Glycated hemoglobin A1c (HbA1c) is used as a measure of glycemic control and also as a diagnostic criterion for diabetes. To discover novel loci harboring common variants associated with HbA1c in East Asians, we conducted a meta-analysis of 13 genome-wide association studies (GWAS; N = 21,026). We replicated our findings in three additional studies comprising 11,576 individuals of East Asian ancestry. Ten variants showed associations that reached genome-wide significance in the discovery data set, of which nine (four novel variants at TMEM79 [P value = 1.3 × 10^{-20}], HBSS1L/MYB [8.5 × 10^{-15}], MYO9B [9.0 × 10^{-12}], and CYBA [1.1 × 10^{-8}]) as well as five variants at loci that had been previously identified [CDKAL1, G6PC2/ABCB11, GCK, ANK1, and FN3K1]) showed consistent evidence of association in replication data sets. These variants explained 1.76% of the variance in HbA1c. Several of these variants (TMEM79, HBSS1L/MYB, CYBA, MYO9B, ANK1, and FN3K1) showed no association with either blood glucose or type 2 diabetes. Among individuals with nondiabetic levels of fasting glucose (<7.0 mmol/L) but elevated HbA1c (≥6.5%), 36.1% had HbA1c <6.5% after adjustment for these six variants. Our East Asian GWAS meta-analysis has identified novel variant-associated with HbA1c as well as demonstrated that the effects of known variants are largely transferable across ethnic groups. Variants affecting erythrocyte parameters rather than glucose metabolism may be relevant to the use of HbA1c for diagnosing diabetes in these populations.
raise the possibility that the impact of these variants on HbA1c relates to their effects on erythrocyte half-life. Alternatively, variants near fructosamine kinase (FN3K) may act through their effects on protein deglycation (14). These effects become particularly relevant now in that HbA1c has been adopted as a diagnosis criterion of diabetes, because it exhibits less intraindividual variability than either fasting glucose or 2-h post challenge glucose after an oral glucose tolerance test and does not require fasting (15,16). It is recognized that the glucose and HbA1c criteria are not completely concordant and that genetic variants result in a significant reclassification of individuals based on HbA1c criteria when compared with fasting glucose criteria (17).

To date, with one exception (4), all GWAS for HbA1c have been conducted in populations of European ancestry. We have already demonstrated that genetic association studies in different ethnic groups offer opportunities

to identify novel loci that harbor variants encoding susceptibility to T2D (18,19). Furthermore, some hereditary anemias are more common in Asians, which may also affect HbA1c (20). In this study, we sought to find common genetic variants at novel loci that are associated with blood HbA1c level in the consortium of the Asian Genetic Epidemiology Network (AGEN; http://www.agenconsortium.org/), which consists of East Asian cohorts.

RESEARCH DESIGN AND METHODS

We conducted a meta-analysis of data from 16 cohorts comprising 32,602 individuals of East Asian ancestry (Table 1). The study was carried out in two stages. Stage 1 involved the meta-analysis of GWAS of 19,017 Chinese, Korean, Japanese, and Malay individuals, as well as an in silico lookup of all index single nucleotide polymorphisms (SNPs) with P value $< 10^{-4}$ and their proxies (in total 198 SNPs) in 2,009 subjects of Chinese ancestry of the Singapore Chinese Health Study (SCHS) of diabetes. This gave a sample size of 21,026 for the discovery stage. In stage 2, we selected five genome-wide significant (P value $\leq 5 \times 10^{-8}$) SNPs at potential novel loci from stage 1 and two SNPs that reached suggestive levels of significance at the fatty acid desaturase 2 (FADS2) and proteasome (prosome, macropain) 26S subunit, non-ATPase, 13 (PSMD13) genes in view of their known impact on blood lipid levels (21) and hematologic traits (22). We then carried out de novo genotyping of these SNPs in 9,592 Japanese individuals. In addition, 48 out of these 198 index SNPs were also genotyped in a study of 1,984 Chinese individuals of the TaiChi study. The findings from all these studies were then meta-analyzed.

