Running head:

Prognostic models of multiple infections
ABSTRACT

Objective To develop predictive models for early triage of burn patients based on hyper-susceptibility to repeated infections.

Background Infection remains a major cause of mortality and morbidity after severe trauma, demanding new strategies to combat infections. Models for infection prediction are lacking.

Methods Secondary analysis of 459 burn patients (≥16 years old) with ≥20% total body surface area burns recruited from six US burn centers. We compared blood transcriptomes with a 180-h cut-off on the injury-to-transcriptome interval of 47 patients (≤1 infection episode) to those of 66 hyper-susceptible patients (multiple [≥2] infection episodes [MIE]). We used LASSO regression to select biomarkers and multivariate logistic regression to built models, accuracy of which were assessed by area under receiver operating characteristic curve (AUROC) and cross-validation.

Results Three predictive models were developed covariates of: (1) clinical characteristics; (2) expression profiles of 14 genomic probes; (3) combining (1) and (2). The genomic and clinical models were highly predictive of MIE status (AUROC_Genomic = 0.946 [95% CI, 0.906–0.986]); AUROC_Clinical = 0.864 [CI, 0.794–0.933]; AUROC_Genomic/AUROC_Clinical P = 0.044). Combined model has an increased AUROC_Combined of 0.967 (CI, 0.940–0.993) compared to the individual models (AUROC_Combined/AUROC_Clinical P = 0.0069). Hyper-susceptible patients show early alterations in immune-related signaling pathways, epigenetic modulation and chromatin remodeling.

Conclusions Early triage of burn patients more susceptible to infections can be made using clinical characteristics and/or genomic signatures. Genomic signature suggests new insights into the pathophysiology of hyper-susceptibility to infection may lead to novel potential therapeutic or prophylactic targets.
Early genomic signature and clinical characteristics of 113 burn patients were used paradigmatically to build three novel predictive models of multiple, repeated infections in burn trauma, which could facilitate early triage of traumatically injured burn patients to prevent or treat sepsis. Genomic signature suggests new mechanistic aspects of hyper-susceptibility to infections.
INTRODUCTION

Although several studies have found association between specific risk factors or clinical characteristics with mortality after trauma,\(^1\)\(^-\)\(^4\) studies attempting to apply those clinical characteristics or genomic biomarkers to appreciate susceptibility to infection and build predictive models are currently lacking. Improvements in early care and trauma centers have reduced early mortality considerably.\(^3\)\(^,\)\(^5\) However, severe trauma, such as burn trauma, cause immunosuppression which predispose patients to infections. Despite all medical improvements, infections remain a major cause of critical injury-related morbidity and mortality, and recurrent sepsis predisposes patients to multiple organ failure, lengthens hospital stays, and increases costs.\(^6\) Therefore, improvements in prevention and treatment of infections are increasingly important.\(^7\)\(^,\)\(^8\) Moreover, the rapid emergence of multi-(MDR) or pan-drug resistant (PDR) pathogens that cause highly problematic acute, persistent or relapsing infections pose a dire threat to healthcare, especially among trauma and surgical patients.\(^9\)\(^,\)\(^10\) The increased use of antibiotics has further accelerated their emergence,\(^11\)\(^-\)\(^13\) and also increased the challenge of treating polymicrobial wound infections.\(^14\)\(^,\)\(^15\) Due to the paucity of novel anti-infectives in development, further improvement in patient care and treatment efficacy may rely heavily on optimizing existing strategies and promoting patients-tailored therapies.\(^16\)\(^-\)\(^18\)

Successful personalized approach requires rigorous triaging: early and accurate identification of patients more susceptible to infections could help tailor the anti-infective treatments,\(^19\)\(^,\)\(^20\) and especially to elaborate long-term treatment plan. Future successful clinical trials aiming to improve sepsis outcome may also rely on biomarkers to identify the right patients for the right treatment.\(^21\)\(^,\)\(^22\) Several studies have reported risk factors associated with increased probability of infection and sepsis in trauma patients,\(^23\)\(^-\)\(^26\) but no specific predictive model has been developed. Existing plasma biomarkers such as C-reactive protein (CRP) and procalcitonin (PCT) are mainly used to diagnose sepsis\(^27\)\(^,\)\(^28\) rather than reflective of susceptibility or health status. The clinical characteristics measurable rapidly upon admission are the current gold standard for prognosis of general patient’s outcome.
As trauma promotes susceptibility to infection and genomic signatures appear to play an increasingly promising role in prognosis, we analyzed the blood transcriptome and clinical characteristics data of 113 patients from the 573 thermally injured patients enrolled in the Inflammation and the Host Response to Injury study. Using clinical characteristics available upon admission and early genomic signatures, we developed novel predictive models that would permit early identification of burn patients at high risk of developing repeated infection indicative of an early hyper-susceptible state. The genomic signature suggests new mechanistic aspects for susceptibility to infection after burn trauma.

