I. INTRODUCTION

Puzzling properties of the high-$T_c$ cuprates have often been attributed to the existence of competing instabilities and proximity (or even coexistence) of several ordered states. Possible instabilities that have been discussed in this context include charge density wave (CDW) order, non-two-sublattice spin density wave (SDW) order,$^{1-4}$ spin Peierls order,$^5$ and orbital magnetism.$^6,7$ Neutron scattering experiments on La$_{1.6-x}$Nd$_{0.4}$Sr$_x$CuO$_4$, $^{8}$ La$_x$Sr$_{1-x}$CuO$_2$,$^{9,10}$ and La$_2$CuO$_{4+\delta}$$^{11}$ demonstrated the coexistence of magnetism and superconductivity, while recent experiments on strongly underdoped YBa$_2$Cu$_3$O$_{6.35}$ (Ref. 12) have seen evidence of CDW order coexisting with superconductivity. Particularly striking in this context are recent scanning tunneling microscopy (STM) experiments on Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$,$^{13-15}$ which see spatial structure in the tunneling density of states with a period of four lattice constants. This structure was originally observed in the experiments in a magnetic field by Hoffman et al. ($^{15}$) and later also seen in zero field by Howald et al.$^{14,15}$ Modulo certain experimental subtleties, these experiments can be thought of as measurements of the spatial Fourier component (at the ordering wave vector $\mathbf{Q}$) of the energy dependent local density of states (LDOS) $\rho_\mathbf{Q}(\epsilon)$.

In this paper, we demonstrate that the energy dependence of $\rho_\mathbf{Q}(\epsilon)$ provides important information about the nature of charge ordering in these materials. It allows us to separate simple charge density wave order, that has only the Hartree-Fock potential modulation, from the more unusual charge orders that involve modulation of the electron kinetic energy (dimerization) or the pairing amplitude (anomalous dimerization). For example, when $Q = (2\pi/4,0)$ (as observed in slightly overdoped Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$), there is a change of sign in $\rho_\mathbf{Q}(\epsilon)$ for energies around 40 meV when dimerizations are present, but not in the case of a simple CDW. When several of the simple distortions are present simultaneously, we can understand the resulting $\rho_\mathbf{Q}(\epsilon)$ as (roughly) a superposition of the corresponding simple cases, since the induced $\rho_\mathbf{Q}(\epsilon)$ is approximately linear in the order parameter for small distortions. Such a superposition is necessary to understand the experiments of Refs. 14, 15.

This superposition principle also applies when we have potential modulation at several wave vectors and $\rho_\mathbf{Q}(\epsilon)$ can be analyzed separately for each wave vector $\mathbf{q}$. This is necessary, for example, when we have randomness that pins the charge order, so that the single particle potential is not a delta function in momentum space but has a narrow distribution centered at the ordering wave vector $\mathbf{Q}$. This leads to a finite $\rho_\mathbf{Q}(\epsilon)$ for a range of wave vectors around $\mathbf{Q}$ and, as we discuss below, taking a reasonable value of the CDW correlation length reproduces well the “weak dispersion” of the CDW peak observed in Ref. 15. Our analysis can be extended to systems with no charge order but, instead, with localized defects, e.g., impurities. In this case we have a potential that is essentially momentum independent and we find strongly dispersing peaks in $\rho_\mathbf{Q}(\epsilon)$ for a wide range of wave vectors. Such peaks have been observed in the STM experiments in Refs. 16,17 and discussed theoretically in Refs. 18,19. We provide a qualitative comparison of the STM spectra for systems with disordered CDW and impurity scattering.

It is common to discuss spin density wave order as the primary competitor to superconductivity in the underdoped cuprates.$^{1,3,20-22}$ An order parameter for non-two-sublattice magnetism is

$$\tilde{S}(\mathbf{r}) = \tilde{\phi} e^{i\mathbf{Q}\cdot\mathbf{r}} + \tilde{\phi}^* e^{-i\mathbf{Q}\cdot\mathbf{r}},$$

where the complex-valued vector $\tilde{\phi}$ acquires an expectation value in a state with broken spin symmetry. When the SDW order in Eq. (1) is collinear, it has an associated spin singlet order parameter that only breaks translational symmetry and can be described as a generalized charge density wave$^{22}$

$$\delta \rho(\mathbf{r}) = \phi e^{i\mathbf{Q}\cdot\mathbf{r}} + \phi^* e^{-i\mathbf{Q}\cdot\mathbf{r}}.$$
Symmetry arguments determine the wave vector $\mathbf{Q}_c = 2\mathbf{Q}$ of such generalized CDW, but they do not clarify its internal structure. For example, modulation of the local Hartree-Fock potential of the electrons and modulation of the electron kinetic energy (hopping) are both spin singlet order parameters that can be defined at the same wavevector and described by Eq. (2). Modulation of the electron pairing amplitude also belongs to the same class of translational symmetry breaking since, in the superconducting state with condensed Cooper pairs, order parameters with charge two and zero are not orthogonal. It is important to note, however, that a long-range SDW order is not a prerequisite for translational symmetry breaking. One can have a situation where quantum or thermal fluctuations destroy the spin order but preserve a long-range order in the charge sector.\(^{9,23}\) This was observed, for example, in underdoped YBa$_2$Cu$_3$O$_{6.35}$,\(^{12}\) where neutron scattering found period eight CDW but no static spin order. For slightly overdoped Bi$_2$Sr$_2$CaCu$_2$O$_{x+\delta}$, on which most of the tunneling experiments have been performed, neutron scattering experiments suggest dynamic spin fluctuations.\(^{24}\) In our analysis we then assume that there is no SDW order and concentrate on the effects of spin singlet translational symmetry breaking. Another possible origin of a generalized CDW with no spin symmetry breaking comes from pinning of SDW by disorder\(^{9,22}\) or vortices.\(^{22,26}\)

We restrict our analysis to the case of weak translational symmetry breaking, when the new order parameter can be treated as a small perturbation to the superconducting mean-field Hamiltonian. This limit clearly applies to the experimental situation in Refs. 13–17, where the measured modulation is weak, and allows us to obtain explicit approximate expressions for $\rho_0(\varepsilon)$. [This circumvents solving a complicated set of equations numerically, as, for instance, carried out in Ref. 25.] Furthermore, we do not address the issue of the origin of charge order, but introduce it phenomenologically and study its consequences for the STM experiments. Our basic motivation is that a comparison of the energy dependence of $\rho_0$ with experimental data can, in principle, be used to identify the correct order parameter(s) which, in turn, is crucial for understanding their origin.