Most of the studies were population-based cross-sectional studies in adults. For the studies that used a case-control design to study genetic association with diabetes, only nondiabetic control individuals were included in this study. For other case-control studies, the association testing was done in cases and controls separately. The average HbA1c across the participating studies varied between 4.8 and 5.8%, while the SDs were less than 0.4%. All subjects provided written informed consent. Detailed information of each study can be found in Table 1 and the Supplementary Data.

SNP Genotyping, Quality Control, and Imputation
Our stage 1 cohorts were genotyped on Affymetrix (Santa Clara, CA) and Illumina SNP arrays. We applied stringent sample and SNP quality control (QC) within each study separately. As a result, the QC criteria varied slightly across these studies, but the following steps have been largely applied (Supplementary Table 1). Firstly, we excluded samples that showed cryptic relatedness, were population outliers, or showed inconsistency between clinical and genetic genders. Secondly, we removed SNPs with minor allele frequency (MAF) $< 1\%$, genotype call rate $< 0.95$, or Hardy-Weinberg equilibrium P value $\leq 1 \times 10^{-6}$.

We imputed our post-QC array genotypes up to the HapMap phase 2 haplotypes (23) using several widely used

The participant cohorts are listed in stage 1 (genome-wide association test) and stage 2 (de novo genotyping), respectively. Age, BMI, and HbA1c are given as the mean value and SE in each cohort. $\lambda_{GC}$ is the inflation factor calculated as per genomic control. CAGE, Cardiovascular Genomic Epidemiology; CRC, Cardiometabolic Risk in Chinese; JMGP, Japanese Millenium Genome Project; KARE, Korea Association Resource; NCGM, National Center for Global Health and Medicine; NHAPC, Nutrition and Health of Aging Population in China; SBCS, Shanghai Breast Cancer Study; SCES, Singapore Chinese Eye Study; SCHS-CHD, Singapore Chinese Health Study of Coronary Heart Disease; SCHS-DB, Singapore Chinese Health Study of Diabetes Mellitus; SIMES, Singapore Malay Eye Study; SP2, Singapore Progressive Study Program; TWSC, Taiwan Super Control Study. 1The International Federation of Clinical Chemistry unit for HbA1c is mmol/mol.
software packages. For the cohorts of Chinese, Korean, and Japanese ancestry, HapMap haplotypes of the Japanese in Tokyo, Japan (JPT) and Chinese in Beijing, China (CHB) were used as the reference panel in the imputation. For Malays, the combined African Yoruba in Ibadan, Nigeria (YRI); Utah residents with ancestry from Northern and Western Europe (CEU); and JPT+CHB panels were used. The combined HapMap panel resulted in about 1.9 million SNPs in the imputed genotypes, while there were 2.4 million in the imputation data when the JPT+CHB panel was used. Imputed SNPs of MAF <1%, Hardy-Weinberg equilibrium $P$ value $\leq 1 \times 10^{-6}$, or poor imputation quality (IMPUTE$^\infty$ info $< 0.5$, BEAGLE allelic $R^2 < 0.5$, or MACH $R^2_{\text{mq}} < 0.3$) were removed (24–26).

In stage 2, the follow-up SNPs were genotyped on three platforms. The two Japanese cohorts were genotyped using the TaqMan system (Life Technologies Corporation, Carlsbad, CA). The TaiChi cohort was genotyped using the Illumina Cardiao-MetaboChip (San Diego, CA). The same SNP QC criteria as in stage 1 were applied to the two Japanese studies, while similar sample QC and SNP QC as in stage 1 were applied to TaiChi study (Supplementary Table 1).

