Abstract

We analyze a candidate theory for the strange metal near optimal hole-doping in the cuprate superconductors. The theory contains a quantum phase transition between metals with large and small Fermi surfaces, but the transition does not directly involve any broken global symmetries. The two metals have emergent SU(2) and U(1) gauge fields respectively, and the transition is driven by the condensation of a real Higgs field, carrying a finite lattice momentum and an adjoint SU(2) gauge charge. This Higgs field measures the local antiferromagnetic correlations in a ‘rotating reference frame’. We propose a global phase diagram around this Higgs transition, and describe its relationship to a variety of recent experiments on the cuprate superconductors.
I. INTRODUCTION

Several recent experiments [1–4] have provided strong evidence for a dramatic change in the nature of the low temperature electronic state of the hole-doped cuprate superconductors near optimal doping \((x = x_c)\). Moreover, zero field photoemission experiments carried out in the normal state have seen evidence for a ‘large’ Fermi-surface for \(x > x_c\), consistent with the overall Luttinger count [5, 6], and disconnected Fermi ‘arcs’ near the nodal regions for \(x < x_c\) [7]. At high fields, quantum oscillations also reveal a ‘large’ Fermi-surface for \(x > x_c\) [8], but a closed electron-like Fermi-surface with an area that constitutes a small fraction of the entire Brillouin-zone for \(x < x_c\) [9]. It is therefore quite natural to associate the transition with decreasing \(x\) at \(x = x_c\) with the loss of a ‘large’ Fermi-surface and the simultaneous opening of a pseudogap. There has also been significant experimental progress [10–18] in understanding the structure of the density-wave ordering at lower doping, which is likely responsible for the reconstructed electron-like Fermi-surface seen in quantum oscillation experiments [19, 20].

In this paper we will use these advances to motivate and develop a previously proposed model [21] for the physics of the strange metal near optimal doping. We argue that the rich phenomenology observed in the underdoped cuprates is primarily driven by a transition between metals with large and small Fermi surfaces which does not directly involve any broken global symmetry. All states with broken symmetry\(^1\) observed at low temperatures and low doping are not part of the critical field theory [22, 23], but are derived as low energy instabilities of the parent small Fermi surface phase. This diminished role for broken symmetries is consistent with absence of any observed order with a significant correlation length at higher temperatures. We will also construct a global phase diagram to describe the many phases and crossovers around the strange metal.

A quantum phase transition which does not involve broken symmetries is necessarily associated with a topological change in the character of the ground state wavefunction. Emergent gauge fields are a powerful method of describing this topological structure, and they remain applicable also to the gapless metallic phases of interest to us here. Given the fundamental connection between emergent gauge fields and the size of the Fermi surface, which was established in Ref. 24 using Oshikawa’s method [25], we are naturally led to a quantum phase transition in which there is a change in the structure of the deconfined gauge excitations. Indeed, this describes a Higgs transition in a metal, such as that discussed in Ref. 21. This argument is a general motivation

\(^1\) We shall ignore the subtleties associated with the presence of quenched disorder, except when it acts as a source of momentum decay for DC transport, as discussed later.
for Higgs criticality near optimal doping in the cuprates, which applies beyond the specific model considered here.

We emphasize that we are using the traditional particle-physics terminology in which a “Higgs transition” describes the breaking of a local gauge invariance. We are not referring to the longitudinal mode of a broken global symmetry, which has also been labeled “Higgs” in condensed matter contexts [26].

The primary new motivation for the model of Ref. 21 arises from our recent work [27] analyzing the d-form factor density waves observed in scanning tunnelling microscopy [16] and X-ray experiments [17]. In this work [27], we argued that such density waves arise most naturally as an instability of a metallic higher temperature pseudogap state with small Fermi surfaces described as a [28, 29] ‘fractionalized Fermi liquid’ (FL*); other works with related ideas on the pseudogap are Refs. 30–36. Specifically, we used a theory of the FL* involving a background U(1) spin liquid with bosonic spinons [37–40]; it is therefore convenient to dub this metallic state for the pseudogap as2 a U(1)-FL*. These results are also easily extended to a Z2 spin liquid, and we will consider this case in Appendix A. The presence of a small Fermi surface without symmetry breaking requires topological order and emergent gauge fields [24], and so also a Higgs transition to the large Fermi surfaces at larger doping; here we provide a natural embedding of a FL* theory into such a transition, and we expect similar approaches are possible for other possible topological orders in the underdoped regime.

We now consider the evolution of the U(1)-FL*, and its small pocket Fermi surfaces, to the ‘large’ Fermi surface Fermi liquid state at large doping. There is an existing conventional theory of the transformation from small to large Fermi surfaces driven by the disappearance of antiferromagnetic order. This is a transition between two Fermi liquids, and the vicinity of the transition is described by the Hertz-Millis theory [41, 42] and its field-theoretic extensions [43–46], as shown in Fig. 1. Here, we describe a detour from this direct route [21] in which two new non-Fermi liquid phases appear between the conventional phases of Hertz-Millis theory. The detour is described by a SU(2) gauge theory, and the the transition from small to large Fermi surfaces is now a Higgs transition without any local order parameter, in which the emergent gauge structure describing the topological order in the ground state changes from U(1) to SU(2). The Higgs field of this transition is a measure of the local antiferromagnetic correlations in a rotating reference frame to

2 However the Fermi surface excitations in this FL* phase carry the same quantum numbers as the electron, and do not couple minimally to the emergent (deconfined) gauge-fields.
FIG. 1: Sketch of the metallic phases of our theory. Only phase A has a broken global symmetry, associated with the presence of long-range antiferromagnetic (AFM) order. The conventional Fermi liquid phases at the top have a transition from small to large Fermi surfaces accompanied by the loss of AFM order. The dashed arrow represents a direct route between these phases, which could be a description of the electron-doped cuprates. The full arrow around the point M is our proposed route with increasing doping in the hole-doped cuprates. The U(1)-FL* descends from the U(1) ACL, as shown in Fig. 2.

be introduced below in Eq. (1). We will present details of this theory starting from a microscopic model in Section III, but first, in Section II, we shall describe some key aspects using our proposed phase diagram in Fig. 2.

Although the Higgs field plays a central role in our phase diagram, its direct experimental detection will be difficult. It is overdamped via its coupling to the Fermi surfaces, and gauge invariance prohibits any experimental probe from coupling linearly to it. Nevertheless, we will see below that it has significant experimental consequences via its strong effect on the fermionic spectrum.
FIG. 2: Our proposed phase diagram for the hole-doped cuprates, building on a theory for Higgs criticality for the optimal doping QCP. The green and red lines correspond to those in Fig. 1. The algebraic charge liquids (ACLs) have Fermi surfaces of spinless $\psi$ fermions which carry the electromagnetic charge: in the SU(2) ACL the Fermi surface is ‘large’ and is coupled to an emergent SU(2) gauge field, while in the U(1) ACL the Fermi surface is ‘small’ and coupled to an emergent U(1) gauge field. The fractionalized Fermi liquid (FL*) descends from the U(1) ACL by the binding of $\psi$ fermions to neutral spinons. The $d$-BDW is the $d$-form factor bond density wave, the SC is the $d$-wave superconductor, and the FL is the large Fermi surface Fermi liquid. We are not concerned here with the physics of the extremely underdoped region. Also, we expect that the crossovers within the superconducting phase will exhibit a ‘back-bending’ [3, 47, 48] which is not shown above, and which we do not discuss further here.

