Abstract

Epidemiological studies have reported inconsistent associations between telomere length (TL) and risk for various cancers. These inconsistencies are likely attributable, in part, to biases that arise due to post-diagnostic and post-treatment TL measurement. To avoid such biases, we used a Mendelian randomization approach and estimated associations between nine TL-associated SNPs and risk for five common cancer types (breast, lung, colorectal, ovarian and prostate cancer, including subtypes) using data on 51 725 cases and 62 035 controls. We then used an inverse-variance weighted average of the SNP-genetic score was significantly associated with increased risk of lung adenocarcinoma (P = 6.3 × 10−15), even after exclusion of a SNP residing in a known lung cancer susceptibility region (TERT-CLPTM1L) P = 6.6 × 10−6). Under Mendelian randomization assumptions, the association estimate [odds ratio (OR) = 2.78] is interpreted as the OR for lung adenocarcinoma corresponding to a 1000 bp increase in TL. The weighted TL SNP score was not associated with other cancer types or subtypes. Our finding that genetic determinants of long TL increase lung adenocarcinoma risk avoids issues with reverse causality and residual confounding that arise in observational studies of TL and disease risk. Under Mendelian randomization assumptions, our finding suggests that longer TL increases lung adenocarcinoma risk. However, caution regarding this causal interpretation is warranted in light of the potential issue of pleiotropy, and a more general interpretation is that SNPs influencing telomere biology are also implicated in lung adenocarcinoma risk.

Introduction

Telomeres are DNA–protein complexes at chromosome ends that help maintain genome stability by protecting DNA from damage and fusion. The DNA component is a six-base TTAGGG repeat sequence that shortens with each cell division. In differentiated cells, telomere shortening eventually leads to loss of telomere protection and genome instability, typically triggering cell senescence or programmed cell death (1). In stem and progenitor cells, the telomerase enzyme elongates telomeres, enabling prolonged cell survival (2). Telomerase is also activated in >90%
of human tumors (3), which typically have short telomeres (a potential cause of genome instability), thus promoting proliferation and survival (4).

The critical role of telomeres and telomerase in carcinogenesis has led to the hypothesis that short telomere length (TL) is a risk factor for cancer (5). Indeed, short relative TL measured in surrogate tissues, such as peripheral blood cells, has been associated with increased risk for lung (6,7), ovarian (8), colorectal (9) and breast cancers (10,11) in epidemiological studies (with the interpretation that blood TL predicts cancer risk because it is a proxy for TL in cancer-prone tissues). However, such associations are not consistent across all cancers or even within cancer types, with some studies reporting null, U-shaped or positive associations (11–16). Furthermore, due to the retrospective nature of case–control studies from which many of these association estimates are obtained, telomere shortening that occurs after diagnosis, potentially due to treatment (17,18) or disease progression, can result in biased estimates of the association between TL and cancer risk (6,8,14).

Table 1. Sample sizes for cancer types included in the Genetic Associations and Mechanisms in Oncology (GAME-ON) consortium. Details on the GAME-ON Network and the contributing GWA studies have been previously described (26) (http://epi.grants.cancer.gov/gameon/).

Table 2. Characteristics of genetic variants associated with TL as reported in prior GWA studies

Table 2. Characteristics of genetic variants associated with TL as reported in prior GWA studies

Genome-wide association (GWA) studies have identified several genomic regions containing variants associated with TL in peripheral blood cells (19–21), including the TERT (telomerase reverse transcriptase) region (Sp15.33). Furthermore, GWA studies of cancer risk have observed that variants in the TERT region influence risk for multiple cancer types, including breast (22), colorectal (23), lung (24), prostate (24) and ovarian (22) cancer, although these associations do not appear to all be driven by the same causal variant. In light of this evidence indicating an important role for telomeres in carcinogenesis, we undertook a comprehensive examination of associations between genetic determinants of TL and cancer risk.