**Phenotype Definition**

The traditional HbA$_1c$ unit (percentage of HbA$_1c$ in total hemoglobin) was used in the analysis. Subjects with diabetes were excluded. Diabetes was diagnosed if the subject gave a history of physician-diagnosed diabetes, was taking medication for diabetes, or had fasting glucose $\geq 7$ mmol/L or HbA$_1c$ $\geq 6.5\%$ (48 mmol/mol) in those studies where fasting glucose was not available. The HbA$_1c$ measurements were fitted into a linear model that adjusted for the sex and BMI of the individuals. The residuals were then normalized to have a mean of 0 and an SD of 1 using inverse-normal transformation.

**Association With HbA$_1c$ and Meta-analysis**

We tested the association of the SNPs with the normalized HbA$_1c$, residuals using linear regression assuming additive effects of the dosage of the effect allele. The linear regression was evaluated by several widely used software packages (Supplementary Table 1). Study-specific covariates, such as principal components and sample recruitment sites, were also considered as required (Supplementary Data).

The results from separate studies were combined using the fixed-effect scheme weighted by the inverse of the SE as implemented in METAL (27). Genomic control was applied within METAL.

**RESULTS**

In total, we identified nine loci harboring variants associated with HbA$_1c$ levels in East Asian populations. Among them, four loci were associated with HbA$_1c$ for the first time. The fixed-effect meta-analysis showed no significant evidence of heterogeneity for most of the index SNPs in the cohorts we have recruited. Although the heterogeneity test for variants near the $G6PC2/ATP$-binding cassette, subfamily B (MDR/TAP), member 11 (ABCB11) locus reached a borderline level of statistical significance, the extent of heterogeneity was moderate (Supplementary Table 2).

**Known Associated Loci Replicated in East Asian Populations**

In stage 1, the maximal inflation factor was 1.052 in the Korea Association Resource (KARE) study, while those of the other studies were all $\sim 1$, indicating that population stratification was unlikely to confound our findings (Table 1). Supplementary Fig. 1 shows the quantile–quantile plots with and without the SNPs known to be associated with HbA$_1c$. This displayed a marked deviation from the null hypothesis of no association that persisted after all known SNPs associated with HbA$_1c$ were removed. In this stage, we had $\sim 81\%$ power to discover genomic variants that explain $0.2\%$ phenotype variance at a significance level of $P = 5 \times 10^{-8}$.

The associations between index SNPs at novel and known loci are presented in Table 2. Ten loci showed associations with HbA$_1c$ with $P$ values that met the criteria for genome-wide significance ($P$ value $\leq 5 \times 10^{-8}$) (Fig. 1). Of these, five were at loci that were known to harbor variants associated with HbA$_1c$ levels. The index SNPs at these known loci were rs7772603 in the CDKAL1 gene region, rs3755157 at the $G6PC2/ABCB11$ locus, rs1799884 near the GCK gene, rs4737009 in the ANK1 gene region, and rs1046875 near the FN3K gene. We investigated the linkage disequilibrium (LD) between our top SNPs, and the reported index SNPs at these loci identified in populations of European ancestry (Supplementary Table 3). At the GCK and FN3K loci, our index SNPs were exactly the same as or were in perfect LD with the index SNPs reported in Europeans. In fact, the SNP identified in populations of European ancestry at both loci (rs1046896 near the FN3K locus and rs730497 near the GCK locus) (3) also showed genome-wide significant associations in our meta-analysis ($P$ value $= 3.4 \times 10^{-13}$ and $1.3 \times 10^{-18}$ after genomic control). For ANK1, we replicated the primary signal rs4737009 reported in populations of European ancestry ($P$ value $= 1.3 \times 10^{-12}$) (3). This same study identified a second variant (rs6474359) in the ANK1 region, which was not in LD with the primary signal at this locus. This second SNP showed only a minor association with HbA$_1c$ for the sex and BMI of the individuals. The residuals were then normalized to have a mean of 0 and an SD of 1 using inverse-normal transformation.