METHODS

Subject Recruitment and Sample Selection

This study was conducted via secondary use of the clinical and genomic data of the Inflammation and the Host Response to Injury Study (“Glue Grant”). Briefly, 573 burn patients with minimum 20% total burn surface area (TBSA) were enrolled from six institutions between 2003 and 2009 in a prospective, longitudinal study. RNA of leucocytes isolated from whole blood samples were extracted for transcriptome analysis using Affymetrix GeneChip Human Genome U133 Plus 2.0 microarrays at University of Florida–Gainesville, as described previously. The complete inclusion/exclusion criteria are described elsewhere. Permission for this secondary use of the de-identified data was obtained from the Massachusetts General Hospital Institutional Review Board (MGH IRB protocol 2008-P-000629/1).

Our patient inclusion process is summarized in Figure 1. From 573 potential patients in the data pool, we selected for patients that were at least 16 years old with early transcriptome data. We set a 180-h cut-off limit on the injury-to-transcriptome interval to include only samples that were obtained early relative to the recovery process, while still allowing enough samples to remain eligible for biomarker discovery. If multiple blood samples were collected from a patient, only the earliest eligible sample was included. We excluded patients who died within 9 days of blood collection and had fewer than two
infection episodes during this time window (Figure 1; Figure 1A). Our method for collection of data related to clinical characteristics is described elsewhere. To enable direct comparisons, as well as combination of clinical and genomic prediction, we used the same set of patients for both our clinical characteristic and our genomic signature prediction models.

**Definition of Outcomes**

We defined infections according to the information collected in the Glue Grant database based on previously described standards. Infection episodes were quantified for each patient for up to 60 days after blood sample collection. We developed a decision tree (Figure 1B; Supplemental Digital Content [SDC] Table 1) for evaluating each record based on: (1) time of infection; (2) type of infection; and (3) the pathogen(s) isolated. Since no genotyping data of the isolated pathogen species were available, we were unable to classify whether a later episode was caused by the same strain isolated earlier. However, once a record was counted, the infection type and isolated pathogen combination (e.g. *Pseudomonas aeruginosa* + lung) was put on a “waiting list” for the next 6 days, which likely reduced the likelihood of an infection episode caused by the same isolate from being counted. Subsequent records that were part of the same infection episode were thereby omitted. The patients were separated into two groups based on susceptibility to infection, measured by the number of independent infection episodes recorded. We defined patients with ≤1 infection episodes as the less susceptible control group (N = 47), and patients with ≥2 (multiple) infection episodes (MIE) as the hyper-susceptible case group (N = 66).

**Microarray Processing and Filtering**

Raw microarray data (.CEL files) were downloaded from the Glue Grant website (http://www.gluegrant.org/trdb/) and filtered using the steps outlined in Figure 1, SDC Table 1 and Figure 1B. We used the germa package on the R/Bioconductor platform to normalize 124 blood samples from
124 eligible patients collected within 180 h post-injury. Samples identified as outliers by arrayQualityMetrics\textsuperscript{35} were excluded from subsequent analysis. One patient was removed due to incompleteness of clinical data. Two patients’ datasets were discarded due to mortality within 9 days after sample collection. After these filtration steps, 113 blood samples were deemed suitable high-quality microarray data sets for subsequent functional analyses, biomarker discovery, and modeling.

We used the EMA package\textsuperscript{36} in R software to filter outlying or information-poor probe sets. We eliminated probe sets with a maximum log\textsubscript{2} expression value below 3.5, reducing the number of probe sets from 54,675 to 26,107. Using limma package,\textsuperscript{37} we selected 1142 probe sets with an at least 1.5-fold difference between less susceptible patients and hyper-susceptible patients and with an average expression level of at least 3 for functional analyses and biomarker panel selection process.

Statistical Analysis

Clinical data set. Continuous variables are reported as means (standard deviations), or as medians with inter-quartile ranges (IQRs) as indicated. Categorical variables are reported as frequencies and percentages. Demographic variables between less susceptible and hyper-susceptible patients were tested for statistical difference with a Wilcoxon rank sums test, a Chi-square test, or a Fisher’s exact test as appropriate. Statistical significance was accepted at $P < 0.05$ (two-tailed when appropriate).

