Production of the cells that ultimately populate the thymus to generate α/β T cells has been controversial, and their molecular drivers remain undefined. Here, we report that specific deletion of bone–producing osteocalcin (Ocn)–expressing cells in vivo markedly reduces T–competent progenitors and thymus–homing receptor expression among bone marrow hematopoietic cells. Decreased intrathymic T cell precursors and decreased generation of mature T cells occurred despite normal thymic function. The Notch ligand DLL4 is abundantly expressed on bone marrow Ocn+ cells, and selective depletion of DLL4 from these cells recapitulated the thymopoietic abnormality. These data indicate that specific mesenchymal cells in bone marrow provide key molecular drivers enforcing thymus–seeding progenitor generation and thereby directly link skeletal biology to the production of T cell–based adaptive immunity.

Bone mesenchymal cells are central participants in hematopoiesis, providing niches regulating stem and progenitor cells. Lymphopoiesis depends on tissues outside the bone marrow for terminal maturation, but antigen–independent specification of lymphoid lineages is hypothesized to occur in bone marrow. B cell generation has been definitively shown to involve osteolineage cells, whereas T cell generation remains controversial (Visnjic et al., 2004; Zhu et al., 2007; Wu et al., 2008). Deletion of CXCL12 in early osteolineage cells decreased B cell progenitors, whereas deletion of osteocytes produced dramatic metabolic changes, primary damage to thymus, and decreased B and T cell generation through an undefined molecular mechanism (Ding and Morrison, 2013; Greenbaum et al., 2013; Sato et al., 2013). Co–culture of hematopoietic progenitors with bone marrow stroma cells overexpressing Notch ligands enabled T cell lineage generation in vitro (Holmes and Zúñiga–Pflücker, 2009), but whether this recapitulates in vivo events in the bone marrow microenvironment is unclear (Uihmann et al., 2011).

The details of the prethymic process are of increasing interest given that early thymic progenitors may serve as a limiting substrate in immune reconstitution after transplant (Zlotoff et al., 2011). It is available under a Creative Commons License (Attribution–Noncommercial–Share Alike 3.0 Unported, as described at http://creativecommons.org/licenses/by-nc-sa/3.0/).
ex vivo generated human pro–T cells improved T cell reconstitution, thymic architecture, and immunological competence in immunodeficient mice (Zakrzewski et al., 2006; Awong et al., 2013). Therefore, understanding and modulating the production of bone marrow–derived cells that can populate the thymus may have practical consequences in medicine.

RESULTS

We generated mouse strains in which Cre recombinase produced by either the Osteocalcin promoter expressed in mature osteoblasts and osteocytes, or the Osterix promoter expressed in distinct, more immature subsets of bone cells, drives expression of the diphtheria toxin (DT) receptor (DTR) on cell surface (OcnCre+/−;iDTR and OssCre+/−;iDTR, respectively; OcnCre+/− and OssCre+/− served as controls). Specific in vivo cell ablation was achieved by intraperitoneal injection of DT. Daily injections into both control and mutant animals began at age 4 wk, and by 6 wk a difference in body size was noted in both the OssCre+/−;iDTR and OcnCre+/−;iDTR mutant mice compared with littermate controls, which is consistent with inhibition of bone formation (Fig. 1 A). In early experiments, OssCre+/−;iDTR and OcnCre+/−;iDTR animals without DT treatment were assessed and no phenotypic difference with the OssCre+/− and OcnCre+/− controls were noted and therefore are not presented further. The T lymphopoeitic effect was observed only in the OcnCre+/−;iDTR strain and not the OssCre+/−;iDTR strain, and thus it is the focus of this work.

Histomorphometry revealed ~70% deletion of osteoblasts and osteocytes in the OcnCre+/−;iDTR mutants (Fig. 1, B and C). To evaluate whether DTR was expressed in the correct cells in bone marrow, immunohistochemistry for DTR without toxin injection was performed and demonstrated overlap with anti–Ocn staining (Fig. 1 D). TUNEL staining after DT administration demonstrated overlap with osteocalcin–specific antibodies (Fig. 1 E), indicating selective cell killing.

Osteocytes were assessed by TRAP staining and histomorphometry (Fig. 1 F), and measuring endogenous osteoclast activity (Fig. 1 G); these indices were not affected by 2 wk of toxin administration in OcnCre+/−;iDTR mice. Testing whether osteolineage cell depletion might lead to an excess of primitive responding bone progenitor cells, primitive mesenchymal progenitors were assessed by colony forming unit–osteoblast (CFU–Ob) assays and found to be unchanged (Fig. 1 H). No detectable changes in CD31−CD45−Ter119−LepR+ stromal cells were observed (Fig. 1 I).

Despite the changes in bone morphology, overall bone marrow cellularity was unaffected as were blood and bone marrow count of mature hematopoietic cells except lymphoid cells (Fig. 2 A). This was associated with reduced common lymphoid progenitors (CLPs) within the bone marrow and blood and in particular, CLP with T cell potential (Lineage−Sca−cKit+IL7R+Thy1.2−Ly6D−; Inlay et al., 2009; Manson et al., 2010; Fig. 2, B and C), whereas B-lineage biased CLP (Lineage−Sca−cKit+IL7R+Thy1.2−Ly6D−; Tsapogas et al., 2011; Welinder et al., 2011) and progenitors of other lineages, including common myeloid progenitor (CMP), granulocyte and macrophage progenitor (GMP), and megakaryocyte-erythroid progenitor (MEP), were not changed (Fig. 2 B). We observed a decrease in bone marrow pro–B subsets, but not in prepro–B cells or downstream pre–B and mature B cells (Fig. 2 D). Spleen weight, cellularity, and B cell count were also not significantly affected. The decrease in B cell intermediates, whereas Ly6D+CLPs were normal suggests that specification of B-lineage was not perturbed, but that support of downstream differentiation events was abnormal, as has been seen in other osteoleineage modifications (Zhu et al., 2007; Wu et al., 2008; Ding and Morrison, 2013; Greenbaum et al., 2013).