In this work, we describe the associations between nine TL-associated genetic variants and risk for five cancer types (breast, lung, colorectal, ovarian and prostate), using data from the Genetic Associations and Mechanisms in Oncology (GAME-ON) network of consortia for post-GWA research. In addition, we estimate the association between a multi-variant TL score and cancer risk, which corresponds to the effect of TL on cancer risk under Mendelian randomization assumptions (25). However, this interpretation requires caution because the validity of the Mendelian randomization assumptions (such as the absence of pleiotropy) cannot be proven.

Because genotype–phenotype associations are not vulnerable to biases caused by reverse causation or confounding by environment, the Mendelian randomization approach used in this study is an attractive approach for estimating relationships between TL and cancer risk.

Results

The Genetic Associations and Mechanisms in Oncology (GAME-ON) Consortium is a network of five consortia focused on cancers of the breast, colon, lung, ovary and prostate. The GAME-ON network represents 33 GWA studies contributing data on >51,000 cancer cases and >62,000 controls (26). Samples sizes for each cancer type and subtype are listed in Table 1.

Association estimates for individual SNPs

Based on the existing literature, we identified nine SNPs showing genome-wide significant associations (P < 5 × 10⁻⁸) with TL in GWA studies (19–21). From these prior papers we obtained the identifier for the lead SNP at each reported locus as well as the ‘long TL’ allele, association estimate for the ‘long’ allele (in
terms of kb of TL per allele), and the standard error and P-value for each SNP’s association with TL (Table 2). We estimated associations between each of the nine TL-associated SNPs and risk for each of the five common cancer types and subtypes in the GAME-ON study, shown as forest plots in Supplementary Material, Figure S1. Of note, for all nine SNPs, the long TL allele had an OR >1 for lung adenocarcinoma, with four of the nine associations being statistically significant (P < 0.05) (Fig. 1, top left). In contrast, no TL-associated SNP was significantly associated with squamous cell carcinoma of the lung (Fig. 1, bottom left). Prostate cancer risk also showed nominally significant positive associations with the long TL alleles for three of the nine SNPs (P < 0.05) (Supplementary Material, Fig. S1).

**Mendelian randomization estimates based on multi-SNP scores**

We estimated the associations between a multi-SNP TL score and risk for each cancer (Table 3) using a previously described Mendelian randomization approach that obtains an estimate using an inverse-variance weighted average of SNP-specific associations (27,28) (see Materials and Methods). Of note, we identified a highly statistically significant association between long TL and increased risk of lung adenocarcinoma with an odds ratio (OR) of 2.78 per 1 kb increase TL [95% confidence interval (CI) 2.16, 3.58; P = 6.3 × 10^-15]. However, we observed no such association for squamous cell carcinoma of the lung. Associations for these two lung cancer subtypes are displayed in Figure 1 (right) as solid red lines (slope = ln[OR]) overlaid on the association estimates for the nine SNPs that were used to generate the OR. A positive slope indicates that longer TL is associated with increased cancer risk, while a negative slope indicates that longer TL is associated with decreased risk. The correlation (r) between the magnitude of the SNPs’ associations with TL and the magnitude of the SNPs’ associations with adenocarcinoma risk was 0.17. Other than lung adenocarcinoma, no other cancer types showed a statistically significant association with the multi-SNP score. However, prostate cancer risk showed suggestive evidence of positive association with long TL with a Mendelian randomization OR of 1.21 per 1 kb increase in TL (95% CI 0.99, 1.46; P = 0.06). Scatter plots for all cancer types are displayed in Supplementary Material, Figure S2.

Additional age- and sex-stratified analyses were conducted for overall lung cancer, with findings indicating similar estimates

</table>

For younger subjects (≤50 years old) (OR = 1.95; 95% CI 1.19, 3.21; \( P = 0.006 \)) and older subjects (>50 years old) (OR = 1.78; 95% CI 1.47, 2.15; \( P = 2.98 \times 10^{-5} \)) and similar estimates for men (OR = 1.72; 95% CI 1.38, 2.14; \( P = 1.06 \times 10^{-5} \)) and women (OR = 1.99; 95% CI 1.42, 2.77; \( P = 5.3 \times 10^{-9} \)).