II. OVERVIEW

Let us begin with a simplified picture of the optimal doping strange metal with a large Fermi surface. We consider a model of electrons $c_{\alpha i}$ on the sites $i$ of a square lattice, with $\alpha = \uparrow, \downarrow$ a SU(2) spin index. We transform the electrons to a rotating reference frame$^3$ using a SU(2) rotation $R_i$

---

$^3$ This allows us to describe phases without long-range antiferromagnetic order.
and (spinless-)fermions $\psi_{i,p}$ with $p = \pm$,
\[
\begin{pmatrix}
    c_{i+} \\
    c_{i-}
\end{pmatrix}
= R_i 
\begin{pmatrix}
    \psi_{i,+} \\
    \psi_{i,-}
\end{pmatrix},
\]
(1)

where $R_i\dagger R_i = R_i R_i\dagger = 1$. Note that this representation immediately introduces a SU(2) gauge invariance (distinct from the global SU(2) spin rotation)
\[
\begin{pmatrix}
    \psi_{i,+} \\
    \psi_{i,-}
\end{pmatrix}
\rightarrow U_i 
\begin{pmatrix}
    \psi_{i,+} \\
    \psi_{i,-}
\end{pmatrix}, \quad R_i \rightarrow R_i U_i\dagger,
\]
(2)

under which the original electronic operators remain invariant, $c_{i\alpha} \rightarrow c_{i\alpha}$; here $U_i$ is a SU(2) gauge-transformation acting on the $p = \pm$ index. So the $\psi_p$ fermions are SU(2) gauge fundamentals, they carry the physical electromagnetic global U(1) charge, but they do not carry the SU(2) spin of the electron. The density of the $\psi_p$ is the same as that of the electrons. Such a rotating reference frame perspective was used in the early work by Shraiman and Siggia on lightly-doped antiferromagnets [49, 50], and the importance of its gauge structure was clarified in Ref. 21.

The strange metal is obtained by forming a large Fermi surface state of the $\psi_p$ fermions, while $R_i$ fluctuate isotropically over all SU(2) rotations with a moderate correlation length. This description suggests a simple trial wavefunction for this strange metal. Begin with a large Fermi surface (LFS) state of free $\psi_p$ fermions:
\[
\prod_{k \text{ inside LFS, } p = \pm} \psi_p\dagger(k) |0\rangle.
\]
(3)

Expand this out in position space, insert the inverse of Eq. (1) to write the wavefunction in terms of $R$ and the physical electrons $c_\alpha$, and finally average over $R$, to obtain
\[
\int \prod_i dR_i \ W[[R_j]] \prod_{k \text{ inside LFS, } p = \pm} \left[ \sum_i e^{ik\cdot r_i} R_{i\alpha p} c_{i\alpha}\dagger \right] |0\rangle,
\]
(4)

where $W$ is a variational weight-function of the $R_i$, invariant under global spin rotations. For $W = 1$, we have a zero correlation length for $R_i$, and we obtain a wavefunction for the $c_\alpha$ involving only empty and doubly-occupied sites. With non-trivial $W$, the correlation length of $R$ increases, we also build in spin singlet pairs of $c_\alpha$ electrons on nearby sites. Comparing to the Gutzwiller-projected trial states commonly used for the underdoped cuprates [51], this wavefunction includes the possibility of doubly-occupied sites and assigns different complex weights to the off-site singlet pairs.

For a more precise and complete description of the strange metal, which accounts for the gauge structure in Eq. (1), we must turn to a quantum effective action for the $\psi_p$ which necessarily
includes an emergent SU(2) gauge field. In the terminology of Ref. 38, such a theory of spinless, gapless fermions coupled to an emergent gauge field is an ‘algebraic charge liquid’ (ACL), and hence we have labeled the strange metal as SU(2) ACL in Fig. 2. This name implies that the SU(2) gauge symmetry is unbroken (i.e. not ‘Higgsed’), and in such a situation the $\psi_p$ fermions have a large Fermi surface with a shape similar to that of the electron Fermi surface in Fermi liquid state at large doping.

Now let us consider the transition to the U(1) ACL in Fig. 2. This is described by the condensation of a real Higgs field $H^a$, where $a = 1, 2, 3$ indicates that the Higgs field transforms as a SU(2) adjoint. As we will see below in Eq. (15), this Higgs field is a measure of the local antiferromagnetic order in the rotating reference frame defined by $R$ (see also Ref. 52 for an illuminating analogy). The condensation of the Higgs field breaks the gauge symmetry from SU(2) to U(1) and reconstructs the $\psi_p$ Fermi surface from large to small. It is this Higgs transition which describes the optimal doping QCP in Fig. 2, and analyzing its structure is the main purpose of the present paper. In the case where $H^a$ is complex, the Higgs phase can break the gauge symmetry down to $\mathbb{Z}_2$, and we consider this case in Appendix A. The Shraiman-Siggia analyses [49, 50] of doped antiferromagnets were effectively within such a Higgs-condensed regime, and this obscured the gauge structure of their formulation [21].

Let us also note from Fig. 2 that the U(1) ACL is the parent of the U(1)-FL*. This was discussed in Refs. 37, 38, and will be reviewed below: the U(1)-FL* arises by the formation of bound states between the spinons and $\psi$ fermions around the small Fermi surface.

The phase-diagram in Fig. 2 is meant to be schematic; determining the exact nature of the various crossover and phase-transition lines is beyond the scope of this work. In particular, we have assumed that the energy scales associated with the ACL/FL* and $d$–BDW vanish with the same power law as a function of $(x - x_c)$ at the QCP\(^4\). Theoretically speaking, other possibilities [53] are also allowed.

A. Field theory

We now specify the imaginary time Lagrangian of the optimal doping QCP in Fig. 2, and its vicinity. For now, the Lagrangian will not include the $R$ bosons: we assume that $R$ fluctuations are short-ranged, but the associated spin-gap in the SU(2) ACL phase of Fig. 2 is small because of

\(^4\) Corresponding to ‘case C’ in Ref. 53.
proximity to the multi-critical point M in Fig. 1; we will include the $R$ contributions in Section III. Then we have,

\[ \mathcal{L}_{\text{QCP}} = \mathcal{L}_\psi + \mathcal{L}_H + \mathcal{L}_Y. \]  

The first term describes a large Fermi surface of $\psi$ fermions minimally coupled to a SU(2) gauge field $A_i^a = (A_i^a, A^a)$:

\[ \mathcal{L}_\psi = \sum_i \psi_{i,p}^\dagger \left[ (\partial_\tau - \mu) \delta_{pp'} + i A_i^a \sigma^a_{pp'} \right] \psi_{i,p'} + \sum_{i,j} t_{ij} \psi_{i,p}^\dagger e^{i \sigma^a A^a \cdot (r_i - r_j)} \psi_{j,p'}, \] 

where $t_{ij}$ are the fermion hopping parameters, $r_i$ are the spatial co-ordinates of the sites, $\mu$ is the chemical potential, and $\sigma^a$ are Pauli matrices acting on the SU(2) gauge indices.

The Higgs Lagrangian is denoted $\mathcal{L}_H$, and it has a form familiar from its particle-physics incarnations,

\[ \mathcal{L}_H = \frac{1}{2} (\partial_\tau H^a - 2 i \varepsilon_{abc} A_i^b H^c)^2 + \frac{\tilde{v}^2}{2} (\nabla H^a - 2 i \varepsilon_{abc} A_i^b H^c)^2 + \frac{s}{2} (H^a)^2 + \frac{u}{24} [(H^a)^2]^2. \] 

The Higgs potential is determined by the parameters $s$ and $u$, and transition across the QCP is controlled by the variation in $s$. As usual, for negative $s$, the Higgs field condenses, and this breaks the gauge symmetry from SU(2) to U(1); and for positive $s$, the Higgs field is gapped, and then the SU(2) gauge symmetry remains unbroken.

