Structural basis for regulation of human calcium-sensing receptor by magnesium ions and an unexpected tryptophan derivative co-agonist

Chen Zhang, Tuo Zhang, Jan Zou, Cassandra Lynn Miller, Raksha Gorkhal, Jeong-Yeh Yang, Anthony Schilmiller, Shuo Wang, Kenneth Huang, Edward M. Brown, Kelley W. Moremen, Jian Hu, Jenny J. Yang

Ca^2+ -sensing receptors (CaSRs) modulate calcium and magnesium homeostasis and many (patho)physiological processes by responding to extracellular stimuli, including divalent cations and amino acids. We report the first crystal structure of the extracellular domain (ECD) of human CaSR bound with Mg^{2+} and a tryptophan derivative ligand at 2.1 Å. The structure reveals key determinants for cooperative activation by metal ions and aromatic amino acids. The unexpected tryptophan derivative was bound in the hinge region between two globular ECD subdomains, and represents a novel high-affinity co-agonist of CaSR. The dissection of structure-function relations by mutagenesis, biochemical, and functional studies provides insights into the molecular basis of human diseases arising from CaSR mutations. The data also provide a novel paradigm for understanding the mechanism of CaSR-mediated signaling that is likely shared by the other family C GPCR (G protein heterotrimeric guanine nucleotide-binding protein)–coupled receptor) members and can facilitate the development of novel CaSR-based therapeutics.

INTRODUCTION

The discovery of the parathyroid Ca^{2+} -sensing receptor (CaSR) established a new paradigm in which extracellular Ca^{2+} ([Ca^{2+}]_o) can act as a first messenger for regulation of diverse cellular processes, including regulating the secretion of parathyroid hormone (PTH) and modulating calcium reabsorption by the kidney, in addition to its well-known role as a second messenger (1, 2). Extracellular divalent cations, particularly [Ca^{2+}]_o and magnesium ([Mg^{2+}]_o), along with amino acids and neurotransmitters, regulate numerous cellular processes via CaSR and 14 other family C proton (heterotrimeric guanine nucleotide-binding protein)–coupled receptors (cGPCRs), including metabotropic glutamate (mGluR) and γ-aminobutyric acid type B (GABAB) receptors (3–7). Small changes in [Ca^{2+}]_o, or [Mg^{2+}]_o, trigger CaSR-mediated intracellular Ca^{2+} signaling and activate mitogen-activated protein kinase [extracellular signal-regulated kinase (ERK) 1 or 2] (8). CaSRs play a central role in regulating [Ca^{2+}]_o and [Mg^{2+}]_o homeostasis by stimulating phospholipase C to generate inositol 1,4,5-trisphosphate, which triggers release of calcium from its intracellular calcium stores to increase the intracellular free calcium concentration ([Ca^{2+}]_i) and activate [Ca^{2+}]_i signaling (9–11), which, in turn, inhibits PTH release, stimulates calcitonin secretion, and promotes renal Ca^{2+} excretion (12–15). Amino acids, especially those with aromatic side chains, potentiate high [Ca^{2+}]_o-elicited activation of CaSR via positive heterotropic functional cooperativity (5). Like other cGPCRs, CaSR functions as a dimer (16–18), with a long (~600 amino acids) N-terminal extracellular domain (ECD) playing an important role in the receptor's cooperative responses to its agonists (7). More than 400 mutations in CaSR cause human disorders with abnormal [Ca^{2+}]_o and [Mg^{2+}]_o homeostasis, including familial hypocalciuric hypercalcemia (FHH), neonatal severe hyperparathyroidism (NSHPT), and autosomal dominant hypocalcemia (ADH); 225 of the mutations map to the ECD, highlighting its critical role (19). To clarify the mechanism for cooperative activation of CaSR by [Ca^{2+}]_o, [Mg^{2+}]_o and amino acids, we solved the first crystal structure of human CaSR-ECD bound with Mg^{2+} ions. Unexpectedly, a high-affinity tryptophan derivative was found in the crystal structure of CaSR. Further identification and characterization of the CaSR ligand (CaSRL) suggest that it plays a role in potentiating the function of CaSR.

