of the first summand. Taking (1) into account, we can distinguish two cases.

1) If $H$ is a RKHS with reproducing kernel $R$, i.e., $H \cong H(R)$, then $H \otimes H$ is also a RKHS with reproducing kernel $R \otimes R$ and thus, (1) implies $K(s,t) = \sum_{s<t} \lambda_i \phi_i(s) \phi_i(t) \psi_i(s,t) \in I$. Moreover, the convergence of the preceding series is absolute in $s,t \in I$. Hence, (11) holds.

2) If $H$ is a $L^2$-space, then (1) does not necessarily imply the pointwise convergence of the series $\sum_{s<t} \lambda_i \phi_i(s) \phi_i(t)$ to $K(s,t)$. For this assertion to hold it is necessary to impose additional conditions on the process $X(t)$. For example, if $\{X(t) : t \in I\}$ is a smooth process, then there exists a finite, non-negative measure $\mu$ on $H$ and the Lebesgue measurable subsets of $I$ which is equivalent to the Lebesgue measure and satisfies $\int K(t) d\mu(t) < \infty$ (12).

In this case, we set $H = L^2(I, H, \mu)$. Moreover, it follows that $K(s,t) = \sum_{s<t} \lambda_i \phi_i(s) \phi_i(t), s,t \in I$, where the series converges absolutely in $s,t \in I$. Therefore, (11) follows.

Asymptotic Achievability of the Cramér–Rao Bound for Noisy Compressive Sampling

Belhtash Babadi, Nicholas Kalouptsidis, and Vahid Tarokh, Fellow, IEEE

Abstract—We consider a model of the form $y = Ax + n$, where $x \in C^M$ is sparse with at most $L$ nonzero coefficients in unknown locations, $y \in C^N$ is the observation vector, $A \in C^{N \times M}$ is the measurement matrix and $n \in C^N$ is the Gaussian noise. We develop a Cramér–Rao bound on the mean squared estimation error of the nonzero elements of $x$, corresponding to the genie-aided estimator (GAE) which is provided with the locations of the nonzero elements of $x$. Intuitively, the mean squared estimation error of any estimator without the knowledge of the locations of the nonzero elements of $x$ is no less than that of the GAE. Assuming that $L/N$ is fixed, we establish the existence of an estimator that asymptotically achieves the Cramér–Rao bound without any knowledge of the locations of the nonzero elements of $x$ as $N \to \infty$, for a random Gaussian matrix whose elements are drawn i.i.d. according to $\mathcal{N}(0,1)$.

Index Terms—Compressive sampling, information theory, parameter estimation.

I. INTRODUCTION

We consider the problem of estimating a sparse vector based on noisy observations. Suppose that we have a compressive sampling (Please see [2] and [5]) model of the form

$$y = Ax_{\text{true}} + n$$

(1)

where $x_{\text{true}} \in C^M$ is the unknown sparse vector to be estimated, $y \in C^N$ is the observation vector, $n \sim \mathcal{N}(0, \sigma^2 I_N) \in C^N$ is the Gaussian noise and $A \in C^{N \times M}$ is the measurement matrix. Suppose that $x_{\text{true}}$ is sparse, i.e., $\|x_{\text{true}}\|_0 \leq L < M$. Let $I = \text{supp}(x_{\text{true}})$ and

$$\alpha \triangleq L/N$$

$$\beta \triangleq M/L > 2$$

be fixed numbers.

The estimator must both estimate the locations and the values of the non-zero elements of $x_{\text{true}}$. If a Genie provides us with $I$, the problem

reduces to estimating the values of the non-zero elements of $\bm{x}_{\text{true}}$. We denote the estimator to this reduced problem by genie-aided estimator (GAE).

Clearly, the mean-square estimation error (MSE) of any estimator is no less than that of the GAE (see [3]), since the GAE does not need to estimate the locations of the nonzero elements of $\bm{x}_{\text{true}}$. Let $\log_2 \left( \frac{\delta^2}{\sigma^2} \right) \geq M H(1/3)$ bits, where $H(\cdot)$ is the binary entropy function.