The index SNP identified in European populations at $G6PC2/ABCB11$ (rs552976) did not show any association with HbA$_1c$ in our meta-analysis ($P$ value = 0.54). However, we did identify an association with rs3755157 near this locus that reached genome-wide significance. Although there was no evidence of LD between this and rs552976 in either HapMap panels of European (CEU) or Asian (JPT and CHB) ancestry (Supplementary Table 3), rs3755157 did show a genome-wide significant association with fasting glucose in populations of European
ancestry (Supplementary Tables 4 and 5). We conducted
association tests with and without conditioning on the
European SNP rs552976 in Singapore cohorts, includ-
ing 5,147 Chinese and Malays. P values for rs3755157
were $1.5 \times 10^{-2}$ and $1.4 \times 10^{-4}$ with and without
conditioning on rs552976, respectively. In addition,
the index SNP at the CDKAL1 locus (rs7772603) was
different from rs7747752 identified in the Korean co-
hort that formed part of this analysis. However, these
two SNPs showed moderate LD in the JPT+CHB panel,
and rs7747752 showed an association with HbA1c that
was in the same direction and similar magnitude as that
reported previously in the Korean population (4), with
a suggestive degree of statistical signi-
ficance in our
study ($P = 1.1 \times 10^{-5}$). This suggests that asso-
ciations with HbA1c for these two variants may repre-
sent the same association signal.

We further compared the direction of the effect for
known HbA1c-associated variants between European and
East Asian populations (Supplementary Table 6). Of the 17
index SNPs associated with HbA1c in previous publications,
rs1800562 (HFE) is monomorphic in East Asians, while
rs16926246 (HK1) was excluded because of the poor im-
putation quality. Most of the remaining 15 index SNPs
showed consistent effects between Europeans and East
Asians (Fig. 2). The only exception was rs6474359 at the
ANK1 locus, for which each copy of the T allele was asso-
ciated with higher HbA1c level by 0.06% in Europeans
($P = 1.2 \times 10^{-8}$) but lower HbA1c level by 0.08 SD of
the normalized HbA1c, which was equivalent to 0.05%
HbA1c ($P = 9.3 \times 10^{-3}$), assuming a normal distri-
bution of HbA1c in our study.

Novel Associated Loci Revealed in East Asian
Populations
The other five genome-wide significant hits in stage 1 were
all novel associations (Table 2). These five variants and
two additional SNPs (rs540078 at PSMD13 and rs174570
at FADS2) were examined in stage 2. Of these, data for
the top SNP at cytochrome b-245, α polypeptide (CYBA;
rs9933309) was available only in the TaiChi study, which
consists of 1,984 Chinese. Four of these seven SNPs were

The index SNPs were grouped into novel loci that were first discovered in our study and known loci that have been reported in previous
publications. Gene refers to the most relevant gene within each locus. The cytoband of 9q31.2 was designated to rs1467311 since no
gene was found in the 400 Kb flanking region nearby. Alleles are given as the effect allele/other allele. Effect and SE are the risk and its
SE, respectively. For the novel loci, association result were given for the stage 1, stage 2, and the meta-analyzed stage 1 and stage 2,
indicated as 1, 2, and 1+2, respectively. Chr, chromosome number. *The index SNPs showed genome-wide significance in stage 1.
replicated successfully in our stage 2 cohorts with consistent effect directions and showed stronger associations after combining the results of stage 2 and stage 1 with $P$ values less than $5 \times 10^{-8}$. They were variants close to the transmembrane protein 79 (TMEM79), Hsp70 sub-family B suppressor 1-like protein/v-myb avian myeloblastosis viral oncogene homolog (HBS1L/MYB), CYBA, and myosin IXB (MYO9B) loci (Table 2). The remaining SNPs,

Figure 1—Manhattan plot of genome-wide meta-analysis of stage 1 cohorts. The $-\log_{10}$ of the association $P$ values ($y$-axis) are plotted against the genomic coordinates ($x$-axis). The horizontal line in the plot indicates the genome-wide significance ($5 \times 10^{-8}$). The most relevant gene of each signal was labeled on the top of it, with the novel loci presented in brown and known loci in blue.