This paper is organized as follows. In Sec. II we introduce mean-field Hamiltonians that describe several kinds of translational symmetry breaking in a lattice system. For these generalized CDW’s we derive an explicit formula for the Fourier component of the tunneling density of states at the ordering wave vector. Section III displays numerical results of this expression in the case of Bi$_2$Sr$_2$CaCu$_2$O$_{6.35}$ type band structure and period four charge order. We show that recent STM experiments by Refs. 14,15 are consistent with a generalized CDW that has modulation of either the electron hopping or the pairing amplitude. We also consider period eight structure that may be relevant to YBa$_2$Cu$_3$O$_{6.35}$. In Sec. IV we extend our analysis to phases with randomness and show that a realistic value of the CDW correlation length ($20a_{0}$, with $a_0$ the unit cell size) provides good agreement with the “weak dispersion” of the CDW peak observed in Ref. 15. As a different application of our formalism we also consider localized perturbations in the crystal, such as impurity potentials, and demonstrate that these can account for the strongly dispersing peaks observed in Refs. 16,17 at wave vectors not corresponding to the CDW order. In Sec. V we review how to include a more realistic model of the atomic wave functions, whose main effect is to introduce a momentum dependent structure factor. An important implication of this result is that the signal at wave vectors differing only by a reciprocal lattice vector should have peaks at the same energies, although their amplitudes may differ. We also discuss complications in the analysis of the STM data introduced by the normalization procedure used in the experiments. Finally, in Sec. VI we discuss several sum rules for the Fourier components of the density of states that may be useful for analyzing experiments.

II. ORDER PARAMETERS AND MEAN-FIELD HAMILTONIANS FOR GENERALIZED CHARGE DENSITY WAVE PHASES

Our starting point is a two-dimensional one-band mean-field Hamiltonian that is commonly believed to be a good model for the physics of the $d_{x^2−y^2}$ superconducting state of the cuprates

$$H = \sum_{\mathbf{k} \sigma} \epsilon_{\mathbf{k}} c_{\mathbf{k}\sigma}^\dagger c_{\mathbf{k}\sigma} + \sum_k \Delta_k (c_{k^+\uparrow}^\dagger c_{k^-\downarrow} + c_{k^-\downarrow} c_{k^+\uparrow}).$$

Here $\epsilon_{\mathbf{k}} = -2t[\cos(k_x) + \cos(k_y)] - 4t\cos(k_x)\cos(k_y) - \mu$, $\Delta_k = (\Delta_0/2)(\cos k_x - \cos k_y)$ (from now on the unit cell size is set to unity), $\epsilon_{\mathbf{k}\sigma} = -\frac{1}{2}\sum_{\mathbf{k}'}\epsilon_{\mathbf{k}'}^\dagger\mathbf{k}'\sigma\mathbf{k}\sigma\mathbf{k}\sigma$, and $N$ is the number of sites in the lattice. The Hamiltonian (3) can be diagonalized using the Bogoliubov transformation $c_{\mathbf{k}\sigma} = u_{\mathbf{k}\sigma}^c c_{\mathbf{k}'\sigma} + v_{\mathbf{k}\sigma}^c c_{\mathbf{k}'\sigma}^\dagger$ with $u_{\mathbf{k}\sigma}^2 + v_{\mathbf{k}\sigma}^2 = 1$, $u_{\mathbf{k}\sigma} v_{\mathbf{k}\sigma} = \Delta_0/2E_{\mathbf{k}}$, and $E_{\mathbf{k}}^e = (\epsilon_{\mathbf{k}}^e + \Delta_{\mathbf{k}})/2$.

Weak charge order may be introduced into the state (3) by assuming the appearance of one or more of the additional order parameters listed below. We note that distinction between site and bond centered orders discussed below is only defined for CDW with integer periods.

Site-centered charge density wave. The local Hartree-Fock potential is modulated along $x$ with potential extrema on the lattice sites [see Fig. 1(a)]; $\Delta H_1 = V_0\Sigma_{\mathbf{k}\sigma}(\alpha^e_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma}^\dagger + Q_0 c_{\mathbf{k}\sigma}^\dagger + \alpha^o_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma}^\dagger + Q_0 c_{\mathbf{k}\sigma})$.

Bond-centered charge density wave. The local Hartree-Fock potential is modulated along $x$ with the extrema of the modulation at midpoints of the horizontal bonds [see Fig. 1(b)]; $\Delta H_2 = V_0\Sigma_{\mathbf{k}\sigma}(\alpha^e_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma}^\dagger + Q_0 c_{\mathbf{k}\sigma}^\dagger + \alpha^o_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma}^\dagger + Q_0 c_{\mathbf{k}\sigma})$.

Transverse dimerization. Single electron tunneling amplitudes are modulated on the horizontal bonds and the wave vector of modulation is along the same direction (i.e., along $x$). The bond centered version, in which the extrema of the modulation lie on the bonds [see Fig. 1(c)] corresponds to $\Delta H_3 = V_0\Sigma_{\mathbf{k}\sigma} \cos(k_x + Q_0/2)(\alpha^e_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma}^\dagger + \alpha^o_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma}^\dagger + Q_0 c_{\mathbf{k}\sigma})$.

Longitudinal dimerization. Single electron tunneling amplitudes are modulated on the vertical bonds, and the wave vector of modulation is along the horizontal direction (i.e., along $x$). The site centered version (i.e., with extrema of the modulation realized on the vertical bonds) is shown in Fig. 1(d), and corresponds to $\Delta H_4 = V_0\Sigma_{\mathbf{k}\sigma} \cos(k_x)(\alpha^e_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma}^\dagger + Q_0 c_{\mathbf{k}\sigma}^\dagger + \alpha^o_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma}^\dagger + Q_0 c_{\mathbf{k}\sigma})$. 

