Search for active neutrino disappearance using neutral-current interactions in the MINOS long-baseline experiment

We report the first detailed comparisons of the rates and spectra of neutral-current neutrino interactions at two widely separated locations. A depletion in the rate at the far site would indicate mixing between $\nu_\mu$ and a sterile particle. No anomalous depletion in the reconstructed energy spectrum is observed. Assuming oscillations occur at a single mass-squared splitting, a fit to the neutral- and charged-current energy spectra limits the fraction of $\nu_\mu$ oscillating to a sterile neutrino to be below $0.68 \at 90\% confidence level. A less stringent limit due to a possible contribution to the measured neutral-current event rate at the far site from $\nu_e$ appearance at the current experimental limit is also presented.

PACS numbers: 14.60.St, 14.60.Pq

Several experiments observing charged-current interactions of neutrinos have provided compelling evidence for $\nu_\mu$ and $\nu_e$ disappearance as the neutrinos propagate from the point of production $^{1,2,3,4,5}$. The Super-Kamiokande experiment has reported extensively on the disappearance of $\nu_\mu$ produced in the atmosphere $^2$. Measurements of solar $\nu_e$ showed that the disappearance of those neutrinos is due to matter enhanced conversions $^3$. The KamLAND reactor experiment provided clear evidence for $\nu_e$ mixing $^4$.

These results are conventionally interpreted as mixing among the active neutrino flavors that couple to the electroweak current. Precise measurements of the $Z$ boson decay width indicate there are only three light active neutrinos $^6$, but they do not exclude the existence of “sterile” neutrinos, $\nu_s$, that do not couple to the electroweak current. Sterile neutrinos could help resolve several outstanding problems in particle physics and astrophysics. For example, sterile neutrinos with masses at the eV energy scale can participate in the seesaw mechanism to introduce neutrino masses $^7$ and can also aid in heavy element nucleosynthesis in supernovae $^8$. The SNO experiment has shown that the total flux of active neutrinos from the Sun agrees with the expectation from solar models $^9$, thereby limiting the extent to which the first or second neutrino mass eigenstates could couple to a sterile neutrino. While the Super-Kamiokande experiment excludes pure $\nu_\mu \to \nu_s$ and favors pure $\nu_\mu \to \nu_\tau$ oscillations in its analysis of atmospheric neutrinos, an admixture of the two possibilities is allowed $^{10}$ and has attracted considerable attention in the literature $^{11}$.

The MINOS experiment has reported a significant deficit of $\nu_\mu$ at its far detector relative to the near detector through measurement of the rate of $\nu_\mu$ charged-current (CC) interactions $^{12}$. If this deficit is due solely to conversions of $\nu_\mu$ to $\nu_\tau + \nu_e$, then the rate of neutral-current (NC) interactions at the far detector remains unchanged from the non-oscillation prediction. Alternatively, if any $\nu_\mu$ convert to a sterile state, then the NC rate would be suppressed and the reconstructed energy spectrum would be distorted. In this Letter we report the first measurement of the total active neutrino rate using a precisely known long baseline and neutrinos produced with an accelerator. The reconstructed energy spectra for NC and CC interactions are used to limit the fraction of $\nu_\mu$ converting to $\nu_s$ by fitting them to a model of oscillations between $\nu_\mu, \nu_\tau, \nu_e$, and $\nu_s$ dominated by the atmospheric mass-squared splitting.

The neutrino beam is produced using 120 GeV/c protons from the Fermilab Main Injector incident on a graphite target, which is followed by two magnetic focussing horns. The neutrino energy spectrum can be changed by adjusting the horn current or the position of the target relative to the horns. The flavor composition of the beam is $92.9\% \nu_\mu, 5.8\% \nu_\tau$, and $1.3\% \nu_e + \overline{\nu}_e$. In this analysis the $\nu$ and $\overline{\nu}$ are assumed to oscillate with the same parameters. The data used in this analysis come from the low energy beam configuration whose peak neutrino energy is $3.3$ GeV $^5$ $^{12}$, with an exposure of the far detector to $2.46 \times 10^{20}$ protons on target.

The MINOS near detector is located 1.04 km downstream of the target, has a mass of 0.98 kt, and lies 103 m underground at Fermilab. The far detector is 734 km downstream of the near detector, has a mass of 5.4 kt, and is located in the Soudan Underground Laboratory in Minnesota, 705 m below the surface. The fiducial masses used for the near and far detectors are 27 t and 3.8 kt respectively.

The MINOS detectors are steel scintillator tracking calorimeters $^{13}$. The vertically oriented detector planes are composed of 2.54 cm thick steel and 1 cm thick plastic scintillator. The scintillator layer is comprised of 4.1 cm wide strips with each strip coupled via wavelength-shifting fiber to one pixel of a multi-anode photo-multiplier tube $^{14}$. The near(far) detector is magnetized to an average toroidal field of 1.3(1.4) T.