Body mass index (BMI) was calculated as weight/height\textsuperscript{2} (kg/m\textsuperscript{2}). For patients $\geq$20 years old, BMI categories of underweight, healthy, overweight and obese were define according to BMI numbers: $<18.5$, $18.5–24.9$, $25–29.9$, and $\geq30$, respectively; whereas for patients $<20$ years old, the same BMI categories were defined using percentile ranking based on Centers for Disease Control and Prevention BMI-for-age growth charts: $<5^{th}$ percentile, $5^{th}$ to $<85^{th}$ percentile, $85^{th}$ to $<95^{th}$ percentile, and $\geq95^{th}$ percentile, respectively.

Genomic data set. In our evaluation of significant expression differences between less susceptible
and hyper-susceptible patients, Benjamini-Hochberg multiple-comparison adjustments were applied to control for false discovery rate.

**Development of the clinical predictive models.** We implemented stepwise logistic regression with an entry level of 0.3 and a stay level of 0.25 to identify significant predictor variables among clinical covariates relevant to the outcome variable of MIE: TBSA, age, BMI, and the presence of inhalation injury. We determined predictive power by calculating area under receiver operating characteristic curve (AUROC), reported with 95% confidence intervals (CIs).

**Development of the genomic predictive models.** We used the LASSO regularized regression method\(^{18}\) implemented in the glmnet package\(^{39}\) in R software to identify probe sets that collectively predicted the likelihood of MIE. We used 10-fold cross-validation (CV) to select the optimal value of LASSO penalty weighting, \(\lambda\). The value of \(\lambda\) that gave the minimum average binomial deviance plus 1 standard error on the test set, \(\lambda_{1se}\), was used to select probe sets (Figure 3A). \(\lambda_{1se}\) is a stronger penalty parameter to guard against over-fitting than \(\lambda_{\text{min}}\), which minimizes the average binomial deviance of CV (Figure 3B). This 10-fold CV process was repeated 100 times to generate 100 \(\lambda_{1se}\) values. The median \(\lambda_{1se}\), 0.0940, yielded selection of a 14-probe-set biomarker panel (Figure 3C; Table 2). Logistic regression was performed to model the MIE outcome with the log\(_2\) expression values of the 14 probe sets as explanatory variables. Furthermore, we conducted multivariate logistic regression with the clinical covariates TBSA, age, and inhalation injury together with the 14 probe sets for the outcome variable of MIE. Leave-one-out cross-validation was used to assess the degree of over-fitting and model performance.

**Functional Analysis**

Functional and pathway analyses were conducted using Ingenuity IPA (Ingenuity® Systems, www.ingenuity.com) and DAVID.\(^{40}\)
Software Platform and Package Versions

R (version 2.15.*); EMA package for R (version 1.3.2); pROC package for R (version 1.5.4); limma package for R (version 3.14.4); glmnet package for R (version 1.9-3); arrayQualityMetrics package for R (version 3.14.0); gcrma package for R (version 2.30.0); JMP Pro 10 and SAS 9.3 (SAS Institute Inc., North Carolina, USA).

RESULTS

Clinical Characteristics

From a pool of 573 patients, 124 met our inclusion criteria, of which 11 were unsuitable for modeling, leaving a cohort of 113 patients (Figure 1), including 47 patients less susceptible to infection (control group with ≤1 infection episodes) and 66 hyper-susceptible patients (case group with multiple [≥2] infection episodes [MIE]). The demographics, injury characteristics, and outcomes of these 113 patients are summarized in Table 1.

From 612 microbiological records for the 113 patients in the final cohort, we identified 325 independent infection episodes, 107 (32.9%) of which are polymicrobial at the species level. Twenty-four patients had no infection episodes, 23 had one episode, and 66 had MIE. The less susceptible and hyper-susceptible patients show significantly different clinical characteristics (Table 1). Relative to the control group, hyper-susceptible patients were slightly older (mean, 38.2, SD 16.4 vs 37.0, SD 14.6), had higher TBSA (46%, IQR 35–71 vs 32%, IQR 23–41, $P < 0.0001$), had more inhalation injuries (41/66 [62.1%] vs 8/47 [17.0%], $P < 0.0001$) and were more severely ill (according to their APACHE II score 24, IQR 18–29 vs 13, IQR 9–20, $P < 0.0001$). They also had longer hospital stays (median, 60, IQR 33–71 vs 20, IQR 15–30, $P < 0.0001$), more days on mechanical ventilation (median, 28, IQR 13–40 vs 2, IQR 0–5, $P < 0.0001$), and had a higher mortality (18/66 [27.3%] vs 3/47 [6.4%], $P = 0.0029$) (Table 1). The median post-injury interval for the second episode in the case group was 15 days (IQR, 10–20; range, 3–43), a
time window that provides opportunity for prophylactic intervention.