Finally, we have the Yukawa coupling in $\mathcal{L}_Y$. As in particle-physics, this is a trilinear coupling between the Higgs field and the fermions, but now it has a different spatial structure:

\[ \mathcal{L}_Y = -\lambda H^a e^{i K \cdot r_i} \psi_{i,p}^\dagger \sigma^a_{pp'} \psi_{i,p'}, \] 

where $K = (\pi, \pi)$ is the antiferromagnetic wavevector. This spatial structure indicates that $H^a$ transforms non-trivially under lattice translations:

\[ H^a \rightarrow H^a e^{i K \cdot a} \text{ under translation by } a; \]

note that this is permitted because $e^{i K \cdot a} = \pm 1$ is real for all spacings $a$. The transformation in Eq. (9) arises from the role of the Higgs field as a measure of the antiferromagnetic correlations in a rotating reference frame. In the presence of the Higgs condensate, this Yukawa coupling reconstructs the $\psi$ Fermi surface from large to small, and the $e^{i K \cdot r_i}$ factor is crucial in the structure of this reconstruction. While in the particle physics context the Higgs condensate gives the fermions a mass gap, here the fermions acquire a gap only on certain portions of the large Fermi surface, and a small Fermi surface of gapless fermions remains.
We note that the effective gauge theory will also acquire a Yang-Mills term for the SU(2) gauge field $A^a$ when high energy degrees of freedom are integrated out. As is well known in theories of emergent gauge fields, such a term helps stabilize deconfined phases of the type considered here. We do not write this term out explicitly here, but will include its contributions in Section IV A, and specifically in the $L_A$ term in Eq. (21).

B. DC transport

The body of our paper will describe a field theoretic analysis of the non-Fermi liquid properties of $\mathcal{L}_{QCP}$. This combines recent progress in the theories of Fermi surfaces coupled to order parameters [43–46] and gauge fields [54–56]. Here we mention one notable result on the electrical resistivity in the quantum-critical region of the Higgs transition. As in recent work [57, 58] on other quantum critical points of metals, we consider the situation in which there is a strong momentum bottleneck i.e. there is rapid exchange of momentum between the fermionic and bosonic degrees of freedom, and the resistivity is determined by the rate of loss of momentum. In particular, it is possible for the resistivity to be dominated by the scattering of neutral bosonic degrees of freedom, rather than that of charged fermionic excitations near the Fermi surface. In our model, we argue that an important source for momentum decay is the coupling of the Higgs field to disorder

$$L_{\text{dis}} = V(\mathbf{r})[H^a(\mathbf{r})]^2,$$

where $V(\mathbf{r})$ is quenched Gaussian random variable with

$$\langle \langle V(\mathbf{r}) \rangle \rangle = 0 ; \quad \langle \langle V(\mathbf{r}) V(\mathbf{r}') \rangle \rangle = V_0^2 \delta^2(\mathbf{r} - \mathbf{r}'),$$

where the double angular brackets indicate an average over quenched disorder. Comparing with Eq. (7), we see that $V(\mathbf{r})$ can be viewed as a random local variation in the value of $s$, the tuning parameter which determines the position of the QCP. We will show that the analysis of the contribution of $L_{\text{dis}}$ to the resistivity closely parallels the computation in Ref. 58 for the spin-density-wave quantum critical point. And as in Ref. 58, we find a resistivity for weak disorder which is proportional to $V_0^2$,

$$\rho(T) \sim V_0^2 T^{2(\Delta + 1 - z)/z},$$

where $\Delta = d + z - \nu^{-1}$ is the scaling dimension of the $(H^a)^2$ operator, $\nu$ is the correlation length exponent and $z$ is the dynamical exponent. As we will see in Section IV B, this predicts a linear-in-$T$ resistivity for the leading order values of the exponents.
The outline for the rest of our paper is as follows. In Section III, we arrive at the above gauge-theoretic description starting from the theory of a metal with fluctuating antiferromagnetism and discuss the mean-field phase diagram as a function of the relevant tuning parameters. In Section IV, we describe the properties of the QCP using a low-energy description of the Fermi-surface coupled to a gauge-field and the critical fluctuations of the Higgs’ field. Finally in Section V, we discuss the relation of our proposed phase-diagram to the actual phase-diagram in the hole-doped cuprates. Appendix A contains the extension to spiral order and $\mathbb{Z}_2$ gauge theory, while technical details are in Appendix B.

### III. SU(2) GAUGE THEORY OF ANTIFERROMAGNETIC METALS

We summarize the derivation in Ref. 21 of the SU(2) gauge theory, starting from a model of electrons on the square lattice coupled to the fluctuations of collinear antiferromagnetism at the wavevector $K = (\pi, \pi)$. The case of collinear antiferromagnetism at other wavevectors was also considered in Ref. 21, and we treat spiral antiferromagnets at incommensurate wavevectors in Appendix A.

We begin with a model of electrons coupled to the quantum fluctuations of antiferromagnetism represented by the unit vector $n_{i\ell}$, with $\ell = x, y, z$ and $\sum_\ell n_{i\ell}^2 = 1$. The Lagrangian is given by

$$L = L_f + L_n + L_{fn},$$

$$L_f = \sum_i c_\alpha^\dagger [(\partial_\tau - \mu)\delta_{ij} - t_{ij}] c_\alpha,$$

$$L_n = \frac{1}{2g} \left[ (\partial_\tau n_{i\ell})^2 + v^2 (\nabla n_{i\ell})^2 \right],$$

$$L_{fn} = -\lambda \sum_i e^{iK\cdot r_i} n_{i\ell} \cdot c_\alpha^\dagger c_\beta,$$

In the above $g$ measures the strength of quantum fluctuations associated with the orientation of $n_{i\ell}$, $\lambda$ is an $O(1)$ spin-fermion coupling and $v$ is a characteristic spin-wave velocity.

Now we insert the parametrization in Eq. (1) into Eq. (13) and proceed to derive an effective theory for $\psi_\rho$ and $R$. The formulation of the latter theory is aided by the introduction of a SU(2) gauge connection $A_\mu^a = (A_\tau^a, A^a)$. As is familiar in many discussions of emergent gauge fields in correlated electron systems, this gauge field arises after decoupling hopping terms via an auxiliary field; here we skip these intermediate steps, and simply write down appropriate hopping terms for the $\psi_\rho$ and $R$ which are made gauge-invariant by suitable insertions of the gauge connection.

With the parameterization in Eq. (1) we notice that the coupling $L_{fn}$ in Eq. (13) maps precisely
onto the Yukawa coupling in Eq. (8) with
\[ H^a_i \sigma_{\rho\rho'} = n_{i\ell} R^a_{i\rho} \sigma_{\alpha\beta} R_{i\beta\rho'}, \] (14)
and so we define the Higgs field \( H^a_i \) by
\[ H^a_i \equiv \frac{1}{2} n_{i\ell} \text{Tr}[\sigma^\ell R_{i\alpha} \sigma^a R^\dagger_{i\alpha}] . \] (15)
This identifies \( H^a \) as the antiferromagnetic order in the rotating reference frame defined by Eq. (1).

An important property of this definition is that the field \( H^a \) is invariant under a global SU(2) spin rotation \( V \), which rotates the direction of the physical electron spin and of the antiferromagnetic order,
\[ \left( \begin{array}{c} c_i^\dagger \\ c_i \end{array} \right) \rightarrow V \left( \begin{array}{c} c_i^\dagger \\ c_i \end{array} \right), \quad R_i \rightarrow VR_i. \] (16)
Note that the SU(2) spin rotation is a left multiplication of \( R \) above, while the SU(2) gauge transformation in Eq. (2) is a right multiplication of \( R \). With these properties, Eq. (15) implies that \( H^a \) transforms as a vector under the SU(2) gauge transformation in Eq. (2).