Accompanying the decreased T-competent CLPs in the bone marrow, downstream T-progenitor and mature cells in the thymus were also reduced (Fig. 2 E). We confirmed that Ly6D−CLPs are T cell competent by transplantation (Fig. 3 A), and we examined populations others have used in defining T-competent CLP (Flt3+Ly6D−CLP [Karsunky et al., 2008; Inlay et al., 2009] and CLP-1 [Seimone et al., 2006; Krueger and von Boehmer, 2007]). Decreases in each of these was seen with Ocn+ cell depletion and levels were comparable to Ly6D−CLP (unpublished data). Of note, there was no detectable DTR expressed on CLPs to suggest ectopic cell killing by DT.

Despite the increased immunophenotypic hematopoietic stem and progenitor cell (HSPC; Lin−Sca−cKit−CD48−CD150+) number, cell cycling (Fig. 3, B–D), and increased reconstitution at 8 and 12 wk after bone marrow transplantation (Fig. 3 E), no long-term advantage in reconstitution was scored at 16 wk after primary transplantation in a competitive transplant assay. There was also no detectable change in secondary transplantation of cells from the Ocn+ deleted animals. These data are consistent with altered cycling of long-term HSC (LT HSC) without an effect on the functionally defined reconstituting ability of these cells by primary and secondary transplantation. The data indicate an effect on short-term HSC (ST HSC) and do not exclude an effect on LT HSC, just not a change in their reconstituting ability from the Ocn+ cell depleted bone marrow. It is possible that longer term exposure to the Ocn+ cell–depleted marrow would affect functional LT HSC number. It is also possible that other important functional changes were induced, but not measured in our studies.

To evaluate the microenvironment dependence of T-lymphopoiesis, WT congenic hematopoietic cells were transplanted into OcnCre+/−;iDTR hosts; the abnormal lymphopoietic phenotype was recapitulated (Fig. 4 A). Reciprocally, OcnCre+/−;iDTR mutant donor bone marrow reverted to normal phenotype when transplanted into WT congenic hosts (Fig. 4 B). Testing whether the effect was on the basis of differential cell proliferation or survival, CLP cell cycling by Ki67 and DAPI staining and cell death by Annexin V and 7-amino-actinomycin D (7-AAD) staining were assessed and found to be unchanged (Fig. 4 A). Accompanying the decreased T-competent CLPs in the bone marrow, downstream T-progenitor and mature cells in the thymus were also reduced (Fig. 2 E). We confirmed that Ly6D−CLP are T cell competent by transplantation (Fig. 3 A), and we examined populations others have used in defining T-competent CLP (Flt3+Ly6D−CLP [Karsunky et al., 2008; Inlay et al., 2009] and CLP-1 [Seimone et al., 2006; Krueger and von Boehmer, 2007]). Decreases in each of these was seen with Ocn+ cell depletion and levels were comparable to Ly6D−CLP (unpublished data). Of note, there was no detectable DTR expressed on CLPs to suggest ectopic cell killing by DT.
Since Notch is an essential determinant of T-lymphoid commitment and is required for progression through the DN stage (Sambandam et al., 2005; Tan et al., 2005; Visan et al., 2006; Rothenberg et al., 2010; Love and Bhandoola, 2011), we hypothesized that Notch may be participating in the phenotype observed. Notch participation in T-lymphopoiesis before thymic location was previously discounted (Krueger and von Boehmer, 2007), but the cells that were examined have since been shown to be precursors of extrathymic maturation and do not represent thymic progenitors (Luche et al., 2013). In contrast, some studies have reported Notch signaling in bone marrow T cell progenitors (Harman et al., 2005; Maeda et al., 2007). We assessed bone marrow CLP by flow cytometry for evidence of activated, or cleaved Notch and lower levels were observed in OcnCre<sup>−/−</sup>;iDTR mutants or WT (Ctrl) mice were assessed histologically. Bottom images are at a higher magnification with arrows pointing to empty lacunae within the cortex and altered endosteal surface; images reflect comparable findings in all animals; n = 8/experiment. (C) Osteoblasts in the OcnCre<sup>−/−</sup>;iDTR and WT mice were quantitated by histomorphometry; n = 7–8 mice/group. Data show mean ± SEM. (D and E) Ocn and DTR expression was examined in bone sections from untreated OcnCre<sup>−/−</sup>;iDTR by immunohistochemistry using Ocn- and DTR-specific antibodies (D), or by immunofluorescence using Ocn-specific antibodies and TUNEL staining after DT treatment (E); n = 6 mice/group. (F) Osteoclast numbers were assessed by TRAP staining (n = 6 mice/group) and (G) osteoclast activity by collagen breakdown in sera using ELISA assay; n = 7–8 mice/group. Data show mean ± SEM. (H) Mesenchymal progenitor activity in the bone marrow of OcnCre<sup>−/−</sup>;iDTR mutants or WT controls was assessed by CFU-Ob assay; n = 9 mice/group. Data show mean ± SEM. (I) CD31<sup>−</sup>CD45<sup>−</sup>Ter119<sup>−</sup>LepR<sup>+</sup> cells in the bone marrow stroma of OcnCre<sup>−/−</sup>;iDTR mutants and controls were quantified by flow cytometry; n = 6–7 mice/group. Data show mean ± SEM. (A–I) For each experiment, 3–6 independent repeats were performed.
Figure 2. Ocn* cell deletion decreases T cell competent lymphoid progenitors and T lineage cells. (A) Flow cytometric evaluation of lymphoid, myeloid, erythroid, and megakaryoctic mature cells and (B) T cell competent (Ly6D−) CLP, B potential enriched (Ly6D+) CLP, CMP, GMP, and MEP populations in the bone marrow of control and Ocn* cell-deleted animals. Minimum of three independent experiments; n = 8–16 mice/group. Data show mean ± SEM. (C) Gene set enrichment analysis (GSEA) comparing Ly6D− CLP versus multipotent progenitor (MPP) microarray data. Experiment was performed twice independently; n = 3/experiment. (D) Flow cytometric quantification of different stages of B progenitors and mature cells in the bone marrow of OcnCre;iDTR mutant and control littermates. Experiment was performed twice independently; n = 5–6 mice/group. Data show mean ± SEM. (E) Flow cytometric quantification of T cell subsets in the thymus. Minimum of four independent experiments; n = 8–12 mice/group. Data show mean ± SEM.
We tested whether Notch ligand expression specifically by Ocn+ cells caused the lymphopoietic phenotype using the conditional OcnCreER;DLL4Fl/Fl strain. Ocn+ cell-specific DLL4 deletion resulted in significantly reduced Notch-activated CLP, T cell–competent Ly6D−CLP, and CCR7-expressing Ly6D−CLP (Fig. 6A, discussed in the following paragraphs), with a decrease comparable in magnitude to that seen with Ocn+ cell depletion (Fig. 2B). Thymic intermediates and blood T-lymphocytes were also decreased (Fig. 6A).