In addition to the inverse-variance weighted approach for obtaining Mendelian randomization estimates, we also used a likelihood-based Mendelian randomization method (28). Both methods produced very similar estimates for all cancer types, although the lung adenocarcinoma estimates varied more between the two methods compared with the other cancer types (Table 3).

**Sensitivity analyses**

The estimates reported above can only be interpreted as the causal effect of average TL on cancer risk when the Mendelian randomization assumptions are valid—namely, when (1) the SNPs from the literature are truly predictive of TL in the cancer-prone tissue, (2) the SNPs are not associated with other factors (confounders) that influence both TL and cancer risk and (3) the SNPs only affect cancer risk through their effects on TL, i.e. there are no alternative causal pathways by which the SNPs influence cancer risk. Violation of any of the assumptions can result in a biased causal estimate for the effect of TL on cancer risk. We performed sensitivity analyses in which SNPs were excluded from the multi-SNP score based on potential violation of these assumptions.

To assess a potential violation of the first assumption, an additional analysis was performed after excluding the SNP near the PXX region (rs6772228), which may be a false-positive association evidenced by its lack of plausible biological explanation, and the lack of consistency in its association with TL across several study sites (21). This ‘strict’ analysis resulted in a notable difference only for prostate cancer risk, which now showed a statistically significant estimate (OR 1.27; 95% CI 1.03, 1.54; \( P = 0.02 \)) (Supplementary Material, Table S1).

To assess potential violation of the second and third assumptions, an additional analysis was performed including only SNPs for which the magnitude of association with cancer risk appeared to be proportional to the magnitude of association with TL. Under Mendelian Randomization assumptions two and three, the ratio of the SNP–cancer association to the SNP–TL association for each SNP should be similar for all SNPs used in the SNP score. An inflation of the ratio for any single SNP may be an indication that the SNP exerts a pleiotropic effect on cancer that is unrelated to its effect on TL. Deviation from this expectation is tested using a goodness-of-fit test (29,30), in which SNPs that exhibit evidence of pleiotropy due to an inflated SNP–cancer to SNP–TL ratio can be detected and excluded from Mendelian randomization analyses (see Materials and Methods).

The exclusion of SNPs that failed the goodness-of-fit test (Supplementary Material, Table S2) resulted in two notable findings (Supplementary Material, Table S1). First, exclusion of the SNPs in the TERT and CTC1 regions from the SNP set used for overall prostate cancer resulted in a stronger, statistically significant association (OR = 1.45; 95% CI 1.18, 1.82; \( P = 7.9 \times 10^{-9} \)). Second, the exclusion of the SNP in the TERT region from the SNP set used for lung adenocarcinoma resulted in a somewhat attenuated association, but the association remained statistically significant: (OR = 2.00, 95% CI 1.48, 2.70, \( P = 6.6 \times 10^{-9} \)). Lung adenocarcinoma had a significant heterogeneity test statistic (Supplementary Material, Table S2), which likely explains why there was a difference in the estimates obtained using the inverse-variance weighted method and the likelihood method noted earlier; the optimization algorithm of the likelihood-based method can have poor convergence when the heterogeneity statistic is strongly significant (28). This difference in estimates between methods is eliminated after excluding the TERT SNP (rs2736100) that drives the heterogeneity in association estimates for lung adenocarcinoma.