Figure 2—The bivariate plot of the effect directions in our meta-analysis and in previous reports. For the index SNPs in the previous GWAS, we plotted the reported effect ($x$-axis) versus the AGEN effect ($y$-axis). Whenever available, we used the effects reported by Soranzo et al. (3). The solid dots represent the SNPs that were significant ($P$ value $\leq 0.05$) in our study, while the hollow red dots represent the insignificant ones. The CDKAL1 top SNP reported in Koreans was specially marked by a diamond. EA, East Asian.
rs1467311 at 9q31.2 (stage 1+2 meta-analysis $P$ value = $1.0 	imes 10^{-6}$), rs174570 in FADS2 ($P$ value = $2.0 	imes 10^{-7}$), and rs540078 in PSMD13 ($P$ value = $3.2 	imes 10^{-5}$) did not show genome-wide significant association with HbA1c in stage 1 and stage 2 meta-analysis. The regional association signals at the novel loci and the known loci were presented in Fig. 3 and Supplementary Fig. 2, respectively.

For the novel loci identified in East Asians, the MAF of the index SNPs in HapMap JPT+CHB panel were comparable to those in CEU panel (Supplementary Table 7). In most cases, the direction of effect was the same in AGEN as it was in the study of European ancestry, with the exception of rs6684514 at TMEM79. However, this SNP showed only a nominal degree of statistical significance in Europeans ($P$ value = $4.0 	imes 10^{-2}$).

**Association With Fasting Glucose and Erythrocyte Traits**

We also looked up the associations between the variants that reached genome-wide significance with glucose-related traits.

---

Figure 3—Regional association plots of the novel loci. The $-\log_{10}$ of association $P$ values are plotted against the genomic coordinates. The index SNPs are indicated in purple, with circles for stage 1 and squares for stage 1+2. Other SNPs are colored from red to blue as per their LD with the index SNP. Chr, chromosome.
traits in Europeans (28–30) and Asians (19,31) (Supplementary Tables 4 and 5). SNPs near GCK and G6PC2 were associated with blood glucose in both Europeans and East Asians. SNPs at the CDKAL1 locus were associated with T2D in East Asians. Among the known loci, FN3K and ANK1 were not associated with glucose level and T2D in either East Asians or Europeans. For the novel SNPs associated with HbA1c that we identified in this study, none showed a statistically significant association with glucose levels except rs9399137 near the HBS1L/MYB loci, which showed an association with fasting glucose with borderline statistical significance that did not survive Bonferroni correction. We next examined the associations between these variants and red-cell-associated parameters in Europeans (6,8) and East Asians (32) (Supplementary Tables 8 and 9). Variants close to TMEM79, HBS1/MYB, CYBA, and ANK1 showed statistically significant associations with red-cell-associated parameters in at least one population.

**Phenotype Variance Explained by the Associated Loci**

We estimated the phenotype variance explained (PVE) by the genome-wide significant index SNPs in our meta-analysis. The PVE in each cohort was calculated by fitting the raw HbA1c in a linear regression model on the allele dosages of the index SNPs under investigation. The adjusted r-squared from the linear regression model was used as the estimation of PVE. The estimates were obtained for the novel, known loci and all loci separately. The estimates from separate studies were combined using a sample-size-weighted scheme.

In Singapore Chinese Eye Study (SCES), Singapore Malay Eye Study (SiMES), and the three Singapore Progressive Study Program (SP2) cohorts, the known loci and the novel loci explained 1.01% and 0.75% of the total HbA1c variance, respectively, while all the index SNPs as a whole explained 1.76% HbA1c variance.

**Reclassification of Diabetes Diagnosis Using HbA1c**

Finally, we calculated the proportion of the samples that were reclassified by adjusting for the allele dosage of index SNPs at the six loci that did not show association with glucose or T2D in populations of either European ancestry (28–30) or Asian ancestry (19,31). These included TMEM79, HBS1L/MYB, CYBA, MYO9B, ANK1, and FN3K.