Similar changes were noted when Mindbomb1 (Mib1), encoding an E3-ligase necessary for Notch ligand processing (Koo et al., 2005), was deleted in Ocn+ cells (Fig. 6B). Together, these data demonstrate the role of Notch ligands expressed by Ocn+ cells as the basis for the decrease in T-lymphopoiesis.

and Osx+Ocn+ cells yellow. This system allowed clear distinction and isolation of different osteolineage subsets within the same animal by flow cytometry. Immunohistochemistry (Fig. 5D) and gene expression data (Fig. 5E) showed that Ocn+ mature osteoblasts, but not other osteolineage cells, potently expressed DLL4, and both mRNA and protein were markedly reduced in OcnCre+/−;iDTR mice with protein notably decreased at the endosteal interface. This change in DLL4 was associated with corresponding alterations in Notch target genes in CLPs in the bone marrow by gene set enrichment analysis (GSEA; Fig. 5F). These data suggest that reduced DLL4 expression from Ocn+ cells led to reduced intracellular Notch activation in the hematopoietic precursors within the bone marrow, thereby limiting T-lineage specification.

We tested whether Notch ligand expression specifically by Ocn+ cells caused the lymphopoietic phenotype using the conditional OcnCreER;DLL4FliDTR strain. Ocn+ cell–specific DLL4 deletion resulted in significantly reduced Notch-activated CLP, T cell–competent Ly6D−CLP, and CCR7-expressing Ly6D−CLP (Fig. 6A, discussed in the following paragraphs), with a decrease comparable in magnitude to that seen with Ocn+ cell depletion (Fig. 2B). Thymic intermediates and blood T-lymphocytes were also decreased (Fig. 6A).
Dll4 specifies thymus-seeding progenitors | Yu et al.

models confirm the role of Notch signaling in early T-lineage differentiation: altering bone marrow generation of thymic progenitors. Further, the comparable changes seen when either the ligand or receptor were modified suggest that the interaction of Ocn$^+$cell and hematopoietic cells may be direct rather than through other microenvironmental cell types and argue against the phenotype being on the basis of stress or secondary metabolic changes.

The abnormality in T-lymphopoiesis could reflect dysfunction of the thymus itself or of the immigrants to the thymus arriving from the bone marrow. To assess this, we evaluated osteocalcin and DTR expression in thymic tissue, but found none by immunohistochemistry; no change in thymic histology or thymic DLL4 mRNA by quantitative PCR was observed after Ocn$^+$cell depletion (unpublished data). To determine if thymic function was altered in Ocn$^+$cell–deleted animals, we adoptively transferred WT Ly6D$^-$CLP or Lin$^-$/Sca$^+$cKit$^+$Flt3$^+$ hematopoietic progenitor cells into the thymi of either OcnCre$^+/-$;iDTR mutant or control recipients in vivo, and detected no difference in thymocyte maturation.

Testing of Notch-signaling in hematopoietic cells was then performed by several models. The Protein O-fucosyltransferase1 gene product (Pofut1) transfers O-fucose to the EGF-like repeats on Notch and is required for the binding of Delta-like ligands (Yao et al., 2011). Deleting it using Mx1-Cre$^+/-$;Pofut1$^{fl/fl}$ mice revealed decreased CLP and Ly6D$^-$CLP compared with controls (Fig. 7 A). Because Pofut1 does not act exclusively on Notch receptors, the downstream signaling mediator RBP-J$^k$ was also assessed. Mx1-Cre deletion of RBP-J$^k$ compromised bone marrow CLP and Ly6D$^-$CLP (Fig. 7 B). Further, intrafemoral injection of the $\gamma$-secretase inhibitor N-[N-(3,5-difluorophenacetyl)-l-alanyl]-S-phenylglycine t-butyl ester (DAPT) reduced CLP and Ly6D$^-$CLP on the ipsilateral side (Fig. 8 A). Lastly, intravenously transplanted $10^6$ Lin$^-$ hematopoietic progenitor cells from Mx1Cre;LSL-NICD-GFP mice expressing a dominant-active Notch intracellular domain (NICD) rescued the OcnCre;iDTR lymphoid defect in Ly6D$^-$CLP and Ly6D$^+$CCR7$^+$CLP compared with Mx1Cre;LSL-GFP controls (Fig. 8 B). Collectively, these in vivo genetic mouse models confirm the role of Notch signaling in early T-lineage differentiation: altering bone marrow generation of thymic progenitors. Further, the comparable changes seen when either the ligand or receptor were modified suggest that the interaction of Ocn$^+$ cell and hematopoietic cells may be direct rather than through other microenvironmental cell types and argue against the phenotype being on the basis of stress or secondary metabolic changes.