Recently, Haupt and Nowak [6] and Candès and Tao [3] have proposed estimators which achieve the estimation error of the GAE up to a factor of $\log M$. In [6], a measurement matrix based on Rademacher projections is constructed and an iterative bound-optimization recovery procedure is proposed. Each step of the procedure requires $O(MN)$ operations and the iterations are repeated until convergence is achieved. It has been shown that the estimator achieves the estimation error of the GAE up to a factor of $\log M$.

Candès and Tao [3] have proposed an estimator based on linear programming, namely the Dantzig Selector, which achieves the estimation error of the GAE up to a factor of $\log M$, for Gaussian measurement matrices. The Dantzig Selector can be recast as a linear program and can be efficiently solved by the well-known primal-dual interior point method. The Dantzig Selector can be used to estimate the locations of the nonzero elements of $\bm{x}_{\text{true}}$, and distributed according to $\mathcal{N}(0, 1)$, $\mathcal{J} \subset \{1, 2, \ldots, M\}$ such that $|\mathcal{J}| = L$ and $\bfA_{\mathcal{J}}$ be the submatrix of $\bfA$ with columns corresponding to the index set $\mathcal{J}$. Then, $\text{rank}(\bfA_{\mathcal{J}}) = L$ with probability $1$.

**Proof:** Let $A_j$ and $A_j$ be any two columns of $A_{\mathcal{J}}$. The law of large numbers implies

$$A_j^* A_j = \sum_k A_{jk}^* A_{jk} \rightarrow N \delta_{jj}$$  

as $N \rightarrow \infty$. Thus, the columns of $A_{\mathcal{J}}$ are mutually orthogonal with probability $1$, which proves the statement of the Lemma.

We can now define the notion of Joint Typicality. We adopt the definition from [1]:

**Definition 3.2:** We say an $N \times 1$ noisy observation vector, $\bfy = \bfA \bfx + \bfz$ and a set of indices $\mathcal{J} \subset \{1, 2, \ldots, M\}$, with $|\mathcal{J}| = L$, are $\delta$-jointly typical if $\text{rank}(\bfA_{\mathcal{J}}) = L$ and

$$\frac{1}{N} \| \Pi_{\mathcal{J}} \bfy \|^2 - \frac{N - L}{N} \sigma^2 < \delta$$  

(3)

where $A_{\mathcal{J}}$ is the submatrix of $\bfA$ with columns corresponding to the index set $\mathcal{J}$ and $\Pi_{\mathcal{J}} \triangleq \bfI - \bfA_{\mathcal{J}} (A_{\mathcal{J}}^* A_{\mathcal{J}})^{-1}$. We denote $\delta$-jointly typicality of $\mathcal{J}$ with $\bfy$ by $\mathcal{J} \sim \bfy$.

Note that we can make the assumption of $\text{rank}(\bfA_{\mathcal{J}}) = L$ without loss of generality, based on Lemma 3.1.

**Definition 3.3 (Joint Typicality Estimator):** The Joint Typicality Estimator finds a set of indices $\mathcal{J}$ which is $\delta$-jointly typical with $\bfy$, by projecting $\bfy$ onto all the possible $(\mathcal{J}) L$-dimensional subspaces spanned by the columns of $\bfA$ and choosing the one satisfying (3). It then produces the estimate $\hat{\bfx}$ by projecting $\bfy$ onto the subspace spanned by $A_{\mathcal{J}}$:

$$\hat{\bfx} = (A_{\mathcal{J}}^* A_{\mathcal{J}})^{-1} A_{\mathcal{J}}^* \bfy.$$  

(4)

If the estimator does not find any set $\delta$-typical to $\bfy$, then it will output the zero vector as the estimate. We denote this event by $E_D$.

We show that the Joint Typicality Estimator has the property stated in the Main Theorem. In order to prove this claim, we first establish the following Lemmas:

**Lemma 3.4:** For any unbiased estimator $\hat{\bfx}$ of $\bfx_{\text{true}}$,

$$E \{ \| \hat{\bfx} - \bfx_{\text{true}} \|^2 \} \geq c_G(N) \triangleq \sigma^2 \text{tr} \left( (A_{\mathcal{J}}^* A_{\mathcal{J}})^{-1} \right)$$  

(5)

where $A_{\mathcal{J}}$ is the submatrix of $\bfA$ with columns corresponding to the index set $\mathcal{J}$.