We have now assembled all the steps taken after substituting Eq. (1) into Eq. (13). The Lagrangian of the resulting gauge theory is then obtained as
\[ \mathcal{L}_{SU(2)} = \mathcal{L}_{\text{QCP}} + \mathcal{L}_R, \] (17)
where \( \mathcal{L}_{\text{QCP}} \) was described below Eq. (5) in Section II A, and \( \mathcal{L}_R \) is the Lagrangian for \( R \). The structure of the latter is determined by the transformations of \( R \) in Eqs. (2) and Eq. (16). So we have
\[ \mathcal{L}_R = \frac{1}{2g} \text{Tr} \left[ (\partial_\tau R - i A^a_\tau R \sigma^a)(\partial_\tau R^\dagger + i A^a_\tau \sigma^a R^\dagger) + v^2 (\nabla R - i A^a R \sigma^a)(\nabla R^\dagger + i A^a \sigma^a R^\dagger) \right]. \] (18)
This completes our derivation of the SU(2) gauge theory.

It is useful here to collect the transformations of the fields under the SU(2) gauge transformation, the global SU(2) spin rotation, and electromagnetic U(1) charge, as summarized in table I.

Finally, we can make contact with other approaches by expressing \( R \) as
\[ R_i = \left( \begin{array}{cc} z_{i\uparrow} & -z_{i\downarrow}^* \\ z_{i\downarrow} & z_{i\uparrow}^* \end{array} \right), \] (19)
with \( |z_{i\uparrow}|^2 + |z_{i\downarrow}|^2 = 1 \), but this parameterization will not be useful to us. Consider the situation in the Higgs phase, where the field \( H^a \) is condensed. Then we are free to choose a gauge in which the
\begin{table}
\centering
\begin{tabular}{|c|c|c|c|}
\hline
 & SU(2)$_{\text{gauge}}$ & SU(2)$_{\text{spin}}$ & U(1)$_{\text{e.m. charge}}$ \\
\hline
$c$ & 1 & 2 & 1 \\
$n$ & 1 & 3 & 0 \\
$\psi$ & 2 & 1 & 1 \\
$H$ & 3 & 1 & 0 \\
$R$ & $\bar{2}$ & 2 & 0 \\
\hline
\end{tabular}
\caption{Summary of the transformations of the fields under the various gauge-transformations. SU(2) representations of spin $S$ are labelled by their dimension of $2S + 1$. The U(1) column contains the charge under the U(1) gauge field.}
\end{table}

Higgs condensate is $H^a = (0, 0, 1)$. In such a condensate, after inverting the relation in Eq. (15) we find

\begin{align}
\langle n_{i\ell} \rangle &= \frac{1}{2} H_{i}^{a} \text{Tr} [\sigma^\ell R_i^a \sigma^a R_i^\dagger] \\
&= z_{i\alpha}^\ell \sigma^\ell_{\alpha\beta} z_{i\beta} \quad \text{for } H^a = (0, 0, 1).
\end{align}

The last relationship is the familiar connection between the O(3) and CP$^1$ variables, but note that it holds here only within the phase where the Higgs field is condensed \textit{i.e.} in the U(1) ACL.

\subsection{Mean field phase diagram}

We now describe the phases of $\mathcal{L}_{\text{SU(2)}}$ obtained in a simple mean field theory [21] in which we allow condensates of the bosonic field $R$ and $H^a$. These phases are obtained by varying the tuning parameters $s$ and $g$, and were shown in Fig. 1; in Fig. 3, we label the phases by their condensates. The phases are:

- The Higgs phase, labelled as (A) in Figs. 1, 3, where both SU(2)$_{\text{spin}}$ and SU(2)$_{\text{gauge}}$ are broken, leading to $\langle R \rangle \neq 0$, $\langle H^a \rangle \neq 0$. The gauge-excitations, $(A_\tau, A)$, are gapped here. This phase describes the \textit{AFM-metal} where the large Fermi-surface gets reconstructed into hole (and electron) pockets due to condensation of $H^a \sim n$, the Néel order parameter.

- The SU(2) confining phase, labelled as (B) in Figs. 1, 3. Note that the SU(2)$_{\text{spin}}$ here remains unbroken. We have $\langle R \rangle \neq 0$, $\langle H^a \rangle = 0$, which is necessary to preserve spin-rotation invariance since $n = 0$ from Eq. (15). This is the usual \textit{Fermi liquid} phase, with a large Fermi-surface.
The Higgs phase, labelled as (C) in Figs. 1, 3, where the SU(2)_{gauge} is broken, but the SU(2)_{spin} remains unbroken, leading to \langle R \rangle = 0, \langle H^a \rangle \neq 0. By recalling the physical interpretation of the fields, this amounts to a locally well developed amplitude of the AFM, without any long-range orientational order. We can choose \( H^a \sim (0, 0, 1) \) by carrying out a gauge-transformation, which immediately implies that a U(1) subgroup of the SU(2)_{gauge} remains unbroken, so that the \( A^z \) photon remains gapless. Thus this phase describes a \textit{U(1) algebraic charge liquid}, or, the \textit{holon-metal} \cite{38}. However, due to the locally well developed AFM order, the Fermi-surface is reconstructed into \( \psi_p \) holon pockets that are minimally coupled to a U(1) gauge-field.

As a function of temperature, there could be a continuous crossover from a U(1) ACL to a U(1) FL* (or a “holon-hole” metal), where some of the holons (\( \psi_{\pm} \)) start forming bound states with the gapped spinons (\( \psi_{\alpha} \)) \cite{59}.

The final phase (D) in Figs. 1, 3 has the full symmetry, with none of the fields condensed: \( \langle R \rangle = \langle H^a \rangle = 0 \). Instead of the above U(1) ACL, where only \( A^z \) was gapless, in this phase there are a triplet of gapless SU(2) photons coupled to a large Fermi-surface. This phase can be described as a \textit{SU(2) algebraic charge liquid}. Formally, this phase a spin gap, but we assume that \( T \) is greater than the gap in the metallic regions of Fig. 2 because of proximity to the point M in Fig. 1. At low enough \( T \), this phase is unstable to superconductivity \cite{59}. 
We should emphasize that the above mean-field analysis has been rudimentary; e.g. we cannot rule out the possibility that higher order couplings could induce first-order transitions, that could even eliminate an intermediate phase.

The next section shall present the theory for the interplay between the fluctuations of the gauge and Higgs’ fields, within a low-energy field-theoretic formulation.

IV. LOW-ENERGY FIELD THEORY

We are interested in studying the properties of the QCP between the SU(2) ACL and the U(1) ACL. At the QCP, \( s = 0 \), the entire Fermi-surface is coupled to the transverse fluctuations of a SU(2) gauge field. There have been studies in the particle physics literature of Fermi surfaces coupled to non-Abelian gauge fields \([60, 61]\); however these have been restricted to spatial dimension \( d = 3 \), where a RPA analysis gives almost the complete answer. In spatial dimension \( d = 2 \) of interest to us here, we shall follow the approach taken for Abelian gauge theories \([54–56]\) which uses a patch decomposition of the Fermi surface. The same approach transfers easily to the non-Abelian case; indeed because of the Landau damping of the gauge bosons, there is little difference between the Abelian and non-Abelian cases \([21, 60, 61]\), as will also be clear from our analysis in Section IV A.

Apart from their coupling to a SU(2) gauge field, the fermionic \( \psi_p \) particles are also coupled to a quantum critical Higgs field. This coupling is strongest at 8 ‘hot spots’ around the Fermi surface, and in Section IV B we shall be able to use the methods developed from the case of a spin-density-wave transition of Fermi liquids \([43–46]\).

Some of the details of the computations appear in Appendix B.