RESULTS AND DISCUSSION

The Venus flytrap domain of human CaSR ECD (hCaSR-ECD; residues 20 to 541) expressed in human embryonic kidney (HEK) 293S (GnTI) cells was crystallized in the presence of 200 mM Mg^{2+} and 10 mM Ca^{2+}. The structure was solved by molecular replacement using the structure of mGluR2 (Protein Data Bank (PDB) ID: 4XAQ) as the search template (Fig. 1A and table S1). hCaSR-ECD contains two globular lobes with an overall structure similar to other cGPCR family members, despite a low sequence similarity between these cGPCR family members (20 to 30%) (fig. S1) (20). Both the large lobe (subdomain 1) and the small lobe (subdomain 2) are typical α/β folds where the central parallel β strands are sandwiched by α helices. hCaSR-ECD forms a homodimer in solution (fig. S2) and in the crystal structure, with both protomers in a closed conformation (Fig. 1B) similar to the equivalent closed conformation of mGluR1 bound with glutamate [root mean square deviation of 1.24 Å for C (Fig. 1C)]. In addition, the direct and extensive homodimeric subdomain 2 interactions in hCaSR-ECD are analogous to those observed in the mGluR2 dimer with a bound agonist (PDB ID: 4XAQ), strongly suggesting that hCaSR-ECD crystal structure represents an active conformation (fig. S3) (21).
Our data indicate that Mg^{2+} binds to hCaSR-ECD and elicits CaSR-mediated [Ca^{2+}]_{i} signaling and ERK1/2 phosphorylation in CaSR-expressing cells with a lower potency than Ca^{2+} (Figs. 2, A and B, and 3C and fig. S4A) (22). Similar to [Ca^{2+}]_{o} activation, [Mg^{2+}]_{o} activation is further potentiated by the known CaSR co-agonist, L-Phe (Fig. 3F) (5, 7). [Ca^{2+}]_{o} potentiates [Mg^{2+}]_{o}-stimulated intracellular response mediated by CaSR because an increase of [Ca^{2+}]_{o} from 0.5 to 1.5 mM results in a reduction of the median effective concentration (EC_{50}) of [Mg^{2+}]_{o} from 7.2 ± 0.4 to 4.5 ± 0.3 mM for stimulation of [Ca^{2+}]_{i} signaling. These results suggest that there is an additive effect of both Ca^{2+} and Mg^{2+} and that they share a similar activation mechanism (Fig. 2A, fig. S5, and table S2) (22, 23). The binding of Mg^{2+} can be visualized by the reduction of intrinsic Trp fluorescence upon addition of Mg^{2+} to the purified ECD and the reduction of Tb^{3+}-sensitized energy transfer by Mg^{2+} competition (fig. S6). In the crystal structure, two Mg^{2+} binding sites were identified at positions designated as site 1 and site 2 (Fig. 2B). Site 1 is located at the dimerization interface of subdomain 2 and the bound Mg^{2+} coordinates with S^{240} and four water molecules with an ideal geometry for a Mg^{2+} ion. Notably, site 1 is surrounded by highly conserved residues (E^{228}, E^{231}, and E^{241}*) (* means from the other protomer) within 5 Å from an “acidic patch” composed of negatively charged residues on subdomain 2 (fig. S7). Site 2 is found on the periphery of subdomain 1, coordinated by S^{84} and backbone interactions with L^{81}, L^{87}, and L^{88}, as well as two water molecules. An equivalent cation binding site has been observed in mGluR (20) and likely plays a structural role. To locate additional high off-rate metal binding sites, we generated Gd^{3+}-derived crystals and identified another metal binding site (site 3) on the acidic patch in proximity to the subdomain 2 di-merization interface (Fig. 2C) and adjacent to Mg^{2+} binding site 1. Site 3 largely overlaps with a previously predicted Ca^{2+} binding site 3 (24). Mutation of site 3 coordinating residues (E228I or an E228I/E229I double mutant) reduced Ca^{2+}/Mg^{2+} sensing as well as Mg^{2+}-evoked intracellular Ca^{2+} mobilization. These results suggest the critical role of these metal binding sites on the acidic patch in both metal sensing (24) and regulation of CaSR function (Fig. 2G, figs. S7 and S9, and tables S3 and S4).