094514-2
Anomalous longitudinal dimerization. The x-components of the $d_{x^2-y^2}$-wave pairing amplitudes are modulated in the x direction. The bond centered version, shown in Fig. 1(c), corresponds to $\Delta \mathcal{H}_5 = V_0 \cos(k_x + Q/2) \left( \alpha c_{\uparrow}^{\dagger} c_{\downarrow}^{\dagger} + \alpha c_{\downarrow} c_{\uparrow} + \text{H.c.} \right)$.

Anomalous transverse dimerization. The y-components of the $d_{x^2-y^2}$-wave pairing amplitudes are modulated in the y direction. The site centered version, shown in Fig. 1(d), corresponds to $\Delta \mathcal{H}_6 = V_0 \cos(k_y + Q/2) \left( \alpha c_{\downarrow}^{\dagger} c_{\uparrow}^{\dagger} + \alpha c_{\uparrow} c_{\downarrow} + \text{H.c.} \right)$.

Note that these subdominant order parameters may appear either as a result of a phase transition in the bulk, or due to pinning by vortices, impurities or any other defects (see discussion in Sec. IV). Following experimental observations in Refs. 14,15,27, we assume that the order is unidirectional, and choose the ordering wavevector to be $Q = Q \hat{e}_z$. However, even if we were to assume checkerboard order, our analysis is carried out to linear order in perturbation theory and, by linear superposition, our results would be identical to those obtained for unidirectional order. For the STM experiments in Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$, $Q = 2\pi/4$, while the neutron scattering experiments on YBa$_2$Cu$_3$O$_{6.35}$ (Ref. 12) correspond to the smaller value $Q = 2\pi/8$. We point out that the six cases listed above are, in general, not orthogonal to each other in a symmetry sense. As a result it is conceivable that more than one order parameter could be simultaneously non-zero; for example, in a microscopic model without particle-hole symmetry, a simple CDW would be expected to induce dimerization as the two order parameters are linearly coupled.

Upon expressing the Hamiltonians $\Delta \mathcal{H}$ in the basis of Bogoliubov quasiparticles, they reduce to the generic form

$$\Delta \mathcal{H}_i = \sum_{\alpha,\sigma} \left[ A_{i,\alpha}^{\dagger} \gamma_{\alpha,\gamma} \gamma_{\alpha,\sigma} + A_{i,\alpha}^{\dagger} \gamma_{\alpha,\gamma} \gamma_{\alpha,\sigma} \right]$$

$$+ \sum_{\alpha} \left[ B_{i,\alpha}^{\dagger} \gamma_{\alpha,\gamma} \gamma_{\alpha,\sigma} + B_{i,\alpha}^{\dagger} \gamma_{\alpha,\gamma} \gamma_{\alpha,\sigma} \right] + \text{H.c.},$$

where

$$A_{i,\alpha}^{\dagger} = V_0 \omega_k, \quad B_{i,\alpha}^{\dagger} = V_0 \eta_k,$$

$$A_{i,\alpha} = V_0 \alpha \omega_k, \quad B_{i,\alpha} = V_0 \alpha \eta_k,$$

$$A_{i,\alpha} = V_0 \cos(k_x + Q/2) \omega_k, \quad B_{i,\alpha} = V_0 \cos(k_x + Q/2) \eta_k,$$

in terms of the coherence factors $\omega_k = u_k + qu_k - v_k + qu_k$ and $\eta_k = u_k + qu_k + v_k + qu_k$.

STM experiments measure the local density of states $\rho(r,e) = \sum_{n\alpha}(\langle \gamma_{\alpha,\gamma}^{\dagger} \gamma_{\alpha,\gamma} \rangle | \delta(e - e_{n\alpha}) + \langle \gamma_{\alpha,\gamma}^{\dagger} \gamma_{\alpha,\gamma} \rangle | \delta(e + e_{n\alpha}) \rangle$, where the summation over $n$ ranges over all excited states. In particular, we are interested in the Fourier transform

$$\rho_Q(e) = \frac{1}{N} \sum_{\gamma} e^{-i e \gamma} \rho(r, e)$$

$$= \frac{1}{N} \sum_{n\alpha} \left[ \langle \gamma_{\alpha,\gamma}^{\dagger} \gamma_{\alpha,\gamma} \rangle | \delta(e - e_{n\alpha}) \rangle + \langle \gamma_{\alpha,\gamma}^{\dagger} \gamma_{\alpha,\gamma} \rangle | \delta(e + e_{n\alpha}) \rangle \right].$$

Although a full treatment of all terms in Eq. (4) is complicated, progress can be made if we assume that the ordering represented by $\Delta \mathcal{H}$ is weak, allowing us to obtain an analytic expression for the Fourier transform that is exact to linear order in $V_0$. This is then the sum of two contributions

$$\rho_Q(e) = \rho_Q(e) + \rho_Q(e) + O(V_0^2),$$

where $\rho_Q(e)$ is obtained by ignoring the $B_k$ term in the perturbation (4) and vice versa.

A small value of $V_0$ leads to another important simplification: We only need to consider the pairwise mixing between states connected by $\Delta \mathcal{H}$. For instance, in computing $\rho_Q(e)$ for $Q = 2\pi/4$ one would have to analyze coupled equations for four quasiparticles $(k, k + Q, k + 2Q)$, and $(k + 3Q = k - Q)$ connected by the perturbation. However, in the limit when $V_0$ is small, there is at most one pair of quasiparticles that have similar energies, and that will be hybridized appreciably by $\Delta \mathcal{H}$. This hybridization can be analyzed by diagonalizing the corresponding two-by-two Hamiltonian, which gives the new eigenstates $|\alpha_{k\sigma}\rangle$. 