A. Fermi-surface coupled to gauge-field

Here we describe the low energy theory of the SU(2) ACL, away from the Higgs condensation at the QCP. We need only consider a SU(2) gauge field coupled to the large Fermi surface of the \( \psi_p \) fermions. As in the U(1) case \([54–56]\), we can make a patch decomposition of the Fermi surface, and treat antipodal pairs of patches separately. For a single pair of antipodal patches, we have the fermions \( \psi_{\pm p} \) (see Fig. 4), with \( \pm \) the patch index, and \( p \) the usual SU(2) gauge index. This is coupled to the transverse components of the SU(2) gauge field, \( A^a \).
FIG. 4: The shaded grey regions represent the occupied states. The transverse gauge-field fluctuations couple strongly to the flavor current arising from the $\psi_\pm$ patches and destroy the Landau quasiparticles all around the Fermi-surface. Across the Higgs transition, the fluctuations of the $H^a$ field couple most strongly to the four-pairs ($m = 1, ..., 4$) of “hot-spots”, shown as the filled circles.

\[
L = L_f + L_A + L_{\text{int}}, \\
L_f = \psi_+^\dagger (\partial_\tau - i \partial_x - \partial_y^2) \psi_+ + \psi_-^\dagger (\partial_\tau + i \partial_x - \partial_y^2) \psi_- , \\
L_A = \frac{1}{2e^2} (\partial_y A_x^a)^2 , \\
L_{\text{int}} = A_x^a (\psi_+^\dagger \sigma_{pp'} \psi_+ \psi_-^\dagger \sigma_{pp'} \psi_- )
\]

(21)

Let us review the one-loop renormalization of the gauge and fermionic matter fields. We start by looking at the self-energy of the gauge-field due to the particle-hole bubble (Fig. 5a). We have,

\[
\Pi_0^A(q) = 2 \sum_s \int \frac{d\ell_x d\ell_y}{(2\pi)^3} G_s^0(\ell) G^0_s(\ell + q),
\]

(22)

where $\ell = (\ell_\tau, \ell)$ and the bare fermionic propagator is given by,

\[
G^0_s(\ell) = \frac{1}{-i\ell_\tau + s\ell_x + \ell_y^2}.
\]

(23)
The final result is of the form\(^5\),
\[
\Pi_0^\Lambda(q) = c_b \frac{|q_r|}{|q_y|}, \quad \text{where } c_b = \frac{1}{2\pi}. \tag{24}
\]

The computations are summarized in Appendix B1.

\[\text{Fig. 5: One loop contributions to the (a) gauge-field, and, (b) Fermion self-energies. Curly lines represent the A propagators, } D(\ell), \text{ while solid lines represent the } \psi \text{ propagators, } G(\ell).\]

Computing the fermionic self-energy due to the bosonic-propagator dressed with the RPA level polarization bubble (Fig. 5b) leads to,
\[
\Sigma_{s,pp'}(k) = -\sigma^a_{po} \sigma^a_{op'} \int \frac{d\ell_r d^2\ell}{(2\pi)^3} \ D(\ell) \ D^0_s(k-\ell),
\tag{25}
\]
\[
= -3 \ \delta_{pp'} \int \frac{d\ell_r d^2\ell}{(2\pi)^3} \ D(\ell) \ D^0_s(k-\ell),
\tag{26}
\]
where \(D(\ell)\) is the gauge-field propagator,
\[
D^{-1}(\ell) = \left( c_b \frac{|\ell_r|}{|\ell_y|} + \frac{1}{e^2} \ell_y^2 \right).
\tag{27}
\]

We then obtain,
\[
\Sigma_s(k) = -\frac{3i}{2} \int \frac{d\ell_r d\ell_y}{(2\pi)^2} \ \frac{\text{sgn}(k_r - \ell_r)}{c_b |\ell_r|/|\ell_y| + \ell_y^2/e^2},
\tag{28}
\]
\[
\Sigma_s(k) = -ic_f \text{sgn}(k_r) |k_r|^{2/3}, \quad \text{where } c_f = 2\sqrt{3} \left( \frac{e^2}{4\pi} \right)^{2/3}. \tag{29}
\]

This self-energy contribution is larger than the bare \(\partial_r\) term at low energies. Therefore, upon including the RPA contribution into the fermionic propagator, we have,
\[
G_s(\ell) = \frac{1}{-ic_f \text{sgn}(\ell_r) |\ell_r|^{2/3} + s\ell_x + \ell_y^2},
\tag{30}
\]
which is the well known result for the quasiparticles being damped all along the Fermi-surface.

\(^5\) We note that since the fermions are strictly in two-dimensions, the non-universal factor of \(\Lambda\), the UV cutoff, drops out. The factor that appears in general is of the form \(\Lambda^{d-2}\), where \(d\) is the number of space-dimensions.
B. Higgs criticality at the QCP

Now we consider the QCP at which the Higgs boson condensed from the non-Fermi liquid SU(2) ACL state described in the previous subsection. Across this Higgs transition from the SU(2) ACL to the U(1) ACL, the Fermi-surface gets reconstructed—this is controlled by the real Higgs field, $H^a$, which carries lattice momentum, $K = (\pi, \pi)$. By the same arguments used for the onset of spin-density-wave order in a Fermi liquid [43–46], the low energy physics of the QCP is dominated by the vicinity of the hot-spots: these are points on the Fermi surface which are connected by $K$ (see Fig. 4). The computation for the present non-Fermi liquid Fermi surface proceeds just as for the Fermi liquid case, by linearizing the bare dispersion for the fermions around the hot spots:

\[
L = L_{hs} + L_H + L_{fH},
\]

\[
L_{hs} = \psi_{1p}^\dagger (\partial_\tau - i \mathbf{v}_1 \cdot \nabla) \psi_{1p}^\dagger + \psi_{2p}^\dagger (\partial_\tau - i \mathbf{v}_2 \cdot \nabla) \psi_{2p}^\dagger,
\]

\[
L_{fH} = \frac{1}{\sqrt{N_f}} H^a \cdot (\psi_{1p}^\dagger \sigma_{pp'} \psi_{2p'}^\dagger + \psi_{2p}^\dagger \sigma_{pp'} \psi_{1p'}^\dagger),
\]

where $L_H$ already appeared in Eq. (7); $m$ is the hot-spot pair index (Fig. 4).

Let us first look at the one-loop self energy of the $H^a$ field (Fig. 6a). This is given by,

\[
\Pi^H (q) = 2 \sum_m \int \frac{d\ell_\tau d^2 \ell}{(2\pi)^3} \left[ G^m_1 (\ell + q) G^m_2 (\ell) + G^m_2 (\ell + q) G^m_1 (\ell) \right],
\]

where we now use the non-Fermi liquid fermion Green’s function renormalized by the gauge field fluctuations, as discussed in Section IV A:

\[
G^m_\alpha (\ell) = \frac{1}{-ic_f \text{sgn} (\ell_\tau) |\ell_\tau|^{2/3} - \mathbf{v}_\alpha \cdot \ell}.
\]

Note the $z = 3/2$ scaling of the fermion self energy, which allows us to drop the bare frequency dependence from above ($\sim \partial_\tau$).
Upon including contributions from all pairs of hot-spots, we obtain (see Appendix B2),

\[ \Pi^{H}(q) = \Pi^{H}(q = 0) + \gamma |q_{\tau}|, \text{ where } \gamma = \frac{n}{2\pi v_{x}v_{y}}, \] (34)

where \( n = 4 \) is the number of pairs of hot spots. Note that the \( c_{f} \) dependence has completely dropped out and the above result is precisely the expression that we would have obtained if we had started with the bare fermion Green’s functions (or, any anomalous power \( \sim |\ell_{\tau}|^{\beta} \)). This result is not surprising—it just reproduces the “Landau-damped” form of the propagator for \( H^{a} \). As we know, the only requirement for the appearance of Landau-damping is the existence of particle-hole excitations around the Fermi-surface in the limit of \( \omega \to 0 \). In the general case, this always leads to \( \sim |q_{\tau}|/|q_{y}| \) for a bosonic order-parameter coupled to a fermion-bilinear. When the order parameter itself carries a finite momentum \( K \), as is the case here, then the denominator in the damping term gets cut off and leads to \( \sim |q_{\tau}| \).