Unexpectedly, an elongated planar electron density was observed in the hinge region between the two subdomains where orthosteric ligand binding is thought to occur (Fig. 3A). No naturally occurring CaSRLs or reagents that were used in sample preparation and crystallization or any currently known CaSRLs fit the density well, suggesting a novel CaSRL. High-resolution liquid chromatography–electrospray ionization–mass spectrometry (LC-ESI-MS) of the purified protein preparation (Fig. 3B) identified a species that was eluted at ~4.65 min with a mass/charge ratio (m/z) of 215.0824 in negative-ion mode. The predicted elemental formula based on the observed mass corresponds to C_{12}H_{11}N_{2}O_{2} (calculated mass, 215.0821; mass accuracy, 1.4 ppm) (Fig. 3B and fig. S8). A search of PubChem identified a tryptophan derivative, L-1,2,3,4-tetrahydronorharman-3-carboxylic acid (TNCA) with the predicted molecular weight (M_{r}) and shape of the observed density. When compared to tryptophan, TNCA contains one extra carbon atom linking the amine nitrogen atom and the C2 atom of the indole ring. TNCA can be detected in various food and biological systems and is likely produced by tryptophan reacting with formaldehyde in humans (25), and is perhaps generated during production of the recombinant protein in HEK cells. Elution time, molecular weight, and MS fragmentation of synthetic TNCA matched those of the CaSRL, confirming the identity of the
compound as TNCA (Fig. 3B and fig. S8). The ligand will be referred to hereafter as TNCA.

TNCA is a strong co-agonist with [Mg\(^{2+}\)]\(_o\) in activating [Ca\(^{2+}\)]\(_i\) oscillations and ERK1/2 phosphorylation (Fig. 3, D to F, and fig. S9). Similar to Trp and other amino acids, addition of exogenous TNCA alone cannot activate the receptor. However, TNCA is ~1000-fold more potent than Phe in reducing the EC\(_{50}\) for [Mg\(^{2+}\)]\(_o\) or [Ca\(^{2+}\)]\(_o\) activation of [Ca\(^{2+}\)]\(_i\) signaling in both wild-type and mutant CaSRs (Fig. 3, F and G), with an apparent EC\(_{50}\) of ≤2 μM (Fig. 3H). Because the bound TNCA can be partially replaced by incubation with 150 mM Phe as assessed by MS (fig. S10), TNCA and Phe likely share the similar binding site in CaSR-ECD. Together, TNCA is a novel, high-affinity co-agonist of CaSR in the activation of both [Ca\(^{2+}\)]\(_i\) signaling and ERK activity.

CaSR strongly prefers aromatic amino acid ligands, such as Phe and Trp, over negatively charged Glu, which is the ligand for mGluRs. Structural comparison of the ligand binding pocket in the hinge region between subdomains 1 and 2 of hCaSR-ECD homodimer. Mg\(^{2+}\) and Gd\(^{3+}\) are depicted as hot pink and dark blue spheres, respectively. An anomalous difference map of Gd\(^{3+}\) (\(\sigma = 8.0\)) is shown in purple. W, water molecules. (D to F) Both site 1 (E) and site 3 (D) are on the “acidic patch” at the dimerization interface of subdomain 2 (fig. S7), whereas Mg\(^{2+}\) at site 2 in subdomain 1 (F) is primarily coordinated by the backbone carbonyl oxygen atoms. (G) Single mutations of E228I on the acidic patch significantly reduce CaSR-mediated [Ca\(^{2+}\)]\(_i\) responses in the cell population assay.