**Discussion**

In this analysis of cancer risk across five cancer-prone organs, we observed that a multi-SNP score for long telomeres was significantly associated with increased risk of lung adenocarcinoma (but not squamous cell carcinoma) and suggestively associated with increased risk of prostate cancer. We did not observe an association between the multi-SNP score and risk of breast, colorectal or ovarian cancer (including subtypes). Under Mendelian randomization assumptions, the associations reported here can be interpreted as effects of TL on cancer risk, although caution regarding such an interpretation is warranted because the validity of these assumptions (such as the absence of pleiotropy) cannot...
be proven. Our results were consistent using two different analytic approaches. After performing sensitivity analyses in which SNPs were excluded from the multi-SNP score based on potential violation of Mendelian randomization assumptions, the association with prostate cancer risk became statistically significant. In addition, the exclusion of the SNP in the TERT region (a known susceptibility locus for lung cancer) from the lung adenocarcinoma analysis resulted in an attenuated but still highly statistically significant association, indicating that the observed association is not solely driven by the SNP in the TERT region. Even after dropping the three SNPs showing nominally significant \( P < 0.05 \) association with lung adenocarcinoma (in TERT, OBF1 and NAF1) the association is still significant \( (OR = 1.54, P = 0.018) \).

Several epidemiologic studies have examined the association between leukocyte TL and lung cancer risk. Three retrospective case–control studies reported an association between long TL and decreased lung cancer risk in US and Korean subjects \((7,31,32)\). However, a fourth stratified retrospective case–control study showed a positive association between TL and adenocarcinoma risk but an inverse association for squamous cell carcinoma \( (33)\). In two studies with prospective TL measurement, long TL was found to be associated with increased overall lung cancer risk among Caucasian male smokers \( (34)\) and East Asian female never-smokers \( (13)\), while a large Danish general population study found no association \( (12)\). In a pooled analysis of three prospective cohort studies including the two aforementioned studies and a third study conducted in the USA, long telomeres were associated with increased lung cancer risk, and the association was present in adenocarcinoma while absent in squamous cell carcinoma \( (35)\). Consistent with findings from the prospective studies and the stratified case–control study, we observed a positive association between the long TL SNP score and lung cancer risk corresponding to an OR of 1.65 per 1000 bp TL for overall lung cancer \( (P = 1.3 \times 10^{-8}) \) and an OR of 2.87 per 1000 bp TL for lung adenocarcinoma \( (P = 6.3 \times 10^{-15}) \) (assuming valid Mendelian randomization assumptions). Seow et al. \((35)\) reported the risk of overall lung cancer between the lowest quartile and highest quartile as \( OR = 1.86 \) (95% CI 1.33–2.62), and the risk of adenocarcinoma as \( OR = 2.52 \) (95% CI 1.38–4.60). While our estimates are not directly comparable to these prior estimates due to differences in the scale of the TL variable (kb vs. quartiles), we used a simple simulation to show that our estimates are similar to these prior estimates. We simulated normally distributed TL variables with a mean of 6000 bp and standard deviations ranging from 400 to 700 bp based on values observed from the prior literature \((36–38)\). The difference between the mean values for quartiles one and four ranged between 1018 and 1781 bp. We then rescaled our ORs to correspond to a difference in 1018–1781 bp rather than 1000 bp. The resulting estimates are \( OR = 1.68–2.94 \) for overall lung cancer risk between the lowest and highest quartiles, and \( OR = 2.92–5.11 \) for lung adenocarcinoma risk between the lowest and highest quartiles. These are comparable with the estimates reported by Seow et al. The observed heterogeneity in our association estimates is likely due to the two subtypes being biologically distinct, having previously been characterized as having different genetic susceptibilities \((39)\), unique gene expression profiles \((40)\), distinct molecular features \((41)\) and different patterns of chromosomal imbalance \((42)\).

The Asian female non-smokers among whom a TL-lung cancer association was observed \((13)\) were also recently studied to evaluate seven TL-associated SNPs in relation to lung cancer risk \((43)\). Consistent with our findings, the risk score for long TL was associated with an increase in lung cancer. Furthermore, their stratified analyses suggested a stronger association among younger individuals \((<60 \text{ years old})\) and significant associations for both adenocarcinoma and squamous cell subtypes. In contrast, our stratified analyses produced similar estimates by age and different estimates by subtype. Potential factors driving these differences in findings may be differences in ancestry or differences in the etiology of subtypes between the two study populations.