Equipped with the above expression, let us now compute the self-energy of the fermions in the vicinity of the hot-spots (Fig. 6b),

\[ \Sigma_{1,pp'}(p) = \sigma_{\alpha\beta}^{a} \sigma_{\alpha\beta'}^{a} \int \frac{d\ell_{\tau} d^{2}\ell}{(2\pi)^{3}} G_{2}(p - \ell) \chi(\ell), \] (35) 

\[ = 3\delta_{pp'} \int \frac{d\ell_{\tau} d^{2}\ell}{(2\pi)^{3}} G_{2}(p - \ell) \chi(\ell), \] (36)

where the propagator tuned to the critical point \( (s = 0) \) is given by : \( \chi^{-1}(\ell) = (\gamma|\ell_{\tau}| + \ell^{2}) \).

We are interested in the singular power law frequency dependence of the self-energy at the hot-spots. For future use, it is useful to express the Green’s function in Eq. (33) in the more general form

\[ G_{\alpha}^{m}(\ell) = \frac{1}{-i\zeta_{f} \text{sgn}(\ell_{\tau})|\ell_{\tau}|^{\beta} - \mathbf{v}_{\alpha} \cdot \ell}, \] (37)

where the exponent \( \beta = 2/3 \) from the coupling to the SU(2) gauge field.

Upon evaluating the momentum integrals, the self-energy (for \( p = 0 \)) becomes (see Appendix B3),

\[ \Sigma_{1}(p_{\tau}) = 3i \int \frac{d\ell_{\tau}}{4\pi^{2}} \tan^{-1} \left( \frac{\sqrt{v_{x}^{2}|\ell_{\tau}| - \zeta_{f}^{2}|p_{\tau} - \ell_{\tau}|^{2\beta}}}{\zeta_{f}|p_{\tau} - \ell_{\tau}|^{\beta}} \right) \frac{\text{sgn}(\ell_{\tau} - p_{\tau})}{\sqrt{v_{x}^{2}|\ell_{\tau}| - \zeta_{f}^{2}|p_{\tau} - \ell_{\tau}|^{2\beta}}}, \] (38)

which correctly reproduces \( \Sigma_{1}(p_{\tau} = 0) = 0 \). Furthermore, note that if \( \zeta_{f} = 0 \), i.e. if the anomalous self-energy contribution were to be absent, then the above reduces to the well known form [44]

\[ \Sigma_{1}(p_{\tau}) = 3i \int \frac{d\ell_{\tau} \text{sgn}(\ell_{\tau} - p_{\tau})}{8\pi \sqrt{v_{x}^{2}|\ell_{\tau}|}} = -\frac{3i}{2\pi \sqrt{v_{x}^{2}}} \frac{\text{sgn}(p_{\tau})\sqrt{|p_{\tau}|}}{2\pi \sqrt{v_{x}^{2}}}, \] (39)
reproducing the $z = 2$ result. Let us now proceed to evaluate the expression in the presence of a finite $\zeta_f$. Rescaling $\ell = \lambda \sqrt{v_f^2}$ leads to,

$$
\Sigma_1(p) = \frac{3i}{2\pi \sqrt{\gamma v_f^2}} \text{sgn}(p)|p|^{1-\beta} \times \int \frac{dx}{2\pi} \tan^{-1} \left( \frac{\sqrt{|p|^{1-2\beta}|x| - c|1-x|^{2\beta}}}{\sqrt{c|1-x|^{2\beta}} \sqrt{|p|^{1-2\beta}|x| - c|1-x|^{2\beta}}} \right) \text{sgn}(x-1),
$$

where the dimensionless parameter, $c = \frac{\zeta_f^2}{\gamma v_f^2}$. An asymptotic analysis of Eq. (40) shows that

$$
\Sigma_1(|p| \rightarrow 0) \sim -i \text{sgn}(p) \sqrt{|p|}, \quad \text{for } \beta \geq 1/2.
$$

So the low energy singularity of the self-energy is independent of the non-Fermi liquid exponent $\beta$ in the fermion Green’s function, and has the same value as in the spin density wave case without the gauge field. This is the key observation of the present subsection. To estimate the co-efficient, we can use a self-consistent approach in which we use a self energy in Eq. (37) with $\beta = 1/2$. This self-energy arises from the coupling to the Higgs field, and is always dominant over the one obtained from the gauge field with $\beta = 2/3$. Assembling all the constraints, the final expression takes the following $z = 2$ form

$$
\Sigma_1(p) = \frac{3i}{2\pi \sqrt{\gamma v_f^2}} \mathcal{I}(c) \text{sgn}(p) \sqrt{|p|},
$$

where the function $\mathcal{I}(c)$ is defined in Appendix B4 and $\mathcal{I}(c \rightarrow 0) = -1$.

So we reach our main conclusion that, in both the fermionic and bosonic sectors, the low energy physics of the Higgs QCP is essentially identical to that of the spin-density-wave onset transition in a Fermi liquid. And the basic reason for this is simple. The hotspot theory has dynamic critical exponent $z = 2$, while the singularities arising from the SU(2) gauge field coupling around the Fermi surface have $z = 3/2$. At a given length scale, the contributions with the larger $z$ dominate because they have a lower energy. Hence the Higgs criticality of a non-Fermi liquid maps onto the spin density wave criticality of a Fermi liquid.

With this conclusion in hand, we can now directly apply the results of Ref. 58 on the DC resistivity to the Higgs QCP. The approach of Ref. 58 requires that there is quasi-particle breakdown around the entire Fermi surface, and the fermionic excitations rapidly equilibriate with all the bosonic modes. While this was only marginally true for the spin-density-wave quantum critical point considered in Ref. 58, it is easily satisfied for the Higgs QCP being considered here: the SU(2) gauge field makes the entire Fermi surface “hot”, while the Higgs field fluctuations induce additional fermion damping at the hot spots on the Fermi surface. As in the previous case, it is possible for
disorder to couple to the square of the Higgs field because such an operator is gauge-invariant, as we noted in Eq. (10). And the corresponding contribution to the resistivity is in Eq. (12). For the exponents $d = 2$, $z = 2$, and $\nu = 1/2$ presented above, this yields a linear-in-temperature results $\rho(T) \sim V_0^2T$.

V. DISCUSSION

The primary goal of this paper has been to propose a candidate theory for the quantum phase transition near optimal doping in the cuprates. We analyzed the QCP between metals with ‘large’ and ‘small’ Fermi-surfaces, which did not involve any broken global symmetries, but instead involved a Higgs’ transition between metals with emergent SU(2) and U(1) gauge fields. The Higgs field acts as a measure of the local antiferromagnetic order in the rotating reference frame defined by Eq. (1). As we discussed in Sections I and II, the symmetry broken phases observed in the underdoped cuprates arise as low temperature instabilities of the ‘small’ Fermi-surface metal.

At the QCP itself, we pointed out that the ‘large’ Fermi-surface becomes critical due to the coupling to the emergent gauge-field fluctuations, and this leads to a loss of Landau-quasiparticles. The reconstruction to the ‘small’ Fermi-surface is driven by the condensation of the Higgs field, and the Higgs critical point has additional singular structure in the vicinity of the “hot-spots”. The Higgs criticality has associated with it an interplay of both $z = 3/2$ physics on the whole Fermi-surface, and $z = 2$ physics in the vicinity of the hot-spots. We showed that near the Higgs QCP the $z = 2$ physics dominates, and hence many critical properties map onto the previously studied problem of the onset of spin density wave order in a Fermi liquid [43–46, 58].