and $|\beta_{k\sigma}|$ with energies $E_{k\pm} = (E_k + E_{k+Q})/2 \pm \frac{1}{2} \left[ \left( (E_k - E_{k+Q})^2 \right) + |A_k|^2 \right]^{1/2}$. Note that these states satisfy $\langle 0 | c_{k+Q\uparrow}^\dagger c_{k\uparrow}^\dagger \alpha_{k\uparrow} \beta_{k\sigma}^\dagger \alpha_{k\sigma} c_{k\sigma} | 0 \rangle = \frac{i}{2} \delta_{k\pm}^a u_k u_{k+Q} \sin 2 \delta_k e^{-i\delta_k}$, where we have defined $A_k = |A_k| e^{i\delta_k}$, and $\tan \frac{\theta_k}{2} = 2 |A_k| / (E_k - E_{k+Q})$. From these results one easily finds

$$
\rho^B_\delta(\epsilon) = \frac{1}{N} \sum_k \frac{A_k^*}{\sqrt{\frac{(E_k - E_{k+Q})^2}{2} + |A_k|^2}} \times \{ u_k u_{k+Q} (\delta(\epsilon - E_{k+Q}) - \delta(\epsilon - E_{k-})) \\
+ v_k v_{k+Q} (\delta(\epsilon + E_{k+Q}) - \delta(\epsilon + E_{k-})) \},
$$

When considering $\rho^B_\delta$, one would naively expect that it is always smaller than $\rho^A_\delta$, because the perturbation terms of the form $\langle \gamma_{k+Q}^\dagger \gamma_k | c_{k+Q\uparrow}^\dagger c_{k\uparrow}^\dagger \alpha_{k\uparrow} \beta_{k\sigma}^\dagger \alpha_{k\sigma} c_{k\sigma} | 0 \rangle$ connect states that differ in energy by $E_k + E_{k+Q}$, a factor that is never small. However, in some cases the coherence factors in $A_k$ vanish at important regions of the Brillouin zone, making $\rho^B_\delta$ anomalously small. In addition, as we discuss below, both $\rho^{A,B}_\delta(\epsilon)$ are large at biases corresponding to the saddle points on the degeneracy lines $E_k = E_{k+Q}$ and van Hove singularities of the Bogoliubov quasiparticles $\epsilon_m = \Delta_0$. A nearly identical analysis of the one above for $\rho^A$ yields

$$
\rho^B_\delta(\epsilon) = \frac{1}{N} \sum_k \frac{B_k^*}{\sqrt{\frac{(E_k + E_{k+Q})^2}{2} + |B_k|^2}} \times \{ u_k u_{k+Q} (\delta(\epsilon - E_{k+Q}) + \delta(\epsilon - E_{k-})) \\
- u_k u_{k+Q} (\delta(\epsilon + E_{k+Q}) - \delta(\epsilon + E_{k-})) \},
$$

where $E_{k\pm} = \pm (E_k - E_{k+Q})/2 \pm \frac{1}{2} \left[ \left( (E_k - E_{k+Q})^2 \right) + |B_k|^2 \right]^{1/2}$. Equations (8),(9), are two key results of this paper. In combination with Eqs. (5), they provide an explicit expression for the energy dependence of the Fourier component of the local density of states $\rho^A_\delta(\epsilon)$ when the translational symmetry breaking is weak.

From the form of $A_k$ and $B_k$, it is obvious that when there is no mixing between bond and site centered CDW, $\rho^A_\delta(\epsilon)$ can be made real at all energies by an appropriate choice of the overall phase, i.e., by a shift in the origin of coordinates when doing the Fourier transform. One obvious observation is that the results for the site-centered and bond-centered CDW are identical modulo an overall phase factor of $e^{iv/2}$. If one defines the Fourier transform in such a way that it is real in both cases, the origin will coincide with one of the sites of the lattice for the site-centered CDW, and it will be at the center of a bond for the bond-centered CDW. Hence careful analysis of the STM data allows one to distinguish two kinds of CDW, a task that is not possible in neutron scattering experiments with current resolution. Mixing site and bond-centered orders breaks inversion symmetry and leads to a complex-valued $\rho^A_\delta(\epsilon)$.

III. CHARGE ORDER WITH NO RANDOMNESS

A. Period four CDW in Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$

We first focus on modulations at $\mathbf{Q} = (2\pi/4,0)$ that is relevant to Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$. Figure 2 shows results of the numerical evaluation of formulas (7),(8), and (9) for various perturbations (5). [As transverse and longitudinal dimerization curves are qualitatively similar, curves corresponding to the former are not displayed.] We choose the band structure and the value of $\Delta_0$ in Eq. (3) appropriate to Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$. $t_1/t = 0.3$, $\mu/t = -0.99$ (this corresponds to 14% doping), $\Delta_0/t = 0.14$ and $\Delta_0 = 40$ meV. We set $V_0/t = 0.02$, although its precise value is inconsequential, as $\rho^A_\delta(\epsilon)$ scales linearly with $V_0$ when the latter is sufficiently small.

If we turn our attention to the expression for $\rho^A$, Eq. (8), we see that the energy denominator is smallest for those quasiparticles lying close to the degeneracy points $E_k = E_{k+Q}$, which are strongly hybridized by the $A_k$ part of the perturbation. Figure 3 shows the four loci of such points, $a$ through $d$, that are degenerate with $a'$ to $d'$ respectively. The pairs $aa'$ and $bb'$ are obvious, since they have $k_z = \pm \pi/4$ and $k_z = \pm \pi/4$ (for the same $k_x$); the other two require a more detailed analysis of the band structure. Out of the set of degeneracy points, we expect large contributions from the neighborhood of points $A$ and $B$, as the dispersion of hybridized energies $E_{k\pm}$ is flat at these points. These same regions
which changes sign whenever measurements. particle-hole symmetry for small biases, as observed in STM example, for a diamond-shaped Fermi surface the energy denominator in Eq. perturbations considered, around 0.5 the degeneracies mentioned above: the peak at energies that dominate the CDW plots can be understood in terms of states.

of the Brillouin zone will dominate the $\rho^d$ contribution, since the energy denominator in Eq. (9) will be small only if both $k$ and $k+Q$ lie close to the Fermi surface, which occurs only in the neighborhood of points A and B. In addition we expect, for both $\rho^A$ and $\rho^B$ pieces, a large contribution at $\epsilon = \Delta_0$, where a van Hove singularity for the Bogoliubov quasiparticles yields a logarithmic divergence in the density states.