A protective effect of short TL on lung cancer risk has a biologically plausible explanation, as short telomeres could protect against cancer by triggering cell senescence or programmed cell death in the presence of functional cell cycle checkpoints and intact apoptotic pathways \((44)\). Conversely, long telomeres may enable additional rounds of cell division, allowing more opportunities for the accumulation of somatic mutations that promote carcinogenesis, resulting in greater susceptibility to malignant transformation \((45,46)\). The association between long TL SNPs and increased risk has also been previously observed for melanoma \((47)\), with a proposed mechanism being that long telomeres increase the proliferative duration of cells, thus delaying senescence and allowing further mutations to occur \((48)\).

Cigarette smoking is a potential confounder in many epidemiologic studies of TL and cancer due to its correlation with short TL \((49)\). However, our study utilizes genetic variants associated with TL as proxy for actual measured TL, and is therefore not subject to the potential confounding effects of smoking and other exposures. TL-outcome confounders such as smoking would only introduce bias if the genetic variants used in the score are also associated with smoking behavior, as it would be a violation of the second Mendelian randomization assumption. Smoking-related violation of Mendelian randomization assumptions (e.g., SNPs that influence TL through smoking behavior) is unlikely due to the lack of an association between the TL SNP score and squamous cell carcinoma of the lung, which would be expected to have a stronger association with smoking-related SNPs than adenocarcinoma \((50)\), and due to the lack of evidence that these SNPs influence smoking behavior based on prior GWAS studies.

There are few published studies on TL and prostate cancer risk. In a small retrospective case–control study \((51)\) and two prospective studies \((12,52)\), no statistically significant association was observed. In contrast, we observe a suggestive association between long TL and increased risk for prostate cancer, an association that increases in significance in the context of the ‘goodness-of-fit’-based sensitivity analyses. This finding warrants further investigation.

Results from prior studies of TL and colorectal cancer risk are also inconsistent. An inverse association between TL and colorectal cancer risk was described in two case–control studies \((9,14)\), while a U-shaped association \((16)\) and three null associations \((12,14,15)\) were observed in prospective studies. Consistent with the previous null-findings, our results show no significant association between TL and colorectal cancer risk, despite the inclusion of the TERC rs10936599 SNP, which was previously reported to be associated with both increased TL and increased risk of colorectal cancer \((53)\). The null findings were also consistent in an analysis of data from the Genetics and Epidemiology of Colorectal Cancer Consortium (GECCO) \((54)\) (Supplementary Material, Fig. S3).

Although one prospective study showed evidence for association between long TL and increased breast cancer risk \((12)\), two different meta-analyses of TL and breast cancer risk based on multiple retrospective and prospective studies concluded
there was no overall evidence of association (6,8). Our findings for
general breast cancer are in agreement with these prior null stud-
ies. In addition, we observe no association between the TL SNP
score and ER-negative breast cancer risk. For ovarian cancer,
two prior case–control studies observed an association between
longer telomeres and decreased risk (55,56), one case–control
study reported no association (57), while a prospective study
also reported no association (12). Our results for overall ovarian
cancer, as well as three subtypes, provide no evidence of associ-
ation with TL-associated SNPs. This lack of association is ob-
served despite the inclusion of SNP rs2736100 located in the
TERT region, which showed a nominally significant association
with the serous subtype of ovarian cancer ($P = 0.023$) and is in
high LD ($r^2 = 0.8$) with a SNP previously observed to be associated
with ovarian cancer (22). Estrogen has been demonstrated in ex-
perimental studies to have positive effects on telomerase activity
(58), and in epidemiologic studies estrogen has been shown to
have a positive association with TL (59). With estrogen as a potential
confounder of the association between TL and ER-positive
breast and ovarian cancers, it will likely be difficult to parse out
the specific role of TL in estrogen-related cancer risk in epidemi-
ological studies. However, Mendelian randomization estimates
such as those reported here will not be biased due to confounding
by estrogen level. These multi-SNP null findings are similar to what
Poooley et al. (21) also observed while investigating individual
TL SNP associations with breast, ovarian and prostate cancer risks.