**Proof:** Assuming that a Genie provides us with $\mathcal{J}$, we have

$$p_{y|x}(y|x) \triangleq \frac{1}{(2\pi)^{N/2} \sigma^N} \exp \left( -\frac{1}{2\sigma^2} \| y - A_{\mathcal{J}} x_{\mathcal{J}} \|^2 \right).$$  

(6)

where $x_{\mathcal{J}}$ is the subvector of $\bfx$ with elements corresponding to the index set $\mathcal{J}$. The Fisher information matrix is then given by

$$\bfJ_{ij} \triangleq -E \left\{ \frac{\partial^2 \ln p_{y|x}(y|x)}{\partial x_i \partial x_j} \right\} = \frac{1}{\sigma^2} (A_{\mathcal{J}}^* A_{\mathcal{J}})_{ij}.$$  

(7)

Therefore, for any unbiased estimator $\hat{\bfx}$ by the Cramér–Rao bound [7],

$$E \{ \| \hat{\bfx} - \bfx_{\text{true}} \|^2 \} \geq \text{Tr}(\bfJ^{-1}) = \sigma^2 \text{tr} \left( (A_{\mathcal{J}}^* A_{\mathcal{J}})^{-1} \right).$$  

(8)

We note that Lemma 3.4 is also presented in [3].

**Lemma 3.5:** Let $\bfA$ be an $N \times L$ matrix whose elements are i.i.d. and distributed according to $\mathcal{N}(0, 1)$. Then

$$\text{Tr} \left( (A_{\mathcal{J}}^* A_{\mathcal{J}})^{-1} \right) \rightarrow \alpha.$$  

(9)
as $N \to \infty$ with $\alpha = L/N$ fixed.

Proof: Let $B \triangleq A^*A$. We have

$$B_{ij} = \frac{1}{N} \sum_{k=1}^{N} A_{ik}^* A_{kj}. \quad (10)$$

Since the elements of $A$ are i.i.d. and normally distributed, we can invoke the law of large numbers as follows:

$$\frac{1}{N} B_{ij} = \frac{1}{N} \sum_{k=1}^{N} A_{ik}^* A_{kj} = E \{ A_{ik}^* \} E \{ A_{kj} \} = 0 \quad (11)$$

if $i \neq j$ and

$$\frac{1}{N} B_{ii} = \frac{1}{N} \sum_{k=1}^{N} A_{ik}^* A_{ki} = E \{ |A_{ki}|^2 \} = 1 \quad (12)$$

as $N \to \infty$. Therefore

$$\frac{1}{N} B = \frac{1}{N} A^* A \to I_L. \quad (13)$$

We note that $1/NB$ is non-singular with probability 1, since it converges to $I_L$, element-wise with probability 1. Thus, the limit $\lim_{N \to \infty} (1/NB)^{-1}$ exists with probability 1. Hence

$$\left( \frac{1}{N} B \right)^{-1} = \left( \frac{1}{N} A^* A \right)^{-1} \to I_L \quad (14)$$

as $N \to \infty$. Taking the trace of both sides of the above equation, along with the linearity of the trace operator, proves the statement of the Lemma.

**Lemma 3.6 (Lemma 3.3 of [1]):** For any $\delta > 0$,

$$P \left( \left| \frac{1}{N} \| \Pi \| y \right|^2 - \frac{N - L}{N} | \delta |^2 > \delta \right) \leq 2 \exp \left( -\frac{\delta^2}{4|\delta|^4} \frac{N^2}{N - L + \frac{2\delta}{|\delta|^2}} \right) \quad (15)$$