We turn now to the numerical results displayed in Fig 2. Consider first the simple CDW curves. The sharp features that dominate the CDW plots can be understood in terms of the degeneracies mentioned above: the peak at energies around 0.5$\Delta_0$ comes from the vicinity of the A point, the peak around 0.7$\Delta_0$ comes from the vicinity of B, and the pile around $\Delta_0$ comes from the van Hove singularity near the $(0,\pi)$ and $(\pi,0)$ points. The longitudinal dimerization results can be similarly understood by taking into account the additional minus sign in the vicinity of the point B due to the $\cos(k_x + \pi/4)$ factor in $A_k$ and $B_k$. The results for the anomalous dimerization can also be understood in this framework after taking into account the extra sign modulation in $u_kv_{k'}$, which changes sign whenever $\Delta_k$ does. Note that, for all perturbations considered, $\rho_Q(\epsilon)$ displays approximate particle-hole symmetry for small biases, as observed in STM measurements.\textsuperscript{14} This is not a generic property of $\rho_Q(\epsilon)$; for example, for a diamond-shaped Fermi surface $\mu = t' = 0$ the CDW signal is exactly antisymmetric. Finally, note that $\rho_Q(\epsilon)$ goes to zero at $\epsilon = 0$ in all cases; this reflects the vanishing density of low-energy quasiparticle states in an ideal $d$-wave superconductor.

While the results in Fig. 2 describe a system with infinite quasiparticle lifetime and no disorder, in a real system disorder will smear the sharp features in $\rho_Q(\epsilon)$. To model this, these curves are redisplayed in Fig. 4 after smearing over an energy width $w = 0.2\Delta_0$. This procedure smooths the sharp features in the spectra, and generates finite intensity at low energies. Notice that the smeared CDW curve does not have the two large peaks surrounding zero bias, nor does it have clear zero crossings at $|\epsilon| \approx \Delta_0$, the dominant features of the STM spectra observed in Refs. 13,14. By contrast, the signal related to longitudinal dimerization or, especially, to either kind of anomalous dimerization, share many of the qualitative properties of the data. However, neither curve by itself accounts for all the observed features in the data. This prompts us to consider a combination of several kinds of order. For example, if we assume that no pairing modulation is present, the combination of longitudinal dimerization and CDW, $(\text{long. dim.)} + 1.05$ (CDW), shown as a solid curve in Fig. 5 reproduces the STM results reasonably well, with only a small difference in the position of the peaks (±17 meV, compared to experimentally observed ±25 meV). Alterna-

FIG. 3. Fermi surface for Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$. Dashed lines correspond to the quasiparticles that satisfy $E_{k+Q} - E_k = 0$, and are strongly affected by $\Delta H$ when $Q = (2\pi/4,0)$. Quasiparticles on line $a$ hybridize with quasiparticles on line $a'$ (and similarly for lines $b$ and $b'$, and curves $c$, $c'$ and $d$, $d'$). Crossings of these lines with the Fermi surface (points A and A', B and B') give the minimal energy of such quasiparticles: 0.5$\Delta_0$ and 0.7$\Delta_0$ respectively. Contributions from these points produce sharp peaks at energies 20 and 30 meV in Fig. 2. The Van Hove singularity for the Bogoliubov quasiparticles at energy $\Delta_0$ leads to a peak at 40 meV.

FIG. 4. The results in Fig. 2 are shown after smearing over an energy range of 8 meV. To simplify the comparison, $\rho_Q(\epsilon)$ was multiplied by $-1$ for CDW and anomalous transverse dimerization, and by a factor of $-\frac{1}{2}$ for transverse dimerization.

FIG. 5. $\rho_Q(\epsilon)$ for Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$ type band structure, ordering wave vector $Q = 2\pi/4$ and a combination of charge orders: longitudinal dimerization and CDW, 1.05 (CDW) + (long. dim.) (solid line); anomalous longitudinal dimerization and CDW, (anom. long. dim.) + 0.2 (CDW) (long-dashed line). The same smearing is assumed as in Fig. 4. For clarity, curves have been offset vertically by 0.25.
tively we can match experimental data by considering the combination of anomalous longitudinal dimerization and CDW, (anom. long. dim.) + 0.2 (CDW), shown as a dashed curve in Fig. 5. It slightly overestimates the peak bias to be ± 29 meV, and yields a low intensity at zero bias. Any intermediate combination between these two scenarios also gives good agreement with experiments. Although CDW was used in both combinations discussed above, it can be substituted by transverse dimerization, which yields a qualitatively similar $\rho_Q(\epsilon)$ to CDW. We note that, for $\epsilon \leq 3 \Delta_0$, the results come from the vicinity of the Fermi surface and are robust against variations in the band structure that do not alter qualitatively the shape of the Fermi surface (e.g., the a and b' lines do not move below the Fermi surface).

We note, however, that a certain care should be exercised when comparing our results to the STM spectra in Refs. 13–17. An additional complication of the experiments is that for every point on the surface of the sample the height of the STM tip is adjusted to keep the tunneling current at a certain voltage fixed. This implies that the local density of states is not measured directly, but instead its product with some space dependent function is measured. In Sec. V we review how this normalization procedure can be included in analysis.

**B. Period eight CDW in YBa$_2$Cu$_3$O$_{6.35}$**

To model YBa$_2$Cu$_3$O$_{6.35}$ for which CDW-type peaks have been observed at $Q = 2 \pi/8$ (Ref. 12) we take the same band structure $t_1/t = 0.3$, but a different value of the chemical potential $\mu/t = 0.14$, $\Delta_0 = 40$ meV, $V_0/t = 0.02$, and keep the energy smearing $w = 0.2 \Delta_0$. The main difference with the charge order at $Q = 2 \pi/4$ is that the analog of line $a$ in this case is inside the Fermi surface, so that the only contributions will come from the vicinity of point B at energies around $0.8 \Delta_0$. This leads to less structure in $\rho_Q(\epsilon)$ and smaller intensity at zero energy (see Fig. 6).