Mapping of disease-associated mutations on the structure of hCaSR-ECD shows that the mutations are clustered in two regions: the hinge region between subdomains 1 and 2 and the dimerization interface (fig. S12) (26, 27). Indeed, our structural and functional data strongly support the pivotal roles of these two regions in CaSR function. The hinge region between subdomains 1 and 2 harbors the binding site of TNCA, supporting its role as a co-agonist of CaSR. Two other co-agonists of CaSR, Phe and Trp, likely bind in the same position (fig. S10). We did not observe metal binding at the previously proposed site 1 for Ca\(^{2+}\) (6, 24, 28). A close inspection of the structure reveals that the side chain of E228I, a critical residue predicted for Ca\(^{2+}\)
Fig. 3. Identification and characterization of a tryptophan derivative bound to hCaSR-ECD as a novel high-affinity co-agonist of CaSR. (A) Fo-Fc omit map (Fo and Fc are the observed and the calculated structure factor amplitudes, respectively) of TNCA at σ = 4.5. The protein is shown in ribbon mode, and the ligand is shown in stick mode. The residues around TNCA are labeled in the zoomed-in figure. (B) LC-ESI-MS of protein sample (top), buffer (middle), and the standard compound (bottom) in negative-ion mode. The high-resolution isotopic MS spectra of the indicated peaks are shown in the inserted figures. (C and D) A representative oscillation pattern from a single HEK293 cell stimulated with various concentrations of extracellular Ca²⁺ or Mg²⁺ in the absence (C) and presence (D) of 0.25 mM TNCA. (E) Frequency distribution of the [Ca²⁺]i oscillation frequency (peak/min) in HEK293 cells transfected with wild-type CaSR stimulated with metals in the presence and absence of TNCA. The frequency was recorded at the point when more than 50% single cells started to oscillate. Around 40 cells were analyzed and further plotted as a bar chart. (F and G) TNCA potentiates [Mg²⁺]o- or [Ca²⁺]o-evoked [Ca²⁺]i responses in a population assay in 5001 cells measured by Fura-2 acetoxymethyl (AM) in the absence (black square) or presence of Phe (blue triangular) or TNCA (red closed circle). (H) A maximally active concentration of 0.1 to 0.5 mM TNCA markedly reduces the EC₅₀ for activation of [Ca²⁺]i, signaling by [Mg²⁺]o, in the presence of 0.5 mM [Ca²⁺]o. Inset: The EC₅₀ changes of [Mg²⁺]o are shown over a narrow concentration range of TNCA.
binding in this proposed site 1, swings away from the other residues in site 1 (S170, D190, Q193, and Y218), probably due to the extra carbon atom and the rigid structure of TNCA, ultimately resulting in its failure to capture the Ca2+ ion in combination with other site 1 residues (fig. S13). Nevertheless, the essential role of E297 in Ca2+ sensing has been supported by previous mutational studies (7, 24) and in the abrogated Mg2+ sensing of the E297I mutant (tables S3 and S4). A bistratican anion was also identified in the hinge region in proximity with TNCA, coordinated by the side chains of R66, R69, W70, and S417 and the backbone amide nitrogen atoms of I416 and S417 (figs. S11 and S14), potentially contributing to the known pH sensitivity of the CaSR (29).

Several lines of evidence indicate a critical role of CaSR-ECD dimerization in CaSR function (Figs. 1 and 4). First, two metal binding sites (site 1 and site 3) are identified within the acidic patch at the dimerization interface of subdomain 2 (fig. 2 and fig. S7). A double mutant of CaSR (E228I/E229I) in site 3 showed a significantly decreased responsiveness to [Ca2+]o and the E228I mutation also reduced activation of CaSR (E228I/E229I) in site 3 showed a significantly decreased responsiveness in CaSR function (Figs. 1 and 4). First, two metal binding sites N118K) and one inactivating FHH mutation are present on loop 2, sub-...
of human diseases arising from CaSR mutations. Finally, these data also provide a novel paradigm for understanding the mechanism of CaSR-mediated signaling that is likely shared by the other members of the family C GPCRs and can facilitate the identification and development of novel CaSR-based therapeutics.