Inhalation injury significantly increased the risk of developing MIE and may be related to pneumonia risk in particular: 78.8% of hyper-susceptible patients had pneumonia vs 10.6% of controls; among cases, 84.7% had both MIE and inhalation injuries, 67.4% had both pneumonia and inhalation injuries. Interestingly, 4/5 of underweight patients had MIE (Table 1), supporting the notion that being overweight and mild obesity may be protective against post-injury infection whereas being underweight increases risk.32,41

Burn wound infection and nosocomial pneumonia were the most frequent types of infection observed (Table 1; Figure 2A). *Pseudomonas aeruginosa* and Staphylococci (both *Staphylococcus aureus* and coagulase negative Staphylococci) were the most commonly isolated micro-organisms (Table 1; Figure 2B). *P. aeruginosa* and *Acinetobacter* infections were more common among patients with MIE than controls, suggesting that hyper-susceptible patients were even more susceptible to nosocomial Gram-negative pathogens.

### MIE Prediction from Clinical Characteristics

We used stepwise logistic regression to select covariates for modeling from TBSA, age, BMI, and the presence of inhalation injury. The final multivariate logistic regression model included three covariates: TBSA, age, and inhalation injury, which were significant independent predictors of MIE. The AUROC, CV AUROC, sensitivity, and specificity values for the clinical characteristics model are 0.845 (95% CI, 0.773–0.916), 0.838 (95% CI, 0.762–0.914), 0.803 (95% CI, 0.683–0.887), and 0.745 (95% CI, 0.594–0.856), respectively (Figure 3). The model’s positive and negative predictive values were 0.815 (95% CI, 0.696–0.843) and 0.729 (95% CI, 0.579–0.843), respectively. Inhalation injury significantly increased MIE incidence (odds ratio [OR], 6.942; 95% CI, 2.482–19.417). Patients who had inhalation injuries were twice as likely to get pneumonia compared to those without them (risk ratio [RR], 2.05; 95% CI, 1.37–
Among those who had inhalation injuries, 67.4% had pneumonia, and 83.67% had MIE. TBSA (OR, 1.078; 95% CI, 1.040–1.118) and age (OR, 1.040; 95% CI, 1.006–1.075) were also associated with increased infection susceptibility.

**MIE Prediction from Genomic Biomarkers in Blood**

Ten-fold CV using LASSO regularized regression of the 1142 probe sets that presented a minimum of 1.5-fold change between the two patient groups yielded a minimal set of 14 predictors (probe sets) that together optimized the fit of the model (Figure 4A and 4B). Of these 14 probe sets—which mapped to 12 genes—4 were upregulated and 10 were down-regulated (Table 2, all \( P < 0.01 \); see Figure 4C for heat map and clustering of patients and biomarkers; see Figure 2 for expression profiles of each probe set).

The biological processes associated with each probe set are presented in Table 3 together with the coefficients of the biomarker panel logistic regression model (model intercept = 0.7449; SDC Table 6).

The AUROC, CV AUROC, sensitivity, and specificity values for the resulting genomic signature model are 0.946 (95% CI, 0.906–0.986), 0.872 (95% CI, 0.804 - 0.940), 0.924 (95% CI, 0.825–0.972), and 0.830 (95% CI, 0.687–0.919), respectively (Figure 3), confirming the model to be highly sensitive and specific.