**IV. DISPERSION OF THE STM SPECTRA**

Recent experiments$^{16,17}$ demonstrated that the STM spectra of Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$ cannot be explained by charge order at a unique wave vector. Peaks in $\rho_Q(\epsilon)$ have been observed away from $(2 \pi/4,0)$ and the wave vectors of the peaks are energy dependent. In this section we review and compare two possible scenarios for such dispersion of the STM spectrum: (1) randomness and pinning of charge order, (2) scattering of BCS quasiparticles by impurities and crystal defects. Both cases can be described using an extension of the formalism presented in the previous section. We consider a single particle Hamiltonian that generalizes Eq. (4)

$$\Delta \mathcal{H} = \sum_{k,q,\sigma} \left[ V_{k,q} c_{k,\sigma}^\dagger c_{k+q,\sigma} + H.c. + W_{k,q} (c_{k,\sigma}^\dagger c_{k-q,-\sigma} + c_{-k-q,\sigma}^\dagger c_{k,\sigma}) + H.c. \right].$$

Here $q$ describes the wave vector of the potential modulation, and the $k$ dependence of $V$ and $W$ gives its internal structure (e.g., simple CDW vs dimerization)$^{31}$ In Sec. II we considered charge order at a unique wave vector that corresponds to taking potentials $V$ and $W$ as $\delta(q-Q)$. In the case of a disordered CDW we expect that these functions are no longer $\delta$ functions but are centered narrowly around some particular wave vector. By contrast, when translational symmetry breaking comes from impurities, we expect to find $V$ and $W$ that extend over a wide range of wave vectors $q$. A crucial property of Eqs. (8) and (9) is that $\rho_Q(\epsilon)$ depends linearly on the perturbations $V_q$ and $W_q$, hence the formalism for computing $\rho_Q(\epsilon)$ can be applied independently to each wave vector $q$.

The charge order observed in Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$ (Refs. 14,15) had strong signatures of randomness and pinning in the form of lattice defects. The correlation length estimated from the distance between defects was $\sim 20 a_0$. If we assume the charge order to be of the form $1.05$ (CDW) + (long. dim.), we can describe it as

$$V_{k,q} = V_0(q) \left[ 1.05 + \cos \left( k_x + \frac{q_x}{2} \right) \right], \quad W_{k,q} = 0, \quad (11)$$

where $V_0(q)$ is a Gaussian distribution function centered at $(2 \pi/4,0)$ with a width $2 \pi/20 a_0$. We display in Fig. 7 the signal produced by a perturbation of this kind, for bias voltages 8, 16, and 20 mV, as a function of wavevectors along the (0,0) to $(\pi,0)$ direction. The resulting dispersion agrees closely with that observed in Refs. 15,16.

In experiments of Hoffman et al.$^{16}$ and McElroy et al.$^{17}$ peaks in the LDOS were observed at very different wave vectors from $(2 \pi/4,0)$ (including some in diagonal directions). This suggests that either $V_{k,q}$ or $W_{k,q}$ must be nonzero over a fairly wide range of values of $q$, and the most natural candidate is scattering by impurities.$^{16-18}$ For concreteness, we assume that the impurity induces a higher chemical potential at a single site, so the perturbation used corresponds...
need to a potential at wave vector reverse the arguments given in Sec. II. There, we started with applied bias voltage. To all cases there is a pronounced peak that disperses with the to (）/H20849 to a simple CDW which is uniform in fi

FIQ. 7. Dispersion in the (0,0) to (π,0) direction in a system with charge order with randomness (momentum is measured in units of 2π). Charge order is assumed to have Gaussian distribution centered around wave vector (2π/4,0) with the width 2π/20. The function V(q) in Eq. (11) is shown, up to a scale, as the thick solid curve. For visual clarity, only results corresponding to the linear combination 1.05 (CDW) to (id) are displayed. Each curve corresponds to a different bias; starting from the bottom, the biases are 8, 12, 16, and 20 mV. Throughout, the quasiparticle smearing is fixed at 8 meV.

to a simple CDW which is uniform in q, Vk,q = V0, Wk,q = 0. In Fig. 8 we show the signal computed along the (0,0) to (π,0) direction at bias voltages 8, 12, 16, and 20 mV. In all cases there is a pronounced peak that disperses with the applied bias voltage. To find the positions of these peaks we reverse the arguments given in Sec. II. There, we started with a potential at wave vector Q and found that only quasiparticles at certain energies were strongly affected by it. Now we need to find the modulation wave vector that affects quasi-

FIG. 8. Dispersion in the (0,0) to (π,0) direction in a model with impurity induced quasiparticle scattering (momentum is measured in units of 2π). Each curve corresponds to a different bias; starting from the bottom, the biases are 8, 12, 16, and 20 mV. Unlike other computations in this paper, the quasiparticle smearing is fixed at 2 meV. This is done since the main features in these curves are averaged out for the usual smearing of 8 meV.

FIG. 7. Dispersion in the (0,0) to (π,0) direction in a system with charge order with randomness (momentum is measured in units of 2π). Charge order is assumed to have Gaussian distribution centered around wave vector (2π/4,0) with the width 2π/20.

 unlike other computations in this paper, the quasiparticle smearing is fixed at 2 meV.

particles at a given energy. From the band structure of Bi2Sr2CaCu2O8+δ we find for the peak positions (in units of 2π): 0.35, 0.32, 0.29, and 0.26. The curves on Fig. 8 show general agreement with this “quasiparticle scattering” argument, except for a consistent small shift to lower wave vector, which comes from the energy smearing procedure. This dispersion is stronger than that displayed in the data at wave vector (2π/4,0), but is in good agreement with the dispersion observed at other wave vectors.