MATERIALS AND METHODS

Purification of hCaSR-ECD secreted from HEK293S GnTI cells

hCaSR-ECD (from residues Tyr20 to Phe612) (fig. S1) was expressed in suspension culture of HEK293S GnTI cells and purified from the culture medium by Ni2+-nitrilotriacetic acid (NTA) chromatography, as previously described (34). To deglycosylate the purified protein, hCaSR-ECD was incubated with recombinant endoglycosidase F1 (Endo F1) at a 1:100 mass ratio of Endo F1 to hCaSR-ECD overnight at 4°C in 10 mM tris buffer (pH 7.4). Further separation of hCaSR-ECD from Endo F1 was achieved by size exclusion chromatography (SEC) in 10 mM Hepes buffer (pH 7.3). hCaSR-ECD forms a homodimer, as determined by the elution volume observed in SEC. The electrophoretic mobility in reducing/nonreducing SDS–polyacrylamide gel electrophoresis (SDS-PAGE) indicates that intermolecular disulfide bonds contribute to dimerization (fig. S2).

Crystallization, data collection, and structure determination

The dimeric hCaSR-ECD was concentrated to 10 mg/ml and crystallized in 10% polyethylene glycol (PEG)–8000, 200 mM MgCl2, 10 mM CaCl2, and 100 mM tris-HCl (pH 7.0), using the sitting drop approach at 21°C. No crystals were formed in the absence of Ca2+ or Mg2+. The plate-shaped crystals were cryoprotected using 25% glycerol and were flash-frozen in liquid nitrogen. Dehydration by soaking with a solution containing 12% PEG-8000, 200 mM MgCl2, 10 mM CaCl2, and 100 mM tris-HCl (pH 7.0), using the sitting drop approach at 21°C. No crystals were formed in the absence of Ca2+ or Mg2+. The plate-shaped crystals were cryoprotected using 25% glycerol and were flash-frozen in liquid nitrogen. Dehydration by soaking with a solution containing 12% PEG-8000, 200 mM MgCl2, 10 mM CaCl2, and 100 mM tris-HCl (pH 7.0), using the sitting drop approach at 21°C. High-resolution LC-ESI-MS and identification of TNCA

As shown in Fig. 3A, there was an unidentified ligand (CaSRL) bound at the putative orthosteric ligand binding site of CaSR-ECD. We examined the known CaSRLs, including phenylalanine, tryptophan, glutathione, and polyamines, as well as the reagents used in sample preparation and crystallization, but none of them fit the density well. Among these initial trials, tryptophan appeared to be the best fit to the electron density of the unknown ligand, but an additional density was unaccounted for when tryptophan was used to fit the electron density. The size of the density suggested that the CaSRL contained 14 to 18 heavy atoms (C/N/O/S/P), and the absence of anomalous signal indicated that it did not contain sulfur or phosphate. Accordingly, the M, of CaSRL must be within the range of ~180 to 250 daltons.

To generate the Gd3+ derivative, the native crystals were soaked with a solution containing 12% PEG–8000, 200 mM MgCl2, 10 mM CaCl2, 100 mM tris-HCl (pH 7.0), and 0.5 mM GdCl3 overnight at 21°C. The anomalous signals of a data set at 2.7 Å collected at the wavelength of 1.6985 Å were used to locate Gd3+ in the structure. The structure was solved at 2.1 Å to dimerization (fig. S2).

Using the above approach, we identified a species eluting at ~4.65 min, detected by MS in both positive-ion mode (m/z of...
217.0990) and negative-ion mode (m/z of 215.0824), exclusively present in protein samples from several different batches but not in the sample buffer. The predicted elemental compositions based on mass are C₁₂H₁₃N₂O₂ (calculated mass = 215.0977 daltons) for positive-ion mode and C₁₂H₁₁N₂O₂ (calculated mass = 215.0824 daltons) for negative-ion mode. A thorough search in the PubChem database led to a list of candidates containing up to 200 compounds with the same Mᵣ and formula. By manually fitting the density map with these compounds, only TNCA fit the density perfectly. Synthetic TNCA dissolved in the SEC buffer was treated in the same way as the protein samples in the LC-ESI-MS experiment, and resulted in a peak detected at the same retention time and having the same mass spectrum. In the LC-ESI-MS experiment, we also noticed a minor species that eluted at ~4.57 min (fig. S10), which was detectable only in the positive-ion mode (m/z of 215.0836) and having a predicted elemental formula of C₁₂H₁₁N₂O₂. The 2-dalton smaller Mᵣ for this related compound suggested that it was a derivative of TNCA, likely due to a double bond formation between the backbone N and a neighboring C. Because it is also likely to be a tryptophan derivative, we cannot exclude the possibility that it binds hCaSR-ECD with high affinity. This compound may also form during extraction of TNCA from the protein sample. Nevertheless, TNCA perfectly fits the electron density at 2.1 Å, and any extra double bonds in the CaSR structure would likely be detrimental to fitting the density.