Although it is not possible to prove the validity of the Mendel-
ian randomization assumptions, it is possible to conduct sen-
sitivity analyses to protect against some potential violations
of these assumptions. To address a potential violation of the first
assumption—that the SNPs are associated with TL in our
study population—we conducted analyses excluding PXX SNP
rs6772228, whose association with TL has been questioned due
to the lack of consistency in its association across several study
sites (21). After exclusion, the results were essentially unchanged.
For overall prostate cancer, however, the association became statis-

tically significant, lending support to the hypothesis that long TL
is associated with an increased risk of prostate cancer.

To address potential violations of the assumption that the
SNPs do not have effects on cancer risk independent of their effec-
t on TL, we re-estimated the associations between the TL SNP
score and cancer after stepwise removal of potentially problem-
atic SNPs from the SNP set using a goodness-of-fit test of the pro-
portionality of the SNPs’ associations with TL and cancer risk.
These exclusions resulted in some attenuation of the association
with lung adenocarcinoma, but did not substantially alter our
conclusions. For prostate cancer, the association with the multi-
SNP score became statistically significant after excluding
TERT SNP rs2736100 and CTC1 SNP rs3027234. The heterogeneity
in association of SNPs in TERT and CTC1 identified by the good-
ness-of-fit test suggests potential pleiotropic effects of these gen-
etic variants through mechanisms other than TL. The associa-
tion between TERT SNPs and breast and ovarian cancer risks via
pathways other than TL has been previously observed (22), and poten-
tial extra-telomeric roles have previously been suggested for both
telomerase (60) and CTC1 (61), providing a plausible biological
basis for excluding the TERT and CTC1 SNPs from our analysis.
It is important to note however, that these secondary sensitivity
analyses are data-driven, and are presented as a supplement to
the primary analyses that include all nine SNPs.

There are several limitations of this work. The summary-level
data did not allow for analyses stratified by covariates of interest
such as sex and age (with the exception of lung cancer, for which
TRICL conducted stratified analyses). Additionally, our analysis
assumed a log-linear association between TL and cancer risk,
and the existence of a non-linear (e.g. U-shaped) association
may limit our ability to detect an association. Our estimates gen-
erated using Mendelian randomization are unbiased only if the
SNPs analyzed do not affect cancer risk through causal pathways
other than those involving TL. This assumption cannot be pro-
ven; however, our confidence in the validity of this assumption
is strengthened by the fact that our primary finding is robust to
the exclusion of SNPs with potential pleiotropic actions based
on prior evidence (TERT) and a goodness-of-fit test (Supplemen-
tary Material, Tables S1, S2) (although it is possible that the good-
ness-of-fit test is underpowered to identify pleiotropic effects).
Our power to detect associations is limited by the small variance
in measured TL explained by SNPs used in this analysis (1–2%)
(62), although the GAME-ON Network provides very large sample
sizes that enable the detection of strong-to-moderate associations
(Supplementary Material, Table S3). Finally, we cannot confirm
that genetic determinants of leukocyte TL also predict tissue-
specific TL due to the lack of tissue-based TL measures in GWA
studies. A potential consequence of selecting SNPs lacking tis-

e-specific association with TL would be a bias toward the null,
reducing our power to detect associations using TL SNP scores.
However, correlations between TL measured in blood and TL mea-
sured in lung (63,64) and other tissues (65) have been reported ($r =
0.35–0.84), consistent with the assumption that SNPs predict TL
across multiple tissues. Systematic studies on other tissue types
are needed to further address this uncertainty.