This reclassification analysis was done in 15,150 individuals with fasting glucose measurements available, which came from SP2, KARE, Nutrition and Health of Aging Population in China (NHAPC), National Center for Global Health and Medicine (NCGM), Cardiometabolic Risk in Chinese (CRC), and TaiChi. Individuals with known diabetes (defined by having diabetic history or using diabetic medication) were removed. In the remaining subjects, undiagnosed diabetes was defined as those having fasting glucose $\geq$7 mmol/L, whereas the nondiabetic individuals had fasting glucose <7 mmol/L. We adjusted the raw HbA1c levels using a linear regression, including the allele dosages of the six SNPs as covariates. We then classified individuals into those with and without diabetes based on HbA1c $\geq$6.5% (15). We compared the concordance between these three methods for diagnosing diabetes (fasting glucose $\geq$7 mmol/L, HbA1c $\geq$6.5%, and HbA1c adjusted for these six SNPs $\geq$6.5%). HbA1c was adjusted on the nonglycemic index SNPs. The subtotal is the number of individuals in each HbA1c category. The reclassification rate in each HbA1c category is the ratio of the number of individuals reclassified after adjustment for the six SNPs to the subtotal. The total is the number of individuals in each fasting plasma glucose category.

In this East Asian GWAS meta-analysis, we showed that most of the variants identified in populations of European ancestry had similar effects in East Asians. Variants close
to the G6PC2/ABCA11, GCK, ANKI, and FN3K that were first identified in populations of European ancestry also showed associations that reached genome-wide significance in our study. However, at the G6PC2/ABCA11, our index SNP was not in LD with the index SNP (rs552976) identified in populations of European ancestry. The latter was not associated with HbA1c in our study (P value = 0.54). Therefore, rs3755157 could represent an additional signal at this locus, particularly given that we did not observe obvious attenuation of the associations in the analysis conditioning on rs552976. Another SNP at this locus (rs560887) was associated with fasting glucose in Europeans (28) but not with HbA1c in our study (P value = 0.10). The majority of the other known SNPs showed similar direction of effect and effect size in our population as in populations of European Ancestry. The exception was a variant at the ANKI locus with showed an association in the opposite direction to that observed in populations of European ancestry. We are not able to explain this finding at this time. However, we would point out that the association in our study, although in a different direction, was far from reaching genome-wide significance. Larger sample sizes will be required to formally test for heterogeneity of effect of this variant in populations of European and East Asian ancestry.

We identified variants at or close to four novel loci associated with HbA1c in this meta-analysis. TMEM79 is a transmembrane protein that is highly expressed in liver, erythrocytes, and adipose tissue (The European Bioinformatics Institute, Expression Atlas database, http://www.ebi.ac.uk/gxa). The index SNP rs6684514 was also associated with mean corpuscular hemoglobin concentration in a GWAS conducted in Japanese (32). Although this suggests that this SNP may exert its effects in HbA1c through its effects on erythrocyte biology, we cannot exclude the possibility that this variant could alter glucose regulation. TMEM79 is downregulated by a high-fat diet in adipose tissue in mice (33). TMEM79 is also differentially methylated in adipose tissue in twins discordant for T2D. However, this association did not survive multiple testing (34). The index SNP at the TMEM79 locus rs6684514 was a common missense variant (Val147Met). However, this was predicted as benign by sorting intolerant from tolerant (SIFT) (35) and polymorphism phenotyping (PolyPhen) (36). We also looked for other functional variants in the nearby genes. Three missense SNPs were found to be in high LD (r² = 0.97; MAF = 0.22) with rs6684514. They were rs10908495 and rs10908496 at the CIor85 locus and rs2230194 at the CCT3 locus. However, their P values were all less than 3.7 × 10⁻⁹ in stage 1. Haplotype analysis showed that there were only two common haplotypes (frequency >0.01) in Chinese cohorts of SCES and SP2. They were A-C-A-A and G-T-G-G for rs6684514-rs10908495-rs10908496-rs2230194, while G-T-G-G carried all the alleles associated with elevated HbA1c. Hence, we are unable to discriminate the genuine causal variant among these four missense variants.

rs2230194 did not exist in the combined reference panel of HapMap CEU, JPT+CHB, and YRI and hence was absent in Malay cohort of SIAMES.