The abnormality in T-lymphopoiesis could reflect dysfunction of the thymus itself or of the immigrants to the thymus arriving from the bone marrow. To assess this, we evaluated osteocalcin and DTR expression in thymic tissue, but found none by immunohistochemistry; no change in thymic histology or thymic DLL4 mRNA by quantitative PCR was observed after Ocn$^+$ cell depletion (unpublished data). To determine if thymic function was altered in Ocn$^+$ cell–deleted animals, we adoptively transferred WT Ly6D$^-$CLP or Lin$^-$/Sca$^+$cKit$^+$Flt3$^+$ hematopoietic progenitor cells into the thymi of either OcnCre$^+/-$;iDTR mutant or control recipients in vivo, and detected no difference in thymocyte maturation.

Figure 4. Ocn$^+$ cell regulation of T lymphopoiesis is dependent on bone marrow microenvironment. (A) $10^6$ WT CD45.1 hematopoietic bone marrow cells were transplanted into lethally irradiated CD45.1 OcnCre;iDTR hosts that were untreated or treated with DT. Animals were bled at 8, 12, and 16 wk after transplantation for blood count and assessment of hematopoietic reconstitution by flow cytometry. (B) $5 \times 10^5$ bone marrow cells from either control or mutant CD45.2 OcnCre$^+/-$;iDTR donors were mixed with $5 \times 10^5$ CD45.1 SJL bone marrow competitors in a 1:1 ratio and transplanted into lethally irradiated WT SJL recipients. Animals were bled at 8, 12, and 16 wk after transplantation for blood count and hematopoietic reconstitution by flow cytometry. (A and B) Two independent transplantations were performed; $n=20–22$ mice/experiment. Data show mean ± SEM. (C) Cell cycle status, apoptosis, and necrosis in CLPs in OcnCre$^+/-$;iDTR mutants and controls were assessed by flow cytometry. 2 independent experiments; $n=5–6$ mice/group. Data show mean ± SEM.
These data argue against an altered thymic microenvironment (or metabolic milieu) induced by the deletion of Ocn+ cells or DT administration as the basis for altered T cell differentiation. They also argue against, but cannot definitively exclude, secondary effects of stress on the lymphopoietic phenotype.

Examining whether the thymocyte production defects were cell autonomous, we adoptively transferred 3 x 10^4 Ly6D-CLPs cells from bone marrow of control or Ocn+ cell-depleted animals intrathymically into WT mice. After 3 wk, no evidence for a defect in the thymocyte maturation sequence was observed for cells derived from the context of the Ocn+ cell-depleted bone marrow (Fig. 9 A). The reversal of abnormalities in all T-intermediate stages in the thymus also led to fully restored mature CD4+ and CD8+ populations in the bone marrow (Fig. 9 A). Similar results were observed using Lin- Sca-Kit+Flt3+ cells. No extrathymic development was observed in organs, including bone marrow, spleen, lymph node, and intestine. Therefore, the perturbation of T cell development induced by Ocn+ cell depletion appears to be in enabling bone marrow thymus-seeding cell formation and migration, not in impaired differentiation capacity of cells once they arrive in the thymus.
Figure 6. Conditional deletion of DLL4 or Notch ligands in Ocn+ cells impaired T lymphopoiesis. (A) OcnCreER+/-;Dll4fl/fl mutants and OcnCreER+/-;Dll4+/+ control littermates were injected with 2 mg 4-OH-tamoxifen/15 g BW eight times over 4 wk to induce deletion of the DLL4 ligand. Mice were harvested immediately after 4 wk of deletion and bone marrow CLPs, thymic T cell progenitors, and peripheral blood mature T cells were enumerated by flow cytometry. Experiment was performed 3 times independently; n = 9–10 mice/group. Data show mean ± SEM. (B) OcnCreER+/-;Mib1fl/fl mutants and OcnCreER+/-;Mib1+/+ control littermates were injected with 2 mg 4-OH-tamoxifen/15 g BW 8 times over 4 wk to induce deletion of the Mib1 gene. Mice were harvested immediately after 4 wk of deletion and bone marrow CLPs, thymic T cell progenitors, and peripheral blood mature T cells were enumerated by flow cytometry. Experiment was performed twice independently; n = 6–8 mice/group. Data show mean ± SEM.

Because Notch has been reported to mediate the expression of chemokine receptors in T cell leukemia (Mirandola et al., 2012), we assessed whether OcnCre+/-;iDTR bone marrow cells properly express the chemokine receptors (Krueger et al., 2010) or ligands (Sultana et al., 2012) necessary for thymic seeding. We observed modestly decreased CCR7 expression intensity in the CLPs without changes in CCR9 or PSGL1, but with a significant decrease in the number of CCR7+CLP and PSGL1+CLP (Fig. 9 B). CCR7+CLP was also decreased in OcnCreErt2+/-;Dll4+/-, OcnCreErt2+/-;Mib1+/-, Mx1Cre+/-;Pofut1+/-, Mx1Cre+/-;RBPjκ-/- mice, and γ-secretase injected femurs compared with littermate controls (Figs. 6–8). Together, these data indicate that Ocn+ cell depletion results in decreased thymic-seeding progenitors and in decreased production of the thymic homing molecule, CCR7, in those progenitors.
Figure 7. Conditional ablation of Notch signaling in hematopoietic cells impaired T lymphopoiesis. (A) Mx1Cre^{+/−};Pofut1^{+/Ft} control littermates and Mx1Cre^{−/−};Pofut1^{+/Ft} control littermates were injected with 12.5 μg/g BW polyinosinic-polycytidylic acid (poly(I:C)) every alternate day for 7 d to induce deletion of the Pofut1 gene. Mice were harvested 4 wk after injection and bone marrow CLPs, thymic T cell progenitors, and peripheral blood mature T cells were enumerated by flow cytometry. Experiment was performed twice independently; n = 4–6 mice/group. Data show mean ± SEM. (B) Mx1Cre^{+/−};RBP-Jk^{−/−} mutants and Mx1Cre^{+/−};RBP-Jk^{+/+} control littermates were injected with 12.5 μg/g BW poly(I:C) every alternate day for 7 d to induce deletion of RBP-Jk. Mice were harvested 4 wk after injection and bone marrow CLPs, thymic T cell progenitors, and peripheral blood mature T cells were enumerated by flow cytometry. Experiment was performed twice independently; n = 6–8 mice/group. Data show mean ± SEM.