In the discussion above we considered two situations: ordered CDW and noninteracting electrons with impurities. There may also be an intermediate regime with interacting electrons close to the CDW instability and with disorder. Qualitatively, this case may be described by Eq. (10) but with the potentials Vk,q and Wk,q coming not only from the external fields but also from the density induced in the electron system. For simplicity let us take only one of the channels discussed in Sec. II, e.g., simple CDW (the generalization to the case of several channels is straightforward). Then

\[
\Delta \mathcal{H} = \sum_q \bar{\rho}_q U_q \hat{c}_q + \sum_q V^\text{ext}_q \rho_q \hat{c}_q^+ \text{ H.c.}
\]  

with

\[
\hat{\rho}_q = \sum_{k\sigma} c_{k\sigma}^\dagger c_{k+q\sigma}.
\]

The response of the quasiparticles to Eq. (12) in the Hartree approximation is determined by the effective perturbation Hamiltonian

\[
\Delta \mathcal{H} = \sum_{k,q,\sigma} V_{q}^\text{eff} c_{k,q\sigma}^\dagger c_{k\sigma} H.c.
\]

\[
V_q^\text{eff} = V_q + U_q \langle \hat{\rho}_q \rangle = \frac{V_q^{\text{ext}}}{1 - U_q \chi_0(q, \omega = 0)},
\]

where \(\chi_0(q, \omega = 0) = \langle \hat{\rho}_q \hat{\rho}_q^\dagger \rangle\) must be computed for the noninteracting system. This corresponds to contributions to the LDOS from the class of diagrams in Fig. 9(a). When the
system is close to the CDW instability, the denominator of Eq. (13) approaches zero around some particular wave vector \( \mathbf{Q} \). Hence, \( V_{\mathbf{q}}^{\text{eff}} \) may be peaked around \( \mathbf{Q} \) even when \( V_{\mathbf{q}}^{\text{ext}} \) is momentum independent. In principle we can go beyond the Hartree approximation, including diagrams such as those shown in Figs. 9(b),9(c). These will introduce a frequency-dependent self-energy, as in the case of pinned spin density fluctuations considered in Ref. 25.

It is interesting to ask whether by analyzing experimental data one can separate contributions of disordered CDW’s from those due to quasiparticle scattering off impurities. Reference 15 pointed out that the presence of a weakly dispersing signal at wave vector \( (2\pi/4,0) \) makes charge order a likely candidate at that wave vector. Here we build on this idea and suggest that a more consistent approach is to analyze \( \rho_\mathbf{q} (\epsilon) \) at many different wave vectors using a reasonable set of basis functions, e.g., simple CDW and dimerization. Such analysis will give the \( \mathbf{q} \) dependence of various components in the potentials \( V_{\mathbf{k},\mathbf{q}} \) or \( W_{\mathbf{k},\mathbf{q}} \). We expect that some of them will be almost uniform in momentum space and correspond to localized defects, such as impurities; whereas others will be centered around particular wave vectors and arise from the existence or at least proximity of charge order.

When the field of view of the STM measurement contains more than one impurity there are several important questions that we need to address. We must ask how the contributions from different impurities add up and whether the system retains the property of uniformity of phase of \( \rho_\mathbf{q} (\epsilon) \) at fixed \( \mathbf{q} \) but different \( \epsilon \). We consider impurities that cause an arbitrary potential \( V_{\mathbf{k},\mathbf{q}} \) in Eq. (10), i.e., they may modify the chemical potential, the electron kinetic energy, or the pairing amplitude, but first we assume that all impurities are identical. The Fourier component of the LDOS is proportional to \( \rho_\mathbf{q} (\epsilon) \), where \( \mathbf{r}_n \) runs over impurity positions. If one impurity does not break parity symmetry, we can make \( V_{\mathbf{k},\mathbf{q}} \) real by choosing the origin at the position of this impurity (see also discussion in Sec. II). This implies that \( V_{\mathbf{k},\mathbf{q}}^{\text{tot}} \), which in turn proves that, at fixed \( \mathbf{q} \), \( \rho_\mathbf{q} (\epsilon) \) has constant phase (modulo \( \pi \)) for all values of \( \epsilon \) [see Eqs. (5)–(9)]. So, in the case of identical impurities we have only one phase to worry about and we can always make \( \rho_\mathbf{q} (\epsilon) \) real by an appropriate choice of origin. When impurities are different, we will have an intrinsically complex \( \rho_\mathbf{q} (\epsilon) \), with possibly energy dependent phase at different bias voltages. In either case, interference among the impurities leads to an appreciable suppression of the amplitude of \( \rho_\mathbf{q} (\epsilon) \). When there are many impurities in the area \( A \) of the STM field of view, and their positions are uncorrelated, each impurity introduces a random phase to \( V_{\mathbf{k},\mathbf{q}}^{\text{tot}} \), whose amplitude can be analyzed in terms of a random walk. Therefore, in a typical experiment we expect that with increasing the system size, \( \langle |\rho_\mathbf{q} (\epsilon)| \rangle \) will decay as \( 1/\sqrt{A} \), with statistical fluctuations of the same order. This argument also applies to the case of disordered CDW, where the role of impurities is played by defects in the CDW lattice.

V. EXPERIMENTAL CONSIDERATIONS

Our discussion in the earlier sections was restricted to models on a square lattice for which we calculated the lattice density of states in the presence of several kinds of translational symmetry breaking. In analyzing actual experimental data, additional effects need to be taken into account: the real space structure of the atomic wave functions, and the current normalization condition used in the STM measurements.\textsuperscript{13–17} These are reviewed below.

A. Structure factors

For lattice Hamiltonians, wave vectors that differ by the reciprocal lattice vectors \( \mathbf{G} \) are equivalent. For the Fourier components of the local density of states \( \rho_\mathbf{q} \) this implies that \( \rho_\mathbf{q}^{\text{lattice}} (\epsilon) = \rho_\mathbf{q}^{\text{lattice}} (\epsilon) \) for any \( \mathbf{G} \). To understand why this equivalence is not observed in experiments we must take into account the real space structure of the Wannier wave functions of electrons in the conduction band. Here we study the effects of a single-band tight-binding model, in which Bloch states at the Fermi level can be written as a superposition of localized atomic orbitals \( \psi_{\mathbf{r}} (\mathbf{r}) = \sum_n e^{i \mathbf{k} \cdot \mathbf{R}} \phi_n (\mathbf{r} - \mathbf{R}) \).