Let us now conclude with a discussion of the relationship of our proposed phase diagram in Fig. 2 to the experimentally obtained phase diagram in the non-La-based cuprates. The $d$–SC and $d$–BDW both arise as instabilities of the U(1) FL*, as has been discussed in Refs. 27, 62 (the SU(2) ACL is also unstable to superconductivity [59]). The high temperature pseudogap phase for $T^{**} < T < T^*$ is a U(1) ACL or more appropriately a holon-hole metal [38]. There is a crossover to the U(1) FL* phase at $T = T^{**}$, where all the holons have formed bound-states with the spinons.

An important feature of the U(1) FL* phase is that its transport and photoemission signatures are mostly identical to those of a Fermi liquid. The primary difference from a Landau Fermi liquid is that the volume enclosed by the Fermi surface is proportional to the density of holes, $x$, and not to the Luttinger density $1 + x$. The U(1) FL* phase also has an emergent U(1) gauge field, as required by the topological arguments in Ref. 24, but the Fermi surface quasiparticles are gauge
neutral. The recent remarkable observation of Fermi liquid transport properties in the pseudogap phase of Hg1201 \[63, 64]\ below \(T^{**}\), with some possibly non-Fermi liquid behavior between \(T^{**}\) and \(T^*\), can therefore be viewed as strong support for the existence of a FL* derived out of a parent ACL. In particular, the alternative ‘fluctuating order’ picture of the pseudogap does not naturally lead to such temperature dependent crossovers from non-Fermi liquid to Fermi liquid regimes.

For the La-based cuprates, there is a larger doping regime with magnetic order, overlapping with the regime of charge order. This can be accommodated in our phase diagram \[27]\ by moving the full red arrow in Fig. 1 just to the other side of the point M, and allowing for incommensurate order as in Appendix A.

An important challenge for future experiments is to detect direct experimental signatures of the complete small Fermi surface of the proposed FL* phase. We presume that it is the small quasiparticle residue on the ‘back side’ of the small Fermi surface \[29, 39]\ which is responsible for the arc-like features in the photoemission spectrum \[65]\. Therefore, we need a probe which does not involve adding or removing an electron from the sample, and so is not sensitive to the quasiparticle residue. Possibilities are Friedel oscillations, the Kohn anomaly, or ultrasonic attenuation.

Within our proposed phase diagram in Fig. 2, the strange metal phase is to be viewed as a SU(2) ACL at the Higgs critical point, and proximate to the multicritical point M to ensure the spin gap is smaller than \(T\). The DC transport properties of this phase are controlled by the coupling of the gauge-invariant square of the Higgs field to long wavelength disorder, following an analysis of Ref. 58 for the spin density wave critical point. Such a coupling leads to a linear-in-temperature resistivity. Also, as emphasized in Ref. 58, the residual resistivity is proportional to short wavelength disorder which can scatter fermions across the Fermi surface. So there is no direct relationship between the residual resistivity and the slope of the linear resistivity. It would be interesting in future work to explore the role of intrinsic umklapp scattering events in the transport properties of such strange metals in the strong coupling regime.

The electron spectral function in the SU(2) ACL is a convolution of the spectra of the \(\psi\) fermions and the \(R\) bosons. As in the computation in Ref. 37, we assume the \(R\) spectrum is thermally overdamped (because of the proximity to M), and the electron spectral function primarily reflects the \(\psi\) spectrum; we also expect precursors of the bound state formation between the \(\psi\) and the \(R\) to enhance the \(\psi\) features in the electron spectrum. Then the electron spectral functions should have an anisotropic structure around the Fermi surface, with the weaker gauge field-induced damping in the nodal region, and the stronger Higgs field-induced damping in the anti-nodal region. Also note that while the Higgs field coupling does show up in the resistivity as discussed above, the gauge
fields coupling has a weaker effect on transport. This is because gauge-invariance prevents a non-derivative coupling between the gauge field and perturbations that violate momentum conversation. An important open question is whether this rich theoretical structure can be made consistent with the complex experimental features of the conductivity and magnetotransport in the strange metal [66–68].

Our linear-$T$ resistivity is proportional to disorder, as in the previous model in Ref. 58. However, because the disorder couples to the Higgs field, the relevant disorder is long-wavelength. This is in contrast to short wavelength disorder, which can lead to efficient large momentum scattering of fermions around the Fermi surface. Modifying the coefficient of the resistivity therefore requires modifying long-wavelength disorder, and this may be difficult to do because of the intrinsic disorder from the dopant ions. Inducing short-wavelength disorder, by including e.g. Zn impurities, may not be effective in modifying the co-efficient of the linear-$T$ resistivity. These features can act as tests of our proposed mechanism for the resistivity of the strange metal [69].

Finally, we note from Figs. 2 and 1,3 that the SU(2) ACL survives for an extended region beyond the Higgs QCP. This implies strange metal behavior over a finite range of doping as $T \to 0$, and not only at a single QCP. Transport measurements [66] in magnetic fields which have suppressed superconductivity appear to be consistent with such a non-Fermi liquid phase.

Appendix A: Spiral order and $\mathbb{Z}_2$ gauge theory

Here we generalize the theory in Eq. (13) to the case of spiral spin order at an incommensurate wavevector $K$. In this case the antiferromagnetic order is not characterized by a single unit vector $n_\ell$, but by two orthogonal unit vectors $n_{1\ell}$ and $n_{2\ell}$ which obey

$$n_{1\ell}^2 = n_{2\ell}^2 = 1 \quad , \quad n_{1\ell} n_{2\ell} = 0.$$  

(A1)
The spin-fermion coupling to the electrons in Eq. (13) is replaced by

\[
\mathcal{L}_{fn} = -\lambda \sum_i [n_{i\ell} \cos (\mathbf{K} \cdot \mathbf{r}_i) + n_{i2\ell} \sin (\mathbf{K} \cdot \mathbf{r}_i)] \cdot c^\dagger_i \sigma^\ell_{\alpha\beta} c_i, \tag{A2}
\]

After the change of variables in Eq. (1), this leads to the Yukawa coupling

\[
\mathcal{L}_Y = -\lambda \frac{1}{2} (H^a \ast e^{i\mathbf{K} \cdot \mathbf{r}_i} + H^a \ast e^{-i\mathbf{K} \cdot \mathbf{r}_i}) \psi^\dagger_{i,p} \sigma^a_{\mu \nu} \psi_{i,p'}, \tag{A3}
\]

where, in contrast to Eq. (8), the Higgs field \( H^a \) is now complex and is defined by

\[
H^a \equiv \frac{1}{2} (n_{1\ell} + in_{2\ell}) \text{ Tr}[\sigma^\ell R_i \sigma^a R^\dagger_{i1}], \tag{A4}
\]

generalizing Eq. (15). It is now also clear from Eq. (A3) that under translation by a distance \( a \), the Higgs field transforms as in Eq. (9), where \( e^{i\mathbf{K} \cdot a} \) can now be complex.