To test whether thymus migratory capacity of bone marrow cells was reduced in vivo, we conducted competitive homing experiments. LKS Flt3+ cells (1.5 × 10⁹) or CLPs (two doses: 3.5 × 10⁹ or 10⁸) from control or Ocn⁺ cell-depleted mice were isolated, stained with distinctive fluorescent tags, and intravenously injected at a 1:1 ratio into SJL recipients (Fig. 9 C). In parallel, equivalent cells sorted from age matched CCR7⁺/− mice labeled with a distinctive fluorescent tag were used as positive controls for homing defective cells and similarly competed in a 1:1 ratio into recipients. Recipient thymi were evaluated 24 h after transplant. OcnCre^{+/−};iDTR mutant or CCR7⁻/− donor cells were similarly compromised in thymic homing ability compared with controls (Fig. 9 C). These data suggest that the reduction in thymocytes may be due to failure to generate thymic-homing competent cells in the bone marrow of Ocn⁺ cell.
deleted animals. The defect in homing capacity may be caused by decreased CCR7 or PSGL1 or the combination of the two in the absence of Ocn+ cells in the bone marrow.

To test our hypothesis that Ocn+ cells instruct early T-lineage specification in bone marrow through DLL4, we injected the Ocn+ cell–depleted animals with recombinant mouse DLL4. Although this ligand is generally cell associated, it has been shown by others to induce Notch activation when administered as a recombinant protein (Androutsellis-Theotokis et al., 2006; Benedito et al., 2012; Moya et al., 2012). Control and mutant OcnCre−/−;iDTR mice were treated with daily DT injections from day −19. At day −5, mutant OcnCre−/−;iDTR mice were co.injected with either 100 ng/g BW or 1 µg/g BW of DLL4 intravenously. All mice were harvested at day 0. Results showed that injection of a high concentration of DLL4 into the bloodstream rescued the OcnCre−/−;iDTR bone marrow CLP and increased CCR7 expression on CLPs (Fig. 10 A)
Figure 9. Ocn+ cell–depleted animals had intact thymic function but impaired CLP homing ability. (A) 30,000 flow sorted bone marrow CLPs from diphtheria treated OcnCre+;iDTR animals (Mut) or controls (Ctrl) were injected into the thymus of either OcnCre+;iDTR DT treated (Mut) or control (Ctrl) animals. Injection of PBS served as mock controls. Thymic T progenitor and mature populations were assessed after 4 wk. Two independent experiments; n = 4–6 mice/group. Data show mean ± SEM. (B) CCR7, CCR9, and PSGL1 cell surface expression on CLP from Ocn+ cell–depleted or control mice was assessed by flow cytometry. Panels on the left show expression levels (indicated by fluorescent intensity on the y axis) and dot plots on the right show numbers of cells with positive expression. Minimum two independent experiments; n = 8–10 mice/group. Data show mean ± SEM. (C) CLPs from diphtheria-treated OcnCre;iDTR control and mutant mice were labeled with green and red fluorescent dyes, respectively, mixed in a 1:1 ratio and transplanted intravenously into congenic SJL recipients, and harvested 24 h after transplant. Equal number of CLPs harvested from CCR7−/− mice was used as another control and competed with OcnCre;iDTR mutant CLPs in a similar manner. Donor-derived cells were enumerated from recipient thymi 24 h after transplant. Experiment was repeated with reciprocal dye to control for dye labeling efficiency. 2 independent experiments; n = 10 mice/experiment. Data show mean ± SEM.

and subsequent thymic T cell development (Fig. 10, B–K), resulting in normalized mature T number in the bone marrow (Fig. 10 L). Supplement of a low concentration of DLL4 only partially increased bone marrow CLP (Fig. 10 A), but restored all subsequent stages of T development downstream in the thymus (Fig. 10, B–K). These data are consistent with...
DLL4 acting at the level of both the bone marrow and thymus. The impact of DLL4 was both in cell number and CCR7 expression in the bone marrow consistent with a role in both processes.

**DISCUSSION**

Immune reconstitution after allogeneic hematopoietic stem cell transplantation is a major clinical problem resulting in significant patient morbidity and mortality. We tested whether the number of Ocn+ cells might be compromised in vivo under settings related to hematopoietic stem cell transplantation. We generated mice that simultaneously label Osx-expressing cells and Ocn-expressing cells with distinct fluorescence markers and enumerated the cells by flow cytometry. A specific and marked reduction of Ocn+ cells was observed in a model of allogeneic transplantation and graft-versus-host disease (GvHD). The number of Osn+, Osn+Ocn+, and Ocn+ cells in femurs were enumerated by FACS. Experiment was performed twice; n = 8 mice/experiment. Results are means ± SEM.