The positive and negative predictive values of the model were 0.884 (95% CI, 0.779–0.945) and 0.886 (95% CI, 0.746–0.957), respectively. We compared each patient’s probability of developing MIE estimated from our clinical or genomic biomarker logistic regression models with each of the observed outcomes, using cut-off points of 30% to 70% as being uncertain. We found that the clinical model correctly predicted outcomes of 73 (65%) patients with certainty. Comparatively, the genomic biomarker model correctly predicted 90 (80%) patients with certainty, showing a 15% improvement over the clinical model. Both models misclassified 9 patients (8%). Collectively, these data suggest that genomic biomarkers may complement triage by clinical characteristics and enhance early prediction of a patient’s likelihood to develop MIE.
**MIE Prediction from a Combined Model**

A multivariate logistic model that included the aforementioned clinical covariates (TBSA, age, presence of inhalation injury) and genomic biomarkers resulted in an AUROC (0.967; 95% CI, 0.940–0.993) that was significantly greater than that for the clinical model ($P = 0.0069$), but not significantly different from that of the genomic biomarker panel model (Figure 3). The positive and negative predictive values of the combined model were 0.881 (95% CI, 0.773–0.943) and 0.848 (95% CI, 0.705–0.932), respectively. The estimates of the above models are listed in SDC Table 6.

**Functional and Canonical Pathway Changes in Patients with MIE Revealed by Transcriptome Data Analysis**

The 1142 probe sets showing a minimum of 1.5-fold change in hyper-susceptible patients versus less susceptible patients were mapped to 844 annotated genes. We identified functionally related genes among these 884 genes using Gene Ontology (GO). Subsequent analysis of the changes in canonical pathways and functions linked to these 844 genes indicated that hyper-susceptible patients’ transcriptomes demonstrated the following early functional changes relative to control transcriptomes: (1) early activation of immune cells, increased chemotaxis and trafficking; (2) decreased expansion of leukocytes, thymocytes, and number of phagocytes, and increased cell death and apoptosis; and (3) suppression of immune cell activation and lymphoid organ development (Table 2). The 1142 probe sets showed enrichment in four main gene ontology biological process categories: (1) immune response; (2) epigenetic modulation of gene expression; (3) transcription; and (4) metabolism (SDC Tables 2). Functional enrichment clustering is also in agreement with the enrichment of the 4 functional groups (SDC Table 3). The top 30 affected pathways were mainly involved in immune cell signaling and cytokine signaling (Figure 5). Canonical pathway analysis using IPA software (Figure 5) largely agrees with KEGG pathway
enrichment analysis using DAVID (SDC Table 5), providing additional confidence. Overall, many of the predicted functional changes (Table 2) are downstream of the affected canonical pathways (Figure 5; SDC Table 5).

**Canonical Pathways and T-cell Signaling**

Significant changes in IL-8 signaling (17 upregulated and 12 down-regulated genes [17 up/12 down]), Gαq signaling (16 up/9 down), Rho family GTPase signaling (20 up/10 down) and integrin signaling (21 up/9 down) suggest that the adhesion and migration of leukocytes are affected (Table 2; SDC Table 3; and Figure 5). The changes in chemotaxis may be partially caused by the presence of bacteria at wound site, as fMLP signaling pathway (12 up/8 down) suggests. Genes involved in phospholipase C signaling, a regulator of chemotactic response are differentially expressed (20 up/16 down). The increased cell movement, adhesion, and chemotaxis are related to phagocytosis process (e.g. FcγR-mediated phagocytosis, SDC Table 6), clearance of the pathogen from the site of infection, and induced by host damage associated molecular patterns (DAMP).

We found strong evidence that T-cells were also differentially regulated in case patients. Several pathways, including T-cell receptors (TCR) (7 up/16 down), JAK-STAT signaling (9 up/7 down), PKCθ signaling (8 up/15 down), and IL-6 signaling pathway (13 up/6 down) are known to regulate T-cell differentiation, activation, and cytokine production. Changes in iCOS-iCOSL signaling (10 up/14 down), CD28 signaling (11 up/16 down), and IL-2 signaling (7 up/7 down), indicate that T helper cell maturation and proliferation were likely affected. In summary, patient transcriptome data is consistent with compromised cellular immune responses mediated by impaired T-cells signaling.