The structure of SU(2) gauge theory with a complex Higgs field remains essentially the same as for the real Higgs discussed in the body of the paper, with one important distinction. The quartic term in Eq. (7) is replaced by two terms

\[
u_1[H^a \ast H^a]^2 + \nu_2[H^a]^2[H^{b\ast}]^2, \tag{A5}
\]

and the presence of spiral order requires that \( \nu_2 > 0 \). Then in the Higgs phase, the minimum energy condensate can always be oriented so that

\[
H^a = (1, i, 0). \tag{A6}
\]

Such a Higgs condensate breaks the SU(2) gauge symmetry all the way down to \( Z_2 \). And using Eq. (19), the analog of the relationship in Eq. (20) for the orientation of the spiral order is

\[
n_{1\ell} + in_{2\ell} = \frac{1}{2} H^a \text{ Tr}[\sigma^\ell R_i \sigma^a R^\dagger_{i1}]
= -\varepsilon_{\alpha\gamma} \varepsilon_{\alpha\beta} \sigma^\ell_{\alpha\beta} z_{\gamma} \quad \text{for } H^a = (1, i, 0). \tag{A7}
\]

This coincides with the conventional representation [70] of the spiral orientation in terms of spinons \( z_\alpha \), and it can be verified that the values in Eq. (A7) obey Eq. (A1).

For the case with \( \nu_2 < 0 \) in Eq. (A5), the Higgs condensate is instead a SU(2) rotation of

\[
H^a = e^{i\theta} (1, 0, 0), \tag{A8}
\]

where \( \theta \) is an arbitrary phase. This corresponds to incommensurate collinear spin order [21].
Appendix B: Feynman diagram computations

1. Self-energy: Gauge-field

Since we are interested in the singular structure of $\Pi_0^A(q)$ in Eq. (22), we shall evaluate the integral over $\ell_x$ first, followed by $\ell_r, \ell_y$. Therefore,

$$\Pi_0^A(q) = 2 \int \frac{d\ell_x d\ell_y}{(2\pi)^2} \frac{i\theta(\ell_r) - \theta(\ell_r + q_r)}{-i\eta q_r + q_x + q_y^2 + 2\ell_y q_y} + q \rightarrow -q,$$

(B1)

$$= \frac{q_r}{\pi} \int \frac{d\ell_y}{(2\pi)} \frac{-i}{-i\eta q_r + q_x + q_y^2 + 2\ell_y q_y} + q \rightarrow -q,$$

(B2)

$$= \frac{|q_r|}{2\pi |q_y|}.$$  

(B3)

This leads to the expression for $\Pi_0^A(q)$ in Eq. (24).

2. Self-energy: Higgs’ field

Focusing on just the $m = 1$ contribution, Eq. (32) becomes,

$$\Pi_{m=1}^H(q) = 2 \int \frac{d\ell_x d^2\ell}{(2\pi)^3} \left[ \frac{1}{-i \phi_0(\ell_r + q_r)|\ell_r + q_r|^2 - 2/3 - v_1 \cdot (\ell + q)} - i \phi_0(\ell_r)|\ell_r|^2/3 - v_2 \cdot \ell \right]$$

(B4)

Let us define $\ell_1 = v_1 \cdot (\ell + q)$ and $\ell_2 = v_2 \cdot \ell$, so that

$$\Pi_{m=1}^H(q) = \frac{1}{v_x v_y} \int \frac{d\ell_x d\ell_1 d\ell_2}{(2\pi)^3} \left[ \frac{1}{-i \phi_0(\ell_r + q_r)|\ell_r + q_r|^2 - \ell_1 - 1} - i \phi_0(\ell_r)|\ell_r|^2/3 - \ell_2 \right]$$

(B5)

It is not hard to see that the only non-zero contribution comes from the imaginary parts of both the terms. Then,

$$\Pi_{m=1}^H(q) = \frac{1}{v_x v_y} \int \frac{d\ell_x d\ell_1 d\ell_2}{(2\pi)^3} \left[ i \phi_0(\ell_r + q_r)|\ell_r + q_r|^2/3 - c_f^2|\ell_r + q_r|^4/3 + \ell_1 + i \phi_0(\ell_r)|\ell_r|^2/3 - c_f^2|\ell_r|^4/3 + \ell_2^2 \right] + q \rightarrow -q.$$  

(B6)

Upon carrying out the $\ell_1, \ell_2-$ integrals, this becomes,

$$\Pi_{m=1}^H(q) = -\frac{1}{4 v_x v_y} \int \frac{d\ell_r}{2\pi} \left[ \phi_0(\ell_r + q_r) \phi_0(\ell_r) + q \rightarrow -q].$$  

(B7)

This directly leads to the expression for $\Pi^H(q)$ in Eq. (34).
3. Fermion self-energy at the hot-spot

The Fermionic self-energy due to the Higgs’ field fluctuations (Eq. (36)) becomes,
\[
\Sigma_1(p) = 3 \int \frac{d\ell_r \, d^2 \ell}{(2\pi)^3} \frac{1}{-i\zeta_f \text{sgn}(p_r - \ell_r)|p_r - \ell_r|^\beta - v_2 \cdot (p - \ell)} \frac{1}{\gamma|\ell_r| + \ell^2}. \tag{B8}
\]
Let us now change coordinates such that \( \ell_\perp = \hat{v}_2 \cdot \ell \) and \( \ell_\parallel \) is the component along the Fermi-surface of \( \psi_2 \). Then,
\[
\Sigma_1(p) = -3 \int \frac{d\ell_r \, d\ell_\perp \, d\ell_\parallel}{(2\pi)^3} \frac{1}{-i\zeta_f \text{sgn}(p_r - \ell_r)|p_r - \ell_r|^\beta - v_2 \cdot p + v_2 \ell_\perp} \frac{1}{\gamma|\ell_r| + \ell_\parallel^2 + \ell_\perp^2}. \tag{B9}
\]
It is straightforward to carry out the integral over \( \ell_\parallel \), which gives,
\[
\Sigma_1(p) = -\frac{3}{2} \int \frac{d\ell_r \, d\ell_\perp}{(2\pi)^2} \frac{1}{-i\zeta_f \text{sgn}(p_r - \ell_r)|p_r - \ell_r|^\beta - v_2 \cdot p + v_2 \ell_\perp} \frac{1}{\sqrt{\gamma|\ell_r| + \ell_\perp^2}}. \tag{B10}
\]
Let us now study the form of the self-energy at the hot-spot, \( p = 0 \), and extract the \( p_r \) dependence. We can symmetrize the above form then to give,
\[
\Sigma_1(p_r) = 3i \int \frac{d\ell_r}{2\pi} \int_0^\infty \frac{d\ell_\perp}{2\pi} \frac{\zeta_f \text{sgn}(\ell_r - p_r)|p_r - \ell_r|^\beta}{\zeta_f^2|p_r - \ell_r|^\beta + v_2^2 \ell_\perp^2} \frac{1}{\sqrt{\gamma|\ell_r| + \ell_\perp^2}}. \tag{B11}
\]
Carrying out the integral over \( \ell_\perp \) (see Appendix B4) leads to the expression in Eq. (38).

4. Integrals

![Graph](image)

FIG. 7: \( \mathcal{I}(c) \) evaluated numerically as a function of \( c \). Note that \( \mathcal{I}(c \to 0) = -1 \), which reproduces Eq.39.

We use the integral (for \( a > 0, b > 0 \)):
\[
\int_0^\infty dx \frac{1}{x^2 + a^2} \frac{1}{\sqrt{x^2 + b^2}} = \frac{1}{a\sqrt{b^2 - a^2}} \tan^{-1} \left( \frac{\sqrt{b^2 - a^2}}{a} \right). \tag{B12}
\]

25
The above is valid irrespective of whether $a > b$ or $a < b$.

The integral in Eq. (40) can be evaluated as a function of the dimensionless parameter, $c = \zeta f/\gamma v^2$, when $\beta = 1/2$. The integral becomes,

$$ I(c) = \int_{-\infty}^{\infty} \frac{dx}{2\pi} \tan^{-1} \left( \frac{\sqrt{|x| - c|1-x|}}{\sqrt{|c|1-x|}} \right) \frac{\text{sgn}(x-1)}{\sqrt{|x| - c|1-x|}}. \quad (B13) $$

We show the functional form of $I(c)$ as a function of $c$ in Fig. 7.