Figure 10. In vivo rescue of T lineage defect by intravenous infusion of DLL4. (A–L) OcnCre;iDTR control and mutant mice were first treated with DT for 21 d to induce Ocn+ cell deletion, then injected with recombinant DLL4 intravenously at two different dosages: 100 ng/g BW or 1 µg/g BW. Flow cytometric evaluation of effects on the number of bone marrow CLPs (A), thymic T cell intermediates (B–K), and mature T cells circulated back to the bone marrow (L). Experiments was performed twice independently; n = 6–12 mice/group. Data show mean ± SEM. (M) Transgenic mice with osteolineage cells at the progenitor stage (OAx+) labeled red, intermediate stage (OAx+Ocn+) labeled yellow, and mature stage (Ocn+) labeled green were treated with either saline control (CNTR), parathyroid hormone (PTH), granulocyte colony-stimulating factor (G-CSF), IFN-γ, LPS, or transplanted in a noncompatible setting to elicit graft-versus-host disease (GvHD). The number of Osn+, Osn+Ocn+, and Ocn+ cells in femurs were enumerated by FACS. Experiment was performed twice; n = 8 mice/experiment. Results are means ± SEM.
robust T-lymphopoiesis in young adult animals. Other studies of
modifying bone cell CCL12 production or deletion of
DMP-1−/− cells have indicated, respectively defects in CLP (but
not mature T cells) or of thymus, T cells, and B cells and
metabolism broadly (Ding and Morrison, 2013; Greenbaum
et al., 2013; Sato et al., 2013). The lack of T cell phenotype
in our OsxCre+;/−;iDTR model was unexpected and there
could be several explanations. Differences in Cre deletion
efficiency could be one reason, as we achieved ~50% cell
deletion in the OsxCre+;/−;iDTR model compared with 70%
deletion in the OcnCre+;/−;iDTR system. Second, the relative
balance of Osx+ cells versus Ocn+ cells in the bone marrow
may be important for creating a B versus T-progenitor niche.
Systemic or indirect effects imposed by Osx+ or Ocn+ cell
deletion also remains possible. Based on our current data,
we present a model where a specific Notch-ligand, produced
by a specific subset of bone cells drive T-lineage competence
and enable thymus-seeding cell production. This model
may inform strategies to improve T-lineage production and
reconstitution in settings of disease, particularly because the
bone cells involved appear to be susceptible to loss in con-
texts like transplantation where T cell generation is of great
clinical consequence.

MATERIALS AND METHODS

Mouse models. All single transgenic mouse strains were maintained in a
C57BL/6J background by backcrossing to C57BL/6J for at least 10 back-
crosses. To specifically delete mature osteolineage cells, the OC−Cre
strain (from T.L. Clemens, Johns Hopkins University, MD; Zhang et al., 2002),
which expressed Cre under the Osteocalcin promoter was crossed to the iDTR
strain (Buch et al., 2005). Temporally controlled ablation was achieved
upon injection of DT into the OcnCre+;/−;iDTR strain. Similarly, Osx+ cell
deletion was achieved by crossing the Oxc1-GFP::Cre mouse (Rodda and
McMahon, 2006) to the iDTR strain. To study the effect of Ocn− cells on
hematopoiesis, OcnCreLox/lox;Mib1−/− injected with DT or OcnCre+;/−;iDTR injected
with PBS served as controls while OcnCre+;/−;iDTR injected with DT were
used as mutants. For osteoprogenitor deletion, control mice were OsxCre+;/−
 injected with DT or OsaCre−/−;iDTR injected with PBS, whereas OsxCre+;/−;iDTR injected with DT served as mutants. For most experi-
ments, 25 ng DT in PBS/g of body weight was injected daily into both con-
trol and mutant animals for 28 d from 4 wk of age to achieve an acute
deletion of specific osteolineage populations. Mice were harvested for analy-
sis the next day after the last dose of diphtheria injection. Notch ligand inac-
nivation in Ocn+ cells was achieved by crossing the Ocn-CreER strain (Park et al., 2012) with Dif/If(10a) strain (K. Hozumi, Tokai University,
Kanagawa, Japan; Hozumi et al., 2008) and with Mib1−/− strain (Koo et al.,
2005; OcnCreER;DLL4−/− and OcnCreER;Mib1−/−). Mouse models of
Notch inactivation in hematopoietic cells was achieved by crossing the
B6.Cg-Tg(Mx1-Cre)1Cgn/J (Mx1-Cre; The Jackson Laboratory) strain with
Pofut1+;/−(−/−) (Y.-Y. Kong, Seoul National University, Seoul, Republic of
Korea; Shi and Stanley, 2003) and RBP-J+;/− (T. Honjo, Kyoto University,
Kyoto, Japan; Han et al., 2002) strains (Mx1Cre;Pofut1−/− and
Mx1Cre;RBPI−/−). Mouse strains Grt(Rosa)26Sortm1(Notch1)1Dam/J
(LSL-NICD-GFP), B6.129X1-Gr(Rosa)26Sortm1(EYFP)Cov/J (LSL-
GFP), and C57BL/6-Tg(BGLAP-Topaz)1Rowe/J (OcnCre-Topaz) were
obtained from The Jackson Laboratory. OoscCre-Cherry;OcnCre-Topaz
was generated by crossing OssCreER (Park et al., 2012), Rosa-LSL-mCherry
(The Jackson Laboratory), and OcnCre-Topaz strains. For all experiments,
lettermates were used as controls. C57BL/6J and B6.SJ-Ly5b−/−;PepC−/−;Boyj
(SJL) strains were obtained from The Jackson Laboratory. All animal usage
and procedures performed were approved by the Institutional Animal Care
and Use Committee of Massachusetts General Hospital.

Bone histology. Tibiae were fixed in 70% ethanol and embedded without
demineralization in methyl methacrylate for histomorphometric analysis.
5-µm sections were stained with toluidine blue to quantify static parameters,
including bone volume per tissue volume, trabecular number, trabecular sepa-
ration, osteoblast and osteocyte number per tissue area, and osteoclast num-
ber per bone perimeter. Unstained sections were used to measure dynamic
parameters, including bone formation rate per tissue volume. A sampling site
with an area of ~1.4 mm2 was established in the secondary spongiosa of the
metaphysis at 450 µm below the growth plate. A standard histomorphometric
analysis was performed using the OsteoMeasure system (Osteometrics, Inc.)
and the results were expressed according to standardized nomenclature
(Parfitt et al., 1987). Statistical analysis was achieved using the nonparametric
Mann–Whitney test (n = 7–8). For paraffin sections, femurs and tibiae were
collected and fixed in 4% paraformaldehyde overnight, decalcified by 20% EDTA for 1 wk, washed in PBS, dehydrated through a series of alcohol
changes up to 70% EtOH, and embedded by paraffin. Paraffin sections were
stained with hematoxylin and eosin for general morphology, as well as von
Kossa and Goldner triochrome. Tartrate-resistant acid phosphatase (TRAP)
staining was used to reveal osteoclasts. Alteration of osteoblastic activity was
assessed by measuring serum levels of osteocalcin and N-terminal propeptide
of type I procollagen (P1NP) using Rat.Laps ELISA kits (n = 22–24). Changes
in osteoclastic bone resorption was assessed by measuring the C-terminal
telopeptides of collagen type I fragments in mouse serum using Rat.Laps EIA
kit (n = 22–24).