**Functional Enrichment in Histone Modification and Chromatin Remodeling**

We found evidence for dramatic epigenetic changes in leukocytes that long precede patient outcome of
MIE. Functions related to epigenetic modulation were commonly enriched in our functional enrichment analyses (SDC Tables 2, 3, and 4). Notably, 42 probe sets (39 genes) have functional annotation associated with chromatin remodeling and histone modifications (SDC Table 4). Two genes from the biomarker panel involved in epigenetic modulation were found to be down-regulated in the case group with MIE: WHSC1L1, which encodes a histone lysine methyltransferase; and SMARCA4, which encodes an ATP-dependent helicase related to the SWI/SNF chromatin remodeling factor. A multitude of differentially expressed genes encoding histone post-translational modifiers as well as key components of the nucleosome remodeling complex mediating ATP-dependent nucleosome sliding, including SMARCC1, SMARCA4, CHD2 and CHD9, were down-regulated (SDC Table 4). Other notable histone methyltransferases/demethylases differentially expressed include KDM4, KDM5C, KDM6, PRDM5, SETD2, SETDB2, and SUZ12. Genes coding for histone deacetylases/acetyltransferases and associated factors including HDAC9, KAT6A and EP400 were down-regulated and histone acetylation recognizing bromodomain containing protein, BRD2, was upregulated in the case group. Furthermore, critical non-histone heterochromatin proteins HP1-α and –γ were down-regulated, as well as core histone cluster. Taken together, our data may suggest a global loss of heterochromatin and genome instability, as well as probable gene-specific transcriptional deregulation in hyper-susceptible patients compared to controls.

DISCUSSION

The work presented reports novel predictive models for hyper-susceptibility to infection among traumatically injured patients, using genomic biomarkers and/or clinical characteristics that have not been used to build statistical prognostic models for the purpose of predicting infection outcomes. We provide evidence that our models can identify burn patients at high risk of developing repeated infections indicative of their hyper-susceptible state. To our knowledge, this work is the first to describe such models in trauma patients, and the first to describe functional transcriptome data of burn patients in
relation to infections. The prediction accuracy of hyper-susceptibility to MIE is significantly increased over clinical markers when the genomic signature is used, providing strong evidence of the promising role of genomic biomarkers in prognosis even when used alone. By combining the biomarker panel with clinical characteristics, we demonstrated even better prediction accuracy, supporting the tremendous potential of using genomic signature to increase confidence in data used for treatment decision-making.

Clinical Implications.

We identified two distinct patient groups with different genomic signatures and clinical characteristics, essentially allowing the rapid identification of patients with a high risk of developing MIE following burn trauma. Although burn patients generally suffer from immunosuppression, clinical experience and our data suggest that the severity of immunosuppression and infection outcome vary. These data suggest that patients could potentially receive personalized therapy depending on their susceptibility to infection, triaged by physical exam and a blood test on admission. This information could facilitate the determination of appropriate treatment courses, particularly in regards to antibiotic use, allowing for selective use of prophylactic antibiotics and more objective justification of length of treatment courses. For the patient, this could limit complications related to unneeded antibiotics, reduce the burden of lines needed to deliver the antibiotics, and streamline hospital care. For the population, this could promote antibiotic stewardship, help stem the emergence of resistant organisms, and reduce the cost of care.

Mechanistic Aspects.

Genomic signatures provide insight into the molecular mechanisms of the more susceptible health status, and may aid in the discovery of novel therapeutic targets. Our findings point to novel potential targets for the prevention and/or early treatment of infections. Functional analyses of the 1142 biomarker candidates suggest new aspects into the pathophysiology of susceptibility to MIE after trauma. Susceptibility to MIE
was associated with early alterations in numerous signaling pathways related to innate and adaptive
immune responses, and changes in epigenetic modulation and metabolism.

Some of our findings are consistent with previous literature. For instance, upregulation of THBS1
(thrombospondin 1), to which 3/14 of the biomarker probe sets were mapped, has been associated with
complicated recovery in blunt trauma patients, supporting the broad applicability of our approach and
findings. The discovery of THBS1 also supports the potential biological relevance of our biomarkers.

Indeed, increased expression of mouse homologue Thbs1 has been reported to be associated with
infection, thrombosis, and increased lipopolysaccharide-induced mortality. Interestingly, Thbs1 -/-
knockout mice show reduced susceptibility to peritoneal sepsis, whereas Thbs1 over-expressing
transgenic mice show impaired wound healing associated with wound angiogenesis inhibition. THBS1
in human wounds could be functioning to provide adhesion target for pathogens through promotion of
thrombosis, and/or delayed wound healing, which could lead to increased susceptibility to infection.

Thus, building on convergent findings in humans and mice, our data confirm that processes related to
coaugulation play important roles in sepsis, and suggest that THBS1 could be a novel target for sepsis
prevention and treatment.

We showed evidence for increased chemotaxis, cell adhesion, and migration of immune cells, and
simultaneously, decreased expansion of immune cells and development of lymphatic system components.
This seeming contradiction may well be the consequences of dysfunctional immune system and cytokine
signaling, especially in T-cells.

