [Fig. 4(c)], which in turn gives rise to
splitting of the reporter electron spin states, $\omega^\pm = \sqrt{(\pm a/2 - \omega_n)^2 + b^2/4}$, as shown in Fig. 4(d). This level
splitting causes reporter spin-echo modulation at frequen-
cies $\omega^+$ and $\omega^-$, with the modulation depth scaling as
$2b\omega_n/|\omega^+\omega^-|$ [24]. When the proton Larmor frequency $\omega_n$
is close to half of the hyperfine interaction strength, the reporter spin-echo signal is strongly modulated at \( \omega^+ \) and \( \omega^- \), whereas the signal modulation decreases when \( \omega_n \) is substantially different from \( a, b \). Data taken at such off-resonance magnetic fields can, within their signal-to-noise ratio, be successfully described with a semiclassical nuclear spin bath model [19].

To analyze the experimental data quantitatively, we compare our measurements with a model that includes coherent hyperfine coupling of a reporter electron spin with a proximal proton, as well as the semiclassical spin bath of protons on the diamond surface [19]. For NV A, the fit to the experimental data shown in Fig. 4(a) yields spin echo modulation frequencies of \( \omega^+ = 30 \) and \( \omega^- = 59 \, \mu s^{-1} \), shown as red squares in Fig. 3(b), from which we extract hyperfine coupling parameters \( a = (66 \pm 18) \) and \( b = (52 \pm 20) \, \mu s^{-1} \). Both the magnetic dipole interaction and the contact hyperfine interaction contribute to the parameters \( a \) and \( b \): \( a = a_0 + (h_\gamma \gamma n/\mathcal{N}_n^3)(1 - 3\cos^2 \theta_n) \), and \( b = (h_\gamma \gamma n/\mathcal{N}_n^3)(3 \cos \theta_n \sin \theta_n) \), where \( a_0 \) is the contact hyperfine interaction, \( r_n \) is the separation between the reporter spin and the proton spin, \( \theta_n \) is the angle that the vector between them makes with the applied magnetic field [19]. The low chemical reactivity of the reporter spins (see discussion below) suggests that direct overlap between the reporter spin wave function and a surface proton is likely minimal, implying that the magnitude of \( a_0 \) is small. If we neglect \( a_0 \), the position of the proximal proton with respect to the reporter spin most strongly coupled to NV A is \( r_n^0 = (2.2 \pm 0.2) \, \AA \) and \( \theta_n^0 = (26 \pm 15)^\circ \), with the azimuthal angle not quantified by the data. The data for NV B [Fig. 4(b)] are consistent with the presence of two proximal protons, coherently coupled to the reporter spin: their best-fit positions are \( r_n^{(1)} = (2.6 \pm 0.2) \, \AA, \theta_n^{(1)} = (47 \pm 3)^\circ \), and \( r_n^{(2)} = (3.2 \pm 0.2) \, \AA, \theta_n^{(2)} = (19 \pm 4)^\circ \), as shown in Fig. 4(e) in a probability density map. In order to quantify the uncertainty in the proton positions due to our lack of information about the magnitude of the contact interaction, we use 40 \( \mu s^{-1} \) as the range of possible values for \( a_0 \), since this is the measured contact hyperfine interaction with the OH-group proton in a hydroxylated carbon-centered radical [25], similar to our presumed bonding configuration (see below). For this range of \( a_0 \), the locations of the detected protons are constrained to be within the contours shown in Fig. 4(e). We note that in diamond \( a_0 \) is likely to be much smaller due to positive electron affinity of the oxidized diamond surface.

While the origin of the reporter spins cannot be unambiguously determined from this study alone, they are likely unsaturated (or “dangling”) bonds, localized near the top two carbon atom layers. We observe that they are stable in ambient conditions over time scales of many days, which indicates that they are sterically protected from direct chemical reactions with species outside the diamond lattice. Nevertheless, the reporter spins are close to the surface, since they experience strong hyperfine coupling with surface protons, and their positions change when exposed to the strongly oxidizing 3-acid mixture (this surface treatment also modifies the results of the reporter echo experiments; see the Supplemental Material [19]). Moreover, they are absent from the diamond surface (no DEER signals) after the diamond is annealed at 465 °C in an O\(_2\) atmosphere [19,26]. The detected protons are likely from covalently bound hydroxyl (OH) or carboxyl (COOH) groups terminating the clean diamond surface under ambient conditions [27]. Their relative locations are consistent with density-functional-theory calculations of these groups on an oxidized diamond surface [28].

NV centers in diamond have emerged as a nanoscale magnetic-field sensor with exquisite sensitivity under ambient conditions [9,29,30], enabling magnetic sensing and imaging of single electron spins [31–33] and nanoscale ensembles of nuclear spins [10,11,34,35]. Our method extends these recent advances into a new domain, enabling magnetic resonance and magnetic resonance imaging of individual reporter spins. This capability extends these recent advances into a new domain, enabling magnetic resonance detection and imaging on surfaces with single nuclear spin resolution. Several paths towards further improving the sensitivity and the broad applicability of our approach should be noted. It may be possible to extend the electron reporter spin coherence times using decoupling pulse sequences, together with dilution of the proton magnetic moments on the diamond surface, e.g., by deuteration. Individual addressing of the reporter spins may be achievable with a careful choice of the duration of the reporter pulse sequence readout intervals, as described above, or via frequency separation of different reporter qubits using a practical magnetic field gradient (less than 1 G/nm) [14]. Polarization transfer from the NV center to the reporter spins [36], and possibly to strongly coupled surface nuclear spins, may allow initialization and entanglement of the surface spin network [37] and hyperpolarization of target nuclei. The hyperfine field gradient, produced by the reporter spins, may also be used to encode spatial information for magnetic imaging. Finally, other reporter spin candidates, such as stable nitroxide radicals, can be explored, possibly providing a more flexible route for sensing applications because they can be directly attached to a reactive site of interest on a molecule under study.

Our approach, with improvements in the coherence properties and robust control of the reporter spins, can enable a number of unique applications. Nuclear magnetic resonance and magnetic resonance imaging of individual molecules and proteins under ambient conditions is one direction that can be pursued. Reporter-based sensing may also find applications in measurements of magnetic fields near complex materials, such as superconductors and topological insulators. Beyond applications in sensing and imaging, our approach provides a powerful new platform for coherent manipulation of coupled electronic and nuclear spins on surfaces or in 2D materials, which can be used to realize and explore new classes of self-assembled quantum systems [38].