In conclusion, in this comprehensive Mendelian randomiza-
tion study of TL and risk for common cancers, we observed a high-
ly significant association between genetic determinants of long
TL and increased risk for lung adenocarcinoma. The estimates re-
ported here are not vulnerable to biases caused by reverse caus-
ation or confounding by unmeasured environmental factors,
strengthening the evidence for a causal role for TL in lung adeno-
carcinoma. However, the validity of Mendelian randomization esti-
mates is dependent upon several assumptions, namely no
pleiotropic effects (independent of TL) of SNPs on the cancer
risk or confounders of the TL-cancer relationship. The multi-
SNP score for TL should be further investigated as a predictor of
adenocarcinoma of the lung, a common lung cancer subtype in
both smokers and non-smokers. Future research efforts need to
be undertaken to determine the value of telomeres as a novel
risk measure or a modifiable pharmacological target, with the
long-term goal of improving cancer prediction and prevention.

Materials and Methods

The GAME-ON network of consortia for post-GWA
research

The goals of the GAME-ON consortium were to pool data from
GWA studies to identify new loci, conduct functional studies to
identify causal SNPs and biological mechanisms, and to investi-
gate gene–gene and gene–environment interactions as a part of
efforts to develop risk prediction models. A secondary goal was
to test hypotheses across the centers that might illuminate com-
mon mechanisms of susceptibility. Details of GAME-ON and the
participating studies are available at http://epi.grants.cancer.gov/
gameon/, and described previously (26).

Identification of SNPs associated with TL

We identified nine SNPs showing independent genome-wide sig-
nificant associations ($P < 5 \times 10^{-8}$) with TL in previously published
GWA studies among individuals of European ancestry (19–21). Although there are specific cancer susceptibility regions of interest such as the previously described TERT locus, our selection of SNPs is based entirely on the SNPs’ ability to predict TL based on prior literature, because predictive accuracy is directly related to statistical power for Mendelian randomization (62). The proportion of variance in measured average TL that is explained by individual SNPs ranges from 0.06 to 0.2% (19), and is up to 1.6% for a combined subset of four SNPs (20) (no estimate is currently available for all nine SNPs). Based on the existing literature, we obtained the identifier for the lead SNP at each reported locus as well as the ‘long TL’ allele, association estimate for the ‘long’ allele (in terms of kb increase in TL per allele), standard error and P-value for each SNP’s association with TL (Table 2). Only the lead SNP from each region was included in the analysis. Although the estimates for these nine SNPs were obtained from three different studies using two different methods (quantitative PCR and Southern blot of the terminal restriction fragment), we scaled the estimates to the same units (kb of TL per risk allele). Comparability between studies is supported by previous studies showing that T/S ratio from qPCR using the Cawthon method is scaled the estimates to the same units (kb of TL per risk allele).

For each study, imputation was performed using the 1000 Genomes Project Phase 1 version 3 reference haplotypes, resulting in up to ~10 million SNPs being available for the analysis for each cancer type.

The second method is a likelihood-based method that has been described previously (28). In brief, TL and cancer risk were jointly modeled using a bivariate normal distribution for each genetic variant. The model parameters, including a joint linear effect between TL and cancer log-odds, were estimated using maximum likelihood on the observed data. The likelihood-based analyses were performed using web-based software (http://spark.rstudio.com/sb452/summarized/) (28).

The estimates obtained from the methods described above can be interpreted as the effect of average TL on cancer risk under the following assumptions as previously described for causal inference based on Mendelian randomization (25): (1) the SNPs from the literature are truly predictive of TL in the cancer-prone tissue, (2) the SNPs are not associated with other factors (confounders) that influence both TL and cancer risk and (3) the SNPs only affect cancer risk through their effects on TL, i.e. there are no alternative causal pathways by which the SNPs influence cancer risk.

To visualize the association results for the SNP score, we plotted the association between each SNP and cancer risk against associations with TL (based on the prior literature). Under the assumption that a SNP’s association with TL is proportional to its association with cancer risk, one would expect the plotted points to fall along a line that passes through the origin and has a slope equal to the Mendelian randomization estimate. Thus, a steeper slope indicates a stronger magnitude of association between TL and cancer risk. Conversely assuming no causal effect of TL on cancer risk, the Mendelian randomization estimate would correspond to a slope of zero.