A phenylalanine replacement experiment was carried out by mixing purified hCaSR-ECD protein (0.26 mg/ml) with phenylalanine (final concentrations are 0, 50, and 150 mM, respectively). After overnight incubation at room temperature, hCaSR-ECD in each sample was repurified with Ni²⁺-NTA beads. The protein samples were adjusted to the same concentration using SEC buffer and analyzed by LC-ESI-MS.

Monitoring Mg²⁺ binding to CaSR-ECD by fluorescence spectroscopy
The imidazole in fractions of hCaSR-ECD eluted from the Ni²⁺-NTA column was removed by passing the protein through desalting columns in Hepes buffer [10 mM Hepes (pH 7.2)]. The Trp fluorescence spectra of hCaSR-ECD were recorded on a QM1 fluorescence spectrophotometer (Photon Technology International) in a 1-cm-pathlength cell with a xenon short-arc lamp at ambient temperature. The emission between 300 and 400 nm was acquired during excitation at the wavelength of 282 nm. A solution containing 2 μM hCaSR-ECD in 10 mM Hepes (pH 7.2), 120 mM NaCl, and 10 mM KCl was gradually titrated by addition of Ca²⁺ prepared in the same Hepes buffer. The binding constants of Mg²⁺ to CaSR-ECD were calculated by fitting the titration curve with the Hill equation. The Ca²⁺-Tb³⁺ competition experiments were performed in solutions containing 35 μM Tb³⁺ and 2 μM hCaSR-ECD as the starting point. MgCl₂ was added to the mixture from a 1 M stock solution while maintaining a constant Tb³⁺ concentration in the solution. The Mg²⁺ binding affinity of the protein was calculated by fitting normalized fluorescence intensity data using the Hill equation

\[
\Delta S = \frac{|M|^n}{K_d + |M|^n}
\]

where ΔS is the total signal change in the equation, K_d is the apparent binding affinity, n is the Hill coefficient, and |M| is the free metal concentration.

TNCA and Mg²⁺ binding site mutation design
All of the full-length CaSR mutants were generated by site-directed mutagenesis on the basis of the sequence of the human CaSR in the pcDNA3.1(+) expression vector (provided by E. Brown). Site-directed mutagenesis was performed using the QuickChange kit (Stratagene) according to the manufacturer’s instructions. Briefly, a pair of complementary primers of 27 to 35 bases was designed for generating each mutant with the mutation placed at the middle of the primers. The template human CaSR in pcDNA3.1(+) was amplified using Pfu DNA polymerase (Stratagene) with these primers for 16 cycles in a polymerase chain reaction instrument (Techne). After digestion of the template DNA with Dpn I (New England Biolabs), the amplified mutant DNA was transformed into XL10-Gold Ultracompetent cells. All the DNA sequences were verified by Genewiz (www.genewiz.com).

Cell culture and transfection
Monolayer cultures of HEK293 cells were purchased from American Type Culture Collection (ATCC CRL-1573) and maintained in Dulbecco’s modified Eagle’s medium (DMEM) supplemented with 10% fetal bovine serum and high glucose (4.5 g/liter) at 37°C. Wild-type CaSR or its mutants were transfected into HEK293 cells using Lipofectamine 2000 (Life Technologies) by following the manufacturer’s instructions.