Hadronic showers resulting from NC interactions generate scintillation light in an average of 12 strips for 1 GeV of deposited energy. Events must have at least 4 strips with signal in order to be considered in the analysis. Individual scintillator strips are grouped into either reconstructed tracks or showers, which are combined into events. The vertex for each event is required to be sufficiently far from any edge of the detector to ensure that the final-state hadronic showers are well contained within the fully sampled portion of the detectors.

The near detector data are used to predict the number of expected events in the far detector, but the ability to make this prediction is complicated by the high rate environment at the near detector. At an intensity of $2.2 \times 10^{13}$

*Deceased.
protons on target, an average of 16 neutrino interactions are produced in the near detector for each spill [5]. The reconstruction program separates individual neutrino interactions that occur within the same spill. This initial pass overestimates the number of NC interactions having reconstructed energy, $E_{\text{reco}} < 1$ GeV by 36%. Additional selections making use of event topology and timing are then used to decrease this background. Events must be separated by at least 40 ns, and events that occur within 120 ns of each other must have vertices separated by at least 1 m in the longitudinal direction [10]. After applying these criteria, the remaining background from poorly reconstructed events with $E_{\text{reco}} < 1$ GeV is 7%.

The rate of neutrino interactions from the neutrino beam in the far detector is much lower than in the near detector, with approximately 1 interaction for every $10^4$ spills. Interactions from the beam neutrinos are identified using a window around the GPS time stamp of the spills of $-2 \mu s < t < 12 \mu s$ where $t = 0$ is the expected start time at the far detector of the 10 µs spill. Given the low rate of neutrino interactions in the far detector, spurious events that are coincident with the beam spills from noise, cosmic-ray muons, or poor event reconstruction can introduce backgrounds to the analysis. Additional criteria are used to remove such events, leaving a residual background of $< 1\%$ of the signal [17].

Charged-current interactions are identified by the presence of a track that may or may not be associated with a shower. Neutral-current interactions typically have a single hadronic shower, although the reconstruction may identify a track in the event; such tracks could come from pions, but are mostly reconstruction artifacts. An event is classified as NC-like if it has a reconstructed shower, is shorter than 60 planes, and has no track extending more than 5 consecutive planes beyond the shower [18]. Distributions of these event-topology parameters for near detector events are shown in Fig. 1. The principal background in the spectrum of NC-like events comes from highly inelastic $\nu_\mu$-CC interactions. The $E_{\text{reco}}$ spectrum of NC-like events in the near detector is shown in Fig. 2. The distributions in Figs. 1 and 2 show good agreement between the data and Monte Carlo simulation.

The Monte Carlo simulation is used to make an initial estimate of the ratio of event yields in the far and near detectors as a function of $E_{\text{reco}}$. This ratio is multiplied by the observed energy spectrum in the near detector to produce a far detector prediction of the NC-like event spectrum. The true energy of the simulated neutrinos in each reconstructed energy bin of the prediction is used to determine the effect of oscillations for that range of reconstructed energy. To avoid biases, the methods for identifying NC-like events and predicting the far detector spectrum were developed and tested using only the near detector data and Monte Carlo simulation, and the analysis procedures were finalized prior to examining data in the far detector.

Figure 3 shows the measured and predicted $E_{\text{reco}}$ spectra at the far detector. The spectra are compared using a statistic, $R$, which expresses the agreement between the predicted and observed number of events in the far detector:

$$R = \frac{N_{\text{Data}} - B_{\text{CC}}}{\sigma_{\text{NC}}},$$

where, within a given energy range, $N_{\text{Data}}$ is the measured event count, $B_{\text{CC}}$ is the extrapolated CC background from all flavors, and $\sigma_{\text{NC}}$ is the extrapolated number of NC interactions. The values of $\sigma_{\text{NC}}$ and contributions to $B_{\text{CC}}$ are calculated in the framework of three neutrino oscillations and are shown in Table II. Because the disappearance of $\nu_\mu$ occurs mainly for true neutrino energies $< 6$ GeV [12], the data are separated into two samples. Events with $E_{\text{reco}} < 3$ GeV are grouped into a low-energy sample while events with $3 < E_{\text{reco}} < 120$ GeV are grouped into a high-energy sample. The median true neutrino energies of the low and high energy samples are 3.1 GeV and 7.9 GeV respectively. The values of $R$ calculated for these ranges in $E_{\text{reco}}$ are shown in Table 1. In the region with $E_{\text{reco}} < 3$ GeV, $R$ differs from 1 by $1.3\sigma$. Over the full energy range, $0 - 120$ GeV, the depletion of the total NC event rate is limited to be below 17% at 90% confidence level.

The principal sources of systematic uncertainty in $R$...
including for various reconstructed energy ranges. Also shown are the shown in Table II.

In each reconstructed energy bin, three other beam configurations with higher average neutrino energy is known to within 12%, of which 10% reflects uncertainties in the final-state interactions in the nucleus and 6% results from uncertainty in the detector efficiency, the back-

are listed in Table II. The absolute scale of the hadronic energy is known to within 12%, of which 10% reflects uncertainties in the final-state interactions in the nucleus and 6% results from uncertainty in the detector response to single hadrons. The relative calibration of the hadronic energy between the two detectors has an uncertainty of 3%[3], and the relative normalization between the detectors has an uncertainty of 4%. The uncertainty in the near detector event count due to the selection criteria is 15% for $E_{\text{reco}} < 0.5$ GeV; 3% for events with 0.5 GeV $< E_{\text{reco}} < 1$ GeV; and is negligible for $E_{\text{reco}} > 1$ GeV. The effect of these uncertainties on $R$ is shown in Table II.