To assess a potential violation of the first assumption (i.e., a true association between each of the variant and TL), an additional analysis was performed after excluding the SNP near the PXX region (rs6772228), which may be a false-positive association evidenced by its lack of plausible biological explanation, and the lack of consistency in its association with TL across several study sites (21). This analysis is referred to as the ‘strict’ analysis. To assess potential violation of the second and third assumptions (i.e., no confounding or pleiotropy), a goodness-of-fit test was performed for each SNP set under the null hypothesis that each SNP included in the SNP score has an association with cancer risk that is proportional to its association with TL. The rejection
of the null hypothesis indicated heterogeneity of the associations between SNPs and cancer risk relative to the associations between the SNPs and TL. In instances where the null hypothesis was rejected, stepwise removal of SNPs from the SNP set was performed until there was no significant heterogeneity, based on a method previously described (http://cran.r-project.org/web/packages/gtx/) (29). Specifically, For K uncorrelated SNPs,\
\[
X_k^2 = \sum_k Y_k^2 \sigma_k^{-2},
\]
(3)\
\[
X_r^2 = \left( \frac{\hat{\beta}_{IVW}}{SE(\hat{\beta}_{IVW})} \right)^2,
\]
(4)\
in which $X_k^2$ and $X_r^2$ are $\chi^2$-distributed test statistics, respectively, for the association between each cancer type and all K SNPs under an unconstrained K degree-of-freedom model, and for the nested 1 degree-of-freedom risk score model, respectively. Then the goodness-of-fit test statistic is\
\[
Q_K = X_K^2 - X_r^2,
\]
(5)\
in which $Q_K$ is $\chi^2_{K-1}$, distributed under the null hypothesis that all K SNPs are associated with cancer risk with true association sizes proportional to the associations with TL. For each analysis in which the goodness-of-fit test null hypothesis was rejected (P < 0.05), we removed the SNP that resulted in the greatest reduction of the $Q_K$ test statistic, and repeated the goodness-of-fit test. If still P < 0.05, we repeated the exclusion procedure until P > 0.05. The association estimates obtained from the subsequent analysis using the remaining SNPs that pass the goodness-of-fit test is referred to as the ‘goodness-of-fit based’ estimates and displayed in Supplementary Material, Table S1. P-values for the goodness-of-fit test before and after exclusion of SNPs, and which SNPs were excluded for each cancer analysis for the ‘goodness-of-fit based’ analysis are shown in Supplementary Material, Table S2. An example for this procedure is as follows: for lung adenocarcinoma, the inclusion of all nine SNPs results in an OR of 2.87 ($P = 6.3 \times 10^{-15}$), but the goodness-of-fit test P-value of 9.0 x $10^{-6}$ indicates the presence of heterogeneity with at least one of the SNPs used in the SNP score. The TERT SNP was identified to be the SNP contributing the most to this heterogeneity (by stepwise exclusion), and once removed, resulted in a SNP score with a goodness-of-fit P-value of 0.09, indicating a lack of substantial heterogeneity in ratio of SNP–cancer to SNP–telomere associations across SNPs. After exclusion of the TERT SNP, we still observe a significant association in the same direction, albeit attenuated (OR = 2.00, P = 6.6 x $10^{-6}$).

We performed power analyses to estimate the minimum detectable magnitude of association for each cancer type given the sample sizes available in the GAME-ON study, in terms of OR per 1 kb increase in TL. This was done using a web-based application (http://glimmer.rstudio.com/KN3in/mRNd/) (69), specifying 80% power, 0.05 type I error rate, and assuming the variance in TL explained by the nine SNPs is $R^2 = 0.01$ or $R^2 = 0.02$, respectively. Because the web application calculates the detectable OR of cancer risk per one standard deviation of TL, which is roughly equivalent to 500 bp (36,37), we exponentiated this OR to the power of 0.5 in order to obtain the detectable OR per 1000 bp increase TL. (Supplementary Material, Table S3).