Immunostaining
Cells transfected with hCaSR-pcDNA3.1(+) were used in the immunostaining experiments, and this construct contained a FLAG tag between Asp³⁷³ and Thr³⁷². After 48 hours post-transfection, cells were fixed with 3.7% formaldehyde for 15 min at room temperature, followed by washing with phosphate-buffered saline (PBS) three times. Mouse anti-FLAG monoclonal antibody was diluted 500 times and incubated with cells overnight at 4°C to stain the cell-surface CaSR. The cells were subsequently washed with PBS and stained with goat anti-mouse Alexa 488–conjugated secondary antibody for 1 hour at room temperature. Nuclei were stained with 4',6-diamidino-2-phenylindole. Fluorescence was visualized using a Zeiss LSM780 confocal microscope.

Measurement of [Ca²⁺], changes triggered by [Mg²⁺]o in single CaSR-transfected cells
Measurement of intracellular free Ca²⁺ was assessed as described by Huang et al. (6). Briefly, wild-type CaSR or its mutants were transiently transfected into HEK293 cells grown on coverslips and cultured for 48 hours. The cells were subsequently loaded for 15 min using 2 μM Fura-2 AM in 2 ml of physiological saline buffer (10 mM Hepes, 140 mM NaCl, 5 mM KCl, and 1.0 mM MgCl₂) (pH 7.4). The coverslips were mounted on a bath chamber on the stage of a Leica DM6000 fluorescence microscope. The cells were alternately illuminated with 340- or 380-nm light, and the fluorescence at an emission wavelength of 510 nm was recorded in real time as the ∆[Ca²⁺]i from excitation at both wavelengths was utilized as a surrogate for changes in [Ca²⁺]i and was further plotted and analyzed as a function of [Mg²⁺]o. All experiments were performed at room temperature. The signals from 20 to 100 single cells were recorded for each measurement. Oscillations
were identified as three successive fluctuations in \([\text{Ca}^{2+}]_o\), after the initial peak.

**Determination of the effect of TNCA on Mg\(^{2+}\)-evoked \([\text{Ca}^{2+}]_i\) signaling by stimulation of CaSR in cell populations**

Changes in \([\text{Ca}^{2+}]_i\), elicited by \([\text{Mg}^{2+}]_o\), in a population of cells were measured by fluorometry as previously described (6). A cell line stably expressing CaSR (5001) was seeded on 13.5 × 20–mm coverslips and cultured in DMEM. After reaching 95% confluence, cells were washed three times using loading buffer [20 mM Hepes (pH 7.4), 125 mM NaCl, 5 mM KCl, 1.25 mM CaCl\(_2\), 1 mM MgCl\(_2\), 1 mM NaH\(_2\)PO\(_4\), 1% glucose, and 1% bovine serum albumin (BSA)] and subsequently incubated with 4 μM Fura-2 and 4 μM Pluronic F127 for 20 min at 37°C to enable sufficient dye loading in the same buffer. After removing the excess Fura-2, coverslips with cells were diagonally positioned in a quartz cuvette filled with 3 ml of experimental buffer (125 mM NaCl, 5 mM KCl, 0.5 mM CaCl\(_2\), 0.5 mM MgCl\(_2\), 1% glucose, and 1% BSA). Measurements of Fura-2 fluorescence at 510 nm when excited at 340 or 380 nm were performed on a QM1 fluorescence spectrophotometer (Photon Technology International). The emission ratio of 340/380 was calculated and used to reflect the changes in \([\text{Ca}^{2+}]_i\) when different concentrations of \([\text{Mg}^{2+}]_o\) were applied to the cells.