and

$$P \left( \left| \frac{1}{N} \| \Pi y \| ^2 - \frac{L}{N} | \delta |^2 \right| < \delta \right) \leq \exp \left( -\frac{N - L}{4} \left( \frac{\sum_{k \in \mathcal{I}} |x_k|^2 - \delta}{\sum_{k \in \mathcal{J} \setminus \mathcal{I}} |x_k|^2 + |\delta|^2} \right)^2 \right) \quad (16)$$

where $\mathcal{J}$ is an index set such that $|\mathcal{J}| = L$ and $|\mathcal{I} \cap \mathcal{J}| = K < L$ and rank($A_{\mathcal{J}}$) = $L$ and

$$\delta = \delta \frac{N - L}{N - L}. \quad (17)$$

**Proof:** Please refer to [1] for the proof.

**Proof of the Main Theorem:** We can upper-bound the MSE of the Joint Typicality Estimator, averaged over all possible Gaussian measurement matrices, as follows:

$$e_8(N) \triangleq \mathbb{E} \left\{ \| x - x_{\text{true}} \|^2 \right\} \leq \int A \|x_{\text{true}}\|^2 P(E_0) dP(A) \quad (18)$$

$$+ \sum_{\mathcal{J}} \int A \left\{ \left\| \left( A_{\mathcal{J}}^* A_{\mathcal{J}} \right)^{-1} A_{\mathcal{J}}^* y - x_{\text{true}} \right\|^2 \right\} \times P(\mathcal{J} \sim y) dP(A) \quad (19)$$

The first term on the right-hand side of (18) can be upper-bounded as

$$\int \|x_{\text{true}}\|^2 P(E_0) dP(A) \leq 2 \|x_{\text{true}}\|^2 \exp \left( -\frac{\delta^2}{4|\delta|^4} \frac{N^2}{N - L + \frac{2\delta}{|\delta|^2}} \right) \quad (20)$$

where the inequality follows from Lemma 3.6. This term clearly tends to zero as $N \to \infty$, since $\|x_{\text{true}}\|^2$ grows polynomially in $N$ by assumption.

Using Lemma 3.5, the second term on the right-hand side of (18) can be expressed as follows:

$$\int A \left\{ \left\| \left( A_{\mathcal{J}}^* A_{\mathcal{J}} \right)^{-1} A_{\mathcal{J}}^* y - x_{\text{true}} \right\|^2 \right\} P(\mathcal{J} \sim y) dP(A) \leq \mathbb{E} A \left\{ \| A_{\mathcal{J}}^* \|^2 \right\} \quad (21)$$

Finally, the third term on the right-hand side of (18) can be upper-bounded as

$$\int \sum_{\mathcal{J}} \mathbb{E} A \left\{ \left\| \left( A_{\mathcal{J}}^* A_{\mathcal{J}} \right)^{-1} A_{\mathcal{J}}^* y - x_{\text{true}} \right\|^2 \right\} \times P(\mathcal{J} \sim y) dP(A) \leq \mathbb{E} \left\{ \| x_{\text{true}} \|^2 \right\} \quad (22)$$

where $x_k$ denotes the $k$th component of $x_{\text{true}}$. The first inequality follows from a trivial upper bound of $(L\delta^2 + \|x_{\text{true}}\|^2)$ on the error variance, and the second inequality follows from Lemma 3.6. The number of index sets $\mathcal{J}$ such that $|\mathcal{I} \cap \mathcal{J}| = K < L$ is upper-bounded by

$$\sum_{K = 0}^{L - 1} \left( \frac{L - K}{K} \right) \left( \frac{L - K}{L} \right)^K \left\{ \sum_{k \in \mathcal{J}} |x_k|^2 \right\} \geq (L - K)\mu^2(x_{\text{true}}).$$

Therefore, we can rewrite the right-hand side of (21) as

$$\sum_{K = 0}^{L - 1} \left( \frac{L - K}{K} \right) \left( \frac{L - K}{L} \right)^K$$

$$\times \exp \left( -\frac{N - L}{4} \left( \frac{\mu^2(x_{\text{true}}) - \delta^2}{\mu^2(x_{\text{true}}) + |\delta|^2} \right)^2 \right) \quad (23)$$

$$= \sum_{K = 1}^{L} \left( \frac{L}{K} \right) \left( \frac{L}{L} \right)^K \times \exp \left( -\frac{N - L}{4} \left( \frac{\mu^2(x_{\text{true}}) - \delta^2}{\mu^2(x_{\text{true}}) + |\delta|^2} \right)^2 \right). \quad (24)$$