Our data suggest that epigenetic changes occur early on, rather than mainly as a consequence of
septic shock. Epigenetic regulation of immune system is a common mechanism for gene expression
regulation and it plays a role in long-term immunosuppression after sepsis. Tightly regulated chromatin
remodeling is required for transcriptional regulation, which is vital for proper host immune and
inflammatory responses. Among the genes associated with epigenetic regulations, several have
confirmed roles in immune responses, such as KAT6A and KDM6B (SDC Table 4). Furthermore, our data further supports the notion that genes related to cell-cycle control and DNA repair have roles in both immune responses and tumorigenesis. In summary, the dramatic epigenetic changes could potentially explain why our biomarker panel could predict MIE that occurred weeks later, and the underlying mechanisms that favor infections by Gram-negative opportunistic pathogens.

**Implications for Future Research.**

With the aforementioned clinical implications and mechanistic aspects, our findings lay the groundwork for a new pathway of investigation potentially applicable to other forms of trauma and possibly even useful in determining patient risk for MIE prior to elective surgical procedures. This study provides a much-needed new direction for future clinical trials. In particular, appropriate biomarkers and additional information regarding patient health status might be essential for successful clinical trials of anti-sepsis drugs. Identification of the hyper-susceptible patients could enable more focused study design when expensive/invasive interventions, such as for the testing of cutting-edge technologies or products are involved by directing intervention to those who need it most. Identification of this group early after admission could also allow adjunctive treatments such as immunotherapy, extra-corporeal lipopolysaccharide removal, and other novel treatments to be tested prior to the decline of the patient’s clinical status due to MIE.

We envision that the development of a comprehensive diagnostic tool set will depend on the integration of genomic signatures of both host and pathogen. The blood biomarkers reported could be further developed and integrated with other diagnostic tools, such as genomic single nucleotide polymorphisms (SNPs) that predispose certain patients to infection, and produce a more comprehensive prognosis of patient susceptibility. Physician decisions rely heavily on blood tests over the course of recovery, and a positive culture is still the most accepted and reliable method for diagnosing infection. Using biomarkers, these blood samples could also allow us to monitor the changes in
susceptibility status and adjust treatments accordingly. Modern molecular based microbiological tests,\textsuperscript{53} such as detection of \textit{P. aeruginosa} in wound biopsy using RT-PCR based assays,\textsuperscript{54} have been developed but not yet widely utilized. Several molecular early detection kits have become commercially available for diagnosing common bloodstream infections, and have been found to show some promise despite of much room left for improvement.\textsuperscript{55,56} Our biomarkers on the host response may work synergistically with these tests to support physician decisions.

The discovery of these biomarkers and the validation of the methods pave the way for identifying biomarkers from other tissues involved in host defense, such as muscle, fat, and skin samples,\textsuperscript{57} of which often become available from surgical procedures or wound debridement. Biomarkers from other tissues may further enhance a combined model or perhaps provide even better prognostic value than blood biomarkers and clinical characteristics.

This study is limited by the unavailability of pathogen genotyping information below species level. We could not distinguish whether a reoccurring infection was caused by persistent or MDR pathogen, and could not identify biomarkers that can potentially differentiate susceptibility to different pathogens, such as Gram positive/negative bacteria, and even to species level. Nonetheless, our 6-day window (SDC Figure 1B) was designed to minimize infection episodes caused by the same strain(s). Our definition of hyper-susceptibility is based on natural definition of having repeated infections. Changing this definition, for example, to having at least three infection episodes, did not significantly change the biomarkers identified (data not shown). However, the \textit{P} values for differential gene expression and clinical characteristics became less significant, suggesting either the criterion is not the best cut off point to separate two different groups, or that the statistical power is reduced due to smaller number of patients in the hyper-susceptible group.

Although this work and our model focused on thermally injured trauma patients, our approach is potentially applicable to other types of trauma and surgical patients. In this study, to ensure portability of
our models, we carried out rigorous internal CV to ensure robustness of our regression models. However, due to the novelty of this clinical and transcriptome dataset, independent cohort data was unavailable for CV. Although our dataset is the largest of its kind to date, the sample size is still too small to build a larger panel without risking over-fitting the model. Our genomics data warrant future trials with a larger randomized cohort study, as well as mechanistic interrogations using animal models. Our findings open new avenues for the prevention and treatment of repeated infections in critical care, and provide novel components for the development of integrated prognosis and diagnosis using biomarkers, SNPs and pathogen detection. Future studies should investigate the potential broad applicability, and assess whether early triage based on predictive models can improve outcomes of trauma patients.