Immunohistochemistry. Expression of the DT receptor on cell surface
was detected by immunohistochemical staining of paraffin sections with
anti-human heparin-binding EGF-like growth factor (anti–hHB-EGF) anti-
body (R&D Systems; AF-259-NA). In brief, deparaffinized and rehydrated
sections were treated with 0.1% trypsin for antigen unmasking and 3% H2O2
to block endogenous peroxidase activity. Sections were then blocked with
reagent containing 5% animal serum in PBS-T for 1 h. Goat polyclonal
anti–hHB-EGF antibody was used at 1:25 dilution, coupled with horse biotin-
ylated anti-goat IgG secondary antibody (Vector Lab) at 1:400 dilution.
Rabbit polyclonal anti-DLL4 antibody (Abcam; ab84081) was used at 1:50
dilution, coupled with biotinylated anti–rabbit antibody at 1:250 dilution
(Vector Lab). After antibody staining, sections were washed in PBS-T, treated
with VECTASTAIN ABC kit for biotin-streptavidin signal amplification,
and subsequently visualized by DAB Peroxidase Substrate kit.
Phycoerythrin-conjugated anti–PECAM1 antibody (BD) was applied
at 1:100 dilution and mounted with DAPI containing mounting medium.
Ocn expressing mature osteoblasts and osteocytes were recognized by goat polyclonal
anti-osteocalcin antibody (Santa Cruz Biotechnology, Inc.; sc-18322) at
1:50 dilution followed by donkey anti-goat IgG secondary antibody conju-
gated to Alexa Fluor 488 at 1:4,000 dilution. Green fluorescent osteocalcin-
antibody staining was individually superimposed with red fluorescent
TUNEL (In situ Cell Death Detection kit MTR Red; Roche) staining.

Colony forming unit–osteoblast (CFU-Ob) assay. Bone marrow cells
were collected from each mouse by flushing end-excess femurs and tibiae
with PBS containing penicillin and streptomycin. Collected bone marrow
cells were incubated with ACK lys buffer to remove red blood cells, washed
with PBS, and plated at 104 cells per well in a 6-well plate supplemented
with DMEM and 10% FBS. Nonadherent cells were removed on the fifth
day and adherent cells were replated at 5 × 103 cells per well and cultured in
the same media until confluent. Once cultures reached confluency, medium
was changed into DMEM containing 50 µg/ml ascorbic acid, 10−8 M dexam-
ethasone, and 8 mM β-glycerophosphate and changed every 2–3 d to
induce osteogenic differentiation. 14 d later, cultures were fixed in 4% PFA,
and stained with 0.5% Alizarin Red for visualization of mineralized nodules
with brightfield microscopy. Cells were stained in triplicates and assayed
was repeated three times.
Flow cytometry. Before sacrifice, peripheral blood was collected from each mouse and subjected to complete blood cell count. For each mouse, lymphocytes, monocytes, neutrophils, eosinophils, basophils, and heterophils were counted on the cytometer. A minimum of 10,000 events per sample was acquired. Analysis was performed using FlowJo software (TreeStar, Ashland, OR). To assess cell viability, a 7-AAD viability stain was used.

Transplantation. Bone marrow was harvested from 4- to 6-week-old SJL donors and transplanted into each of 10 age-matched (mean age 9.5 weeks) recipients. Recipient mice were injected with 500 µg of cyclophosphamide (100 mg/kg) and xylazine (10 mg/kg). Sorted Lin- Sca+ cKit+ cells were transplanted into SJL recipients in the same manner as described previously (Goldschneider et al., 1986) with the following modifications: recipient mice were injected with 500 µg of cyclophosphamide, and the following day, the mice were injected with 100 µg of 3H-Iododeoxyuridine (3H-IDU) and 50 µg of 3H-desoxycytidine (3H-DCTD). The mice were killed on day 7 posttransplantation, and the femurs, iliac crests, spines, ulnae, radii, and humeri were collected for bone marrow harvest. Bone marrow cells were harvested from each animal and counted. We routinely stained 5 × 10^6 cells per sample for the hematopoietic stem population, and 10^4 cells per sample for each progenitor and mature population. Lineage cocktail consists of biotinylated B220, CD3e, CD4, CD8a, CD19, CD11b, Gr1, Ter119, CD11c, and NK1.1 antibodies. Fluorescence conjugated to streptavidin was used to recognize lineage cocktails. The following antibody combinations were employed to recognize different hematopoietic populations: hematopoietic stem and progenitor cells (Lineage-Pacific Orange, Sca-Pacific Blue, cKit-APC-Cy7, CD48-APC, CD150-PE-Cy7), CLP (Lineage-Pacific Orange, Sca-Pacific Blue, cKit-APC-Cy7, CD127-PE-Cy7, Thy1.2-IFITC, Ly6D-APC), GMP, CMP, and MEP (Lineage-Pacific Orange, Sca-Pacific Blue, cKit-APC-Cy7, CD34-FTTC, CD16-32-PE-Cy7), B cells (B220-APC), mature T cells (CD4-Pacific Blue, CD8-APC), monocytes (CD11b-APC), granulocytes (Gr1-FTTC), erythrocyte cells (CD45-APC, Ter119-PE), megakaryocytes (CD41-APC). For Thymic T cell development, we used: CD25-FTTC, CD44-PE, cKit-APC-Cy7, CD4-Pacific Blue, CD8-APC. Kit67-FTTC and DAPI staining were coupled with staining of any specific populations to reveal cell cycle status, while Annexin V and 7-AAD staining were used for apoptotic analysis.