The index SNP rs9399137 is located in the intergenic region between HBSIL and MYB genes and resides in a LD block (HMIP 2), which contains SNPs associated with various hematological traits (5–8,22,37,38), including HbA2 (39) and Hbf (40). Another SNP in the same LD block was associated with mean corpuscular hemoglobin, erythrocyte count, and other hematological traits significantly in the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) consortium (6). The index SNPs reported by CHARGE were in moderate/high LD with rs9399137 (r² ranges from 0.45 to 1.00 in HapMap release 22 CEU panel). This observation was also supported by recent GWAS in African Americans (9,41). A study has shown a distal regulatory element may exist here to control the expression of MYB gene (42), which plays an important role in erythrocyte formation and differentiation. MYO9B codes for a single-head myosin isoform that was found to be expressed primarily in peripheral blood white cells (43). The product of the gene is important for actin remodeling of epithelial enterocytes, hence it has been associated with several inflammatory bowel diseases, such as Crohn disease and celiac disease, in which the impairment of the enterocyte function explained part of the disease syndrome (44). MYO9B function could have an impact on both glycemic and nonglycemic determinants of HbA1c. Celiac disease can result in anemia (45) due to various nutrient deficiencies. This can alter red cell turnover and thus HbA1c level. In addition, celiac disease is also associated with lower BMI and a lower prevalence of T2D (46). Actually, the T allele of our index SNP rs11667918 was associated with lower BMI in another meta-analysis conducted by AGEN (P value = 0.03) (47), as well as lower HbA1c level in our study. Furthermore, intestinal permeability may have a role in the pathogenesis of type 1 diabetes (T1D) (48). MYO9B’s expression is altered by a hydrolyzed casein diet, which is also able to prevent diabetes in the DP-BB mouse, a mouse model of T1D (49). Variants at this locus showed an association with T1D in a Spanish population (50). However, this finding was not replicated in Dutch and British populations (51). Another SNP rs2279008 at MYO9B was associated with human height (52), which was weakly associated with T2D (53), but this SNP is not in LD with our index SNP rs11667918 in both CEU and JPT+CHB panels.

Although, the association of the index SNP of CYBA rs9933309 in our replication cohort was not statistically significant, this SNP was only genotyped in a small number of individuals as part of the replication cohorts due to limitations of resources. However, the association after meta-analysis did reach GWAS significance, and the same SNP showed an association with HbA1c in the Meta-Analyses of Glucose and Insulin-Related Traits Consortium
Genetic Associations With HbA1c in East Asians

HbA1c levels in East Asians are higher compared with Caucasians, with a mean difference of 0.2–0.5% higher in East Asians compared with Caucasians. This difference in HbA1c levels is observed in large-scale population-based studies, such as the Women's Genome Health Study (6). However, the genetic basis of this difference is not well understood.

In a recent study, nine genetic variants were reported to influence HbA1c levels (2). Among these variants, six were found to be associated with HbA1c in East Asians, while three were not. The association with HbA1c was significant for all six variants, with a minor allele frequency of 0.005–0.5%.

The effect size of these variants is small, with an odds ratio of 1.02–1.10 for each minor allele. However, the cumulative effect of these variants is substantial, with a total effect size of 0.27–0.36 SD for HbA1c. This suggests that these genetic variants may have a role in the higher HbA1c levels observed in East Asians.

The biological mechanisms underlying these genetic variants are not well understood. However, they may be associated with changes in glucose metabolism or red cell parameters. Further studies are needed to elucidate the mechanisms underlying these genetic associations and their impact on HbA1c levels.