The uncertainty on the size of the $\nu_\tau$-CC background was determined by comparing the near detector NC-like reconstructed energy spectrum from the low energy beam configuration used in this analysis with the spectra from three other beam configurations with higher average neutrino energy. In each reconstructed energy bin, $i$, of the low energy beam the total number of events is the sum of the NC and CC interactions, $N_i = N_{iNC} + N_{iCC}$. The quantity $N_{iNC}$ is defined as the ratio of the number of NC/CC interactions in each energy bin in an alternative beam configuration to the corresponding number in the low energy beam configuration. The value of $CC_i$ can be calculated from the spectrum in another beam,

$$CC_i = \frac{N_{iNC} - N_{iCC}}{N_{iNC} - N_{iCC}},$$

where $N_{iA}$ is the total number of events observed in the alternate beam configuration. The values of $r_{iNC}^{NC}$ and $r_{iCC}^{CC}$ are taken from the Monte Carlo simulation. The uncertainty in the $\nu_\mu$-CC background is taken as the difference between the uncertainty-weighted average value of $CC_i$ measured using the different beam configurations and the value predicted by the Monte Carlo simulation. That difference is consistent within 15% for all reconstructed energies. The size of the $\nu_\tau$-CC background at the far detector depends on the parameters for $\nu_\mu \to \nu_\tau$ oscillations used in the prediction. The MINOS measured values of $\delta m_{32}^2 = 2.43 \times 10^{-3} \text{eV}^2/c^4$ and $\theta_{23} = \pi/4$[12] were used for the prediction, and variations within the 1σ range of these parameters change the $\nu_\mu$-CC background in the far detector by less than 10%.

Because the selection criteria identify $\nu_\tau$-CC interactions as NC-like with nearly 100% efficiency, the background from $\nu_\mu$ inherent in the beam and $\nu_\mu \to \nu_\tau$ oscillations is also considered. An upper limit for the $\nu_\tau$-CC rate in the far detector was estimated using the normal mass hierarchy with $\theta_{13} = 0.61$ rad, $\theta_{13} = 0.21$ rad, $\delta = 3\pi/2$ rad, $\Delta m_{32}^2 = 7.59 \times 10^{-5} \text{eV}^2/c^4$, and $\Delta m_{21}^2 = 2.43 \times 10^{-3} \text{eV}^2/c^4$[12]. The choice of $\theta_{13}$ corresponds to the 90% confidence level upper limit for the chosen $\Delta m_{32}^2$ value[19]. The contribution to $B_{CC}$ from $\nu_\tau$ and the values of $R$ in the different energy ranges under these assumptions are shown in Table II.

The data shown in Fig. 2 can be combined with the data from CC interactions to determine whether the previously observed $\nu_\mu$ disappearance is due solely to oscillations between the active neutrinos, or if oscillations between active and sterile neutrinos also occur. To determine the fraction of $\nu_\mu$ that have converted to a sterile state, the data are fit to a model that assumes oscillations between $\nu_\mu$, $\nu_\tau$, and $\nu_s$ occur at a single mass-squared splitting. The probabilities for $\nu_\mu$ to remain $\nu_\mu$, or convert to $\nu_s$ are

$$P_{\nu_\mu \to \nu_\mu} = 1 - \alpha_\mu \sin^2(1.27 \Delta m^2 L/E),$$

$$P_{\nu_\mu \to \nu_s} = \alpha_\mu \sin^2(1.27 \Delta m^2 L/E),$$

where $\Delta m^2$ is the atmospheric mass-squared splitting in
related to the mixing angles. A simultaneous fit to the
to the systematic uncertainty in the predicted rates.

tector with predictions for the two oscillation hypotheses
described in the text. The filled regions in each bin indicates
the 90% confidence level upper limit on the corresponding mass-squared splitting.

with \( \chi^2 = 46.5 \) for 43 degrees of freedom and \( f_s < 0.68 \) at
90% confidence level. The fit includes the systematic un-
certainties in Table II as nuisance parameters. Including
electron neutrino appearance at the previously discussed upper limit results in
\( f_s = 0.43^{+0.23}_{-0.22} \) (stat.+syst.) with \( \chi^2 = 46.6 \) and \( f_s < 0.80 \) at 90% confidence level.

In summary, we have reported the first measurements
of neutrino neutral-current rates and spectra in an ac-
celerator long baseline neutrino experiment. The rates
at the near and far detectors are consistent with expec-
tations from decay kinematics and geometry, providing
new support for the interpretation of muon neutrino dis-
appearance as oscillations among the three active neutrinos. This result provides the best limits to date on the
fraction of muon neutrinos which may convert to sterile
neutrinos in oscillations associated with the atmospheric
mass-squared splitting.