To examine the coactivation of CaSR by TNCA and \([\text{Mg}^{2+}]_o\) or \([\text{Ca}^{2+}]_o\), different concentrations of TNCA were placed in the experimental buffer with a fixed concentration of \([\text{Ca}^{2+}]_o\) and varying concentrations of \([\text{Mg}^{2+}]_o\) or vice versa, as described in the Results section. The effects of other ligands were analyzed by comparing the changes in \([\text{Ca}^{2+}]_i\) produced by \([\text{Mg}^{2+}]_o\), alone or by coactivation of \([\text{Mg}^{2+}]_o\) with other ligands. The EC\(_{50}\) of \([\text{Mg}^{2+}]_o\) obtained during incubation with various concentrations of TNCA is compared with that observed in the presence of \([\text{Mg}^{2+}]_o\) alone. The EC\(_{50}\) changes were plotted as a function of TNCA concentration, and the curve was fit to the Hill equation. The activation of CaSR by the TNCA, functioning as a co-agonist with \([\text{Mg}^{2+}]_o\), was indicated by the increasingly left-shifted EC\(_{50}\) for \([\text{Mg}^{2+}]_o\) as the concentration of TNCA increases (table S5).

**Determination of ERK1/2 phosphorylation**

The 5001 cell line stably expressing hCaSR was starved in serum-free DMEM medium supplemented with 0.2% (w/v) BSA overnight, followed by washing with Hanks’ balanced salt solution (HBSS) three times and a subsequent 10-min HBSS incubation in the morning of the second day. To induce ERK1/2 phosphorylation, varying concentrations of \([\text{Mg}^{2+}]_o\) (0 to 50 mM) or \([\text{Ca}^{2+}]_o\) (0 to 30 mM) with or without 0.5 mM TNCA were added to cells and incubated for 10 min at 37°C. The cells were then lysed with Pierce radioimmunoprecipitation assay buffer (Thermo Scientific). Total protein concentration was measured using the Bio-Rad assay. Lysates containing 100 μg of total protein were loaded onto 4 to 20% gradient SDS-PAGE gels for separation. After electrophoresis, proteins on the gel were transferred to nitrocellulose membranes and were further analyzed by Western blotting. Anti-phospho-p44/42 ERK (1:1000 dilution) and anti-p44/42 (1:2000) polyclonal antibodies were utilized as probes to detect the phospho-ERK1/2 and total ERK1/2, respectively. A chemiluminescent detection method (AP Conjugate Substrate Kit, Bio-Rad) was applied to detect phospho-ERK1/2 and total ERK1/2. The respective bands on Western blots were evaluated by densitometry. The EC\(_{50}\) of \([\text{Mg}^{2+}]_o\)- or \([\text{Ca}^{2+}]_o\)-dependent responses were obtained by fitting the \([\text{Mg}^{2+}]_o\) or \([\text{Ca}^{2+}]_o\) concentration-response curves with the Hill equation (Eq. 1).

**SUPPLEMENTARY MATERIALS**

Supplemental material for this article is available at http://advances.sciencemag.org/cgi/content/full/2/5/e1600241/DC1

table S1. Crystallographic statistics of hCaSR-ECD and hCaSR-ECD/Gd\(^{3+}\).

table S2. EC\(_{50}\) of \([\text{Mg}^{2+}]_o\) for stimulation of \([\text{Ca}^{2+}]_i\) signaling in the presence of different coactivators.

table S3. EC\(_{50}\) of \([\text{Mg}^{2+}]_o\) for stimulation of \([\text{Ca}^{2+}]_i\) signaling in single cell assay with or without TNCA.

table S4. EC\(_{50}\) of \([\text{Mg}^{2+}]_o\) for stimulation of \([\text{Ca}^{2+}]_i\) signaling in cell population assay with or without TNCA.

**REFERENCES AND NOTES**

Acknowledgments: We thank R. Das and D. Cox for their help with the confocal experiments. We also thank D. A. Jones at Michigan State University for experimental instructions and thoughtful discussion of mass spectrometry experiments. We thank Y. Zhou for his critical review of this manuscript. Funding: This work was supported by NIH grants GM081749 and EB007266 (to J.J.H.) and by a Michigan State University Startup Fund (to J.H.). This work was also supported by P41GM103390 (to K.W.M.), a Center for Diagnostics and Therapeutics fellowship (to K.W.M.), a Center for Diagnostics and Therapeutics fellowship (to J.H.), and both glutamate and Gd3+. Recognition of human mGlu2 and mGlu3 amino terminal domain structures. J. Med. Chem. 58, 1776–1794 (2015).