We use the inequality
\[ \binom{L}{K'} \leq \exp \left( K' \log \left( \frac{L}{K'} \right) \right) \]  
(23)
in order to upper-bound the \( K' \)th term of the summation in (22) by
\[ \exp \left( L K' \log \left( \frac{e}{K'} \right) + L K' \log \left( \frac{\beta - 1}{K'} \right) \right) \]
\[ - C_0 L \left( \frac{L K' \mu^2(x_{\text{true}})}{L} \mu^2(x_{\text{true}}) + \sigma^2 \right)^2 \]  
(24)
where \( C_0 \triangleq (N - L)/4L \). We define
\[ f(z) \triangleq L z \log \frac{e}{z} + L z \log \frac{\beta - 1}{z} - C_0 L \left( \frac{L K' \mu^2(x_{\text{true}})}{L} \mu^2(x_{\text{true}}) + \sigma^2 \right)^2 . \]  
(25)

By Lemmas 3.4, 3.5 and 3.6 of [1], it can be shown that \( f(z) \) asymptotically attains its maximum at either \( z = 1/L \) or \( z = 1 \), if \( L \rho^2(x_{\text{true}})/\log L \to \infty \) as \( N \to \infty \). Thus, we can upper-bound the right-hand side of (21) by
\[ (L \sigma^2 + \|x_{\text{true}}\|^2) \sum_{K'=1}^L \exp \left( \max \left\{ f \left( \frac{1}{L} \right), f(1) \right\} \right) \]
\[ = \exp \left( \log \left( L^2 \sigma^2 + L \|x_{\text{true}}\|^2 \right) + \max \left\{ f \left( \frac{1}{L} \right), f(1) \right\} \right) . \]  
(26)

It is straightforward to obtain
\[ f(1/L) = 2 \log L + 2 + \log(\beta - 1) - C_0 L \left( \frac{\mu^2(x_{\text{true}})}{\mu^2(x_{\text{true}})} + \sigma^2 \right)^2 \]  
(27)
and
\[ f(1) = L (2 + \log(\beta - 1)) - C_0 L \left( \frac{\mu^2(x_{\text{true}})}{\mu^2(x_{\text{true}})} + \sigma^2 \right)^2 , \]  
(28)
Since \( C_0 > 2 + \log(\beta - 1) \) due to the assumption of \( \alpha < 1/(9 + 4 \log(\beta - 1)) \), both \( f(1) \) and \( f(1/L) \) will grow to \( \infty \) linearly as \( N \to \infty \). Hence, the exponent in (26) will grow to \( -\infty \) as \( N \to \infty \), as long as \( \|x_{\text{true}}\|^2 \) grows polynomially in \( N \). Thus, the MSE of the Joint Typicality Estimator is asymptotically upper-bounded by
\[ e_6(N) \leq c \sigma^2 . \]  
(29)

By Lemma 3.5, we know that this is the asymptotic Cramér–Rao bound on the mean squared estimation error of the GAE, which proves the statement of the main theorem. 

IV. DISCUSSION OF THE MAIN RESULT

We consider the problem of estimating a sparse vector, \( x_{\text{true}} \in \mathbb{C}^M \), using noisy observations. Let \( \|x_{\text{true}}\|_0 = L < M \). The estimator must both estimate the locations and the values of the non-zero elements of \( x_{\text{true}} \). Clearly, the mean squared estimation error of any estimator is no less than that of the genie-aided estimator, for which the locations of the non-zero elements of \( x_{\text{true}} \) are known. We have constructed a Joint Typicality Estimator that asymptotically achieves the Cramér–Rao bound on the mean squared estimation error of the GAE without any knowledge of the locations of nonzero elements of \( x_{\text{true}} \), as \( N \to \infty \) for \( \alpha \equiv L/N \) a fixed number.