Quantitative PCR. Flow sorted cells were extracted for RNA using the RNeAqueous-PCR kit (Ambion). Washed and crushed femoral bones of mutant or control animals were used for RNA extraction by TRIzol. Quantitative PCR were performed with TaqMan probes using the expression of the housekeeping GAPDH gene for normalization.

Competitive thymic homing experiment. 5,000 or 10,000 Ly6D-CLPs (Lin- Sca+ cKit+IL7R+Thy1.2-Ly6D+) were sorted from Ocncre;iDTR control and mutant donors (CD45.2-Pacific Blue), labeled with 10 µM CFDA-SE (Invitrogen) and 1 µg/ml VivoTag680 (VT680, VisEn Medical), respectively, mixed in a 1:1 ratio, and transplanted into each congenic SJL recipient (CD45.1-PE) by retro-orbital injection. The same number of progenitor cells sorted from CCR7+ mice served as another control to compete with Ocncre;iDTR mutant donors. Recipient thymi were harvested 24 h after transplant and donor-derived cells (CD45.2-Pacific Blue) from Ocncre;DTR control (CFDA-SE-) and mutant (VT680) were enumerated by flow cytometry. To account for differential dye-labeling efficiency, the experiment was repeated with the competing cells stained with reciprocal dyes, mixed in equal ratio, and transplanted into SJL mice in the same manner. Experiment was also performed using 15,000 sorted Lin- Sca+ cKit+Flk3+ hematopoietic progenitors as donor cells.

Intrathymic adoptive transfer assay. We follow the procedure described previously (Goldschneider et al., 1986) with the following modifications: mice were anesthetized with intraperitoneal injection of a mixture of ketamine (100 mg/kg) and xylazine (10 mg/kg). Sorted Ly6D-CLP (Lin- Sca+ cKit+IL7R+Thy1.2-Ly6D+) or Flk3+ LKS (Lin- Sca+ cKit+Flk3+) cells (30,000 cells in 20 µl PBS) were injected at two sites in the anterior superior portion of each thymus lobe (10 µl/site) using a Hamilton syringe mounted with a 30-gauge needle. After surgical procedure, mice were placed under the heat lamp for 30 min to aid recovery from anesthesia and were monitored daily for any signs of discomfort after the Pain Assessment Protocol published by the National Research Council (US) Committee. Mice that demonstrated signs of persistent pain were euthanized. Mice were sacrificed on the 14th day after surgery by CO2 asphyxiation and cervical dislocation, and thymi were harvested for cell analysis by flow cytometry.
DLL4 rescue experiment. Control OcnCre+/− and mutant OcnCre+/−;dTTR mice were intraperitoneally injected with 100 ng/g BW DT daily since day −19. Starting from day −5, OcnCre;DTTR mutants were co-injected daily with either 100 ng/g BW or 1 µg/g BW of recombinant mouse DLL4 (R&D Systems) intravenously. All mice were harvested at day 0 for bone marrow cells and thymic collection. Bone marrow cells were red blood cell lysed and stained for CLP, CD4, and CD6-specific antibodies, whereas thymocytes were stained for T developmental specific antibodies for flow cytometric analysis. The experiment was repeated twice.

Intrathelial injection of DAPT. We injected 10 µl of either 2.5 mM DAPT (EMD Millipore) or PBS control into the left tibia of each of eight C57BL/6 mice at day −12, −9, and −6, and harvested the left femur, thymus, and peripheral blood at day 0 for flow cytometric analysis.

GvHD model. For the induction of GvHD, 5 × 10^6 bone marrow cells were mixed with 2 × 10^6 CD4/CD8+ purified splenic T cells from BALB/c donors and mouse and injected in Oxa-Cre; Rosa-β-TOP-β-mCherry; Ocyt-GFP triple transgenic recipient mice that had been previously irradiated with 9.5 Gy. Control recipient mice received 5 × 10^6 bone marrow cells mixed with 2 × 10^6 CD4/CD8+ splenic T cells from C57BL/6 donor mice. The purification of the CD4/8 T cells was achieved using the MACS LD cell separation columns and the MACS Streptavidin MicroBeads (Miltenyi Biotech). Mice were monitored for signs of GvHD daily and the degree of clinical GvHD was assessed weekly by a scoring system that sums changes in five clinical parameters: weight loss, posture (hunching), activity, fur texture, and skin integrity. 2 wk after the transplantation, mice were sacrificed.

Statistical analysis. Statistical analysis of all paired experiments was analyzed by two-tailed Student’s t test. All graphs were represented with mean and standard error of the mean, where *, P < 0.05; **, P < 0.01; ***, P < 0.001; and ****, P < 0.0001, unless otherwise stated. Statistical comparison of multiple parameters were analyzed by One-way ANOVA, followed by Bonferroni post-test, where *, P < 0.05; **, P < 0.01; ***, P < 0.001; and ****, P < 0.0001.

Online supplemental material. Fig. S1 shows flow gating strategies for bone marrow singlets and B cells. Fig. S2 depicts flow gating strategies for bone marrow T cells, monocytes, granulocytes, erythroid cells, and megakaryocytes. Fig. S3 illustrates flow gating strategies for bone marrow hematopoietic progenitor cells. Fig. S4 diagrams flow gating strategies for intrathymic T cells. Fig. S5 describes flow gating strategies for LepR+ cells in the bone marrow stroma. Online supplemental material is available at http://www.jem.org/cgi/content/full/jem.20141843/DC1.

We are grateful to the following investigators for the original generation and sharing of strains: Dr. Thomas L. Clemens (OC-cre), Dr. Katsuto Hozumi (Dll4f/f), Dr. Young-Yun Kong (Mb-cre), Dr. Pamela Stanley (Psut), and Dr. Tatsuo Honjo (Bmpr-J). The authors would like to thank Oliver Hofmann and John Hutchinson of the HSPH Bioinformatics Core, Harvard School of Public Health, Boston, MA for assistance with microarray analysis.