Figure 4. Biomarker selection by LASSO regularized regression. A. A representative repetition of 10-fold CV LASSO that chose 14 probe sets at \( \lambda_{1se} \). The first vertical dotted line corresponds to the \( \lambda_{\min} \) that minimized binomial deviance during CV. The second dotted line corresponds to \( \lambda_{1se} \), used for the selection of 14 probe sets as shown in B. B. LASSO coefficient profile plot of the coefficient paths. At \( \lambda_{1se} \), as shown with the dotted line, 14 probe sets have their coefficients significantly different from zero and thus were chosen as part of the biomarker panel. C. Heat map showing the expression levels of the 14 probe sets selected by LASSO as covariates for the genomic model. Each column corresponds to one of the 113 patient samples. Each row corresponds to one of the 14 probe sets. Whenever available, gene names were provided (see Table 2 for Affymetrix probe identification). The heat map color-coding is based on probe-set-specific, re-normalized expression values, with red signifying upregulation, blue
signifying down-regulation, and white indicating no difference in the hyper-susceptible patients compared to the controls. Patients that developed MIE are labeled red and those that had <2 infection episodes are labeled green at the bottom of the heat map.

**Figure 5. Pathways significantly altered.** Top 30 pathways significantly altered in case group with MIE. X-axis is the negative log $P$ value calculated from Fisher's exact test right-tailed. Red/Green inside bars are the number of upregulated/down-regulated genes. The total number of genes in a pathway is indicated in the parenthesis after pathway name. $P$ value is calculated by Fisher’s exact test by IPA software.

Mini-Abstract

Early genomic signature and clinical characteristics of 113 burn patients were used paradigmatically to build three novel predictive models of multiple, repeated infections in burn trauma, which could facilitate early triage of traumatically injured burn patients to prevent or treat sepsis. Genomic signature suggests new mechanistic aspects of hyper-susceptibility to infections.
ABSTRACT

Objective To develop predictive models for early triage of burn patients based on hyper-susceptibility to repeated infections.

Background Infection remains a major cause of mortality and morbidity after severe trauma, demanding new strategies to combat infections. Models for infection prediction are lacking.

Methods Secondary analysis of 459 burn patients (≥16 years old) with ≥20% total body surface area burns recruited from six US burn centers. We compared blood transcriptomes with a 180-h cut-off on the injury-to-transcriptome interval of 47 patients (≤1 infection episode) to those of 66 hyper-susceptible patients (multiple [≥2] infection episodes [MIE]). We used LASSO regression to select biomarkers and multivariate logistic regression to built models, accuracy of which were assessed by area under receiver operating characteristic curve (AUROC) and cross-validation.

Results Three predictive models were developed covariates of: (1) clinical characteristics; (2) expression profiles of 14 genomic probes; (3) combining (1) and (2). The genomic and clinical models were highly predictive of MIE status (AUROC_{Genomic} = 0.946 [95% CI, 0.906–0.986]; AUROC_{Clinical} = 0.864 [CI, 0.794–0.933]; AUROC_{Genomic}/AUROC_{Clinical} P = 0.044). Combined model has an increased AUROC_{Combined} of 0.967 (CI, 0.940–0.993) compared to the individual models (AUROC_{Combined}/AUROC_{Clinical} P = 0.0069). Hyper-susceptible patients show early alterations in immune-related signaling pathways, epigenetic modulation and chromatin remodeling.

Conclusions Early triage of burn patients more susceptible to infections can be made using clinical characteristics and/or genomic signatures. Genomic signature suggests new insights into
the pathophysiology of hyper-susceptibility to infection may lead to novel potential therapeutic or prophylactic targets.

Figure 1.

573 burn patients enrolled.

124 eligible patients.

113 patients suitable for modeling.

449 patients ineligible:
- 114 patients < 16 years old.
- 335 patients do not have blood samples or their blood samples collected after 180 hours post injury.

11 patients unsuitable for modeling:
- Eight patients with transcriptome identified as outliers.
- Two patients with ≤ 1 infection who died < 9 days after sample collection.
- One patient with missing clinical data.

Control group: 47 patients with ≤ 1 infection episodes.

Case group: 66 patients with ≥ 2 infection episodes (MIE).

</table>

An absolute z-score of ≥2 was designated as significant by the IPA software. The numbers of genes used to predict functional changes are indicated in the column with the heading “# of genes”.