We begin by projecting the Bogoliubov–de Gennes (BdG) wave functions in terms of the single-band wave functions

\[
U_n (r) = \sum_k a_k n \psi_k (r),
\]

\[
V_n (r) = \sum_k b_k n \psi_k (r).
\]

If we know how an operator \( \hat{\Theta} \) acts on the Bloch wave functions \( \psi_k \), \( \hat{\Theta} \psi_k = \sum_k \Theta_{k,k'} \psi_k \), then the above relation induces an action on \( a_k \) through \( \hat{\Theta} a_k = \sum_k \Theta_{k,k'} a_k \) (and similarly for \( b_k \)). Thus, the solutions to the BdG equation

\[
\begin{pmatrix}
cc \hat{\xi} + \hat{V} & \hat{\Delta} + \hat{W} \\
\hat{\Delta}^\dagger + \hat{W}^\dagger & -\hat{\xi} - \hat{V}
\end{pmatrix}
\begin{pmatrix}
a_k^\dagger \\
b_k^\dagger
\end{pmatrix}
= E_n
\begin{pmatrix}
a_k \\
b_k
\end{pmatrix}
\]

will be independent of the Wannier wave function \( \phi (\mathbf{r}) \) once we determine the action of the BdG operator on the Bloch wave functions \( \psi_k \).

For positive biases \( \epsilon > 0 \) (the \( \epsilon < 0 \) case can be analyzed analogously), the LDOS is given by

\[
\rho_\mathbf{q}^{\text{phys}} (\epsilon) = \int d^2 r e^{i \mathbf{q} \cdot \mathbf{r}} \sum_n u_n^\dagger (\mathbf{r}) u_n (\mathbf{r}) \delta (\epsilon - E_n)
\]

\[
= \sum_n \delta (\epsilon - E_n) \sum_{k,k'} a_k^\dagger n a_k n J(k,k',\mathbf{q}),
\]

where

\[
J(k,k',\mathbf{q}) = \int d^2 r e^{i \mathbf{q} \cdot \mathbf{r}} \phi_k^\dagger (\mathbf{r}) \phi_k (\mathbf{r})
\]

\[
= \sum_{\mathbf{G}} \delta (\mathbf{q} - (k - k') + \mathbf{G})
\]

\[
\times \sum_\mathbf{R} e^{i \mathbf{k} \cdot \mathbf{R}} \int d^2 r e^{i \mathbf{q} \cdot \mathbf{r}} \phi_k^\dagger (\mathbf{r}) \phi_k (\mathbf{r} - \mathbf{R}).
\]
If we assume that the relevant electronic wave function is well localized, we can ignore terms involving the overlap across different sites ($\mathbf{r} \neq 0$) in the last integral. Then, the only dependence of $J$ on $\mathbf{k}$ and $\mathbf{k}'$ is through the crystal momentum conservation condition, and we find

$$\rho^\text{phys}_q(\epsilon) = S_q \rho^\text{lattice}_q(\epsilon)$$  \hspace{1cm} (14)

with

$$\rho^\text{lattice}_q(\epsilon) = \sum_{k,n} \delta(\epsilon - E_n) a_k^\dagger n a_{k+q}^n$$

$$S_q = \int d^2 \mathbf{r} |\phi(\mathbf{r})|^2 e^{i\mathbf{q} \cdot \mathbf{r}}.$$

One immediately recognizes that in Eq. (14) $\rho^\text{lattice}_q(\epsilon)$ is the Fourier component of the lattice density of states that we analyzed in the earlier sections and $S_q$ is the structure factor determined by the atomic wave functions. Peaks in the STM spectra arise from $\rho^\text{lattice}_q(\epsilon)$, whereas $S_q$ only provides additional wave vector dependence. Hence in our tight binding model we expect that wave vectors which differ only by reciprocal lattice vectors have peaks at the same energies, but with generally different intensities.

B. Current normalization condition

An additional subtlety of STM experiments in Refs. 13–17 is the space-dependent normalization used. It is natural to assume that the tunneling matrix elements do not change appreciably with energy over the energy range of interest. Thus, if $z$ is the height of the STM tip above the sample, and $\mathbf{r}$ is its two-dimensional 2D coordinate along the plane of the sample surface, then the differential tunneling conductance $g$ can be written as

$$g(\mathbf{r},z,\epsilon) = f(\mathbf{r}) \rho^\text{phys}(\mathbf{r},\epsilon),$$

where $\rho^\text{phys}(\mathbf{r},\epsilon)$ is the 2D density of states in the CuO plane. The experiments in Refs. 13–17 adjust the $z$ coordinate at every point $\mathbf{r}$ along the surface, so as to keep the current at $V_f$ fixed at a predetermined value $I_f$. The differential conductance normalized in this fashion is

$$g^\text{meas}(\mathbf{r},\epsilon) = f(\mathbf{r}) \rho^\text{phys}(\mathbf{r},\epsilon),$$

where $f(\mathbf{r}) = I_f/\int d^2 \mathbf{r} \rho^\text{phys}(\mathbf{r},\epsilon)$. Let us now discuss some properties of $g^\text{meas}(\mathbf{r},\epsilon)$.

The spatial variation in $f(\mathbf{r})$ is dominated by the inhomogeneous quasiparticle weight within a unit cell. To see this, write

$$\rho^\text{phys}(\mathbf{r},\epsilon) = \rho^\text{per}(\mathbf{r},\epsilon) + \rho^\text{TSB}(\mathbf{r},\epsilon),$$

where $\rho^\text{per}(\mathbf{r},\epsilon)$ is periodic with the lattice and is of order one, whereas $\rho^\text{TSB}(\mathbf{r},\epsilon)$ breaks lattice translational symmetry and is of order $V_0^2$ in our formalism. If we define $f^\text{per}(\mathbf{r}) = I_f/\int d^2 \mathbf{r} \rho^\text{per}(\mathbf{r},\epsilon)$, then

$$f(\mathbf{r}) = f^\text{per}(\mathbf{r})[1 - H(\mathbf{r})]$$

in terms of a TSB function $H(\mathbf{r})$ of order $V_0$.

It is convenient to absorb $f^\text{per}$ into $\rho$ by introducing a new function $\rho'(\mathbf{r},\epsilon) = f^\text{per}(\mathbf{r}) \rho^\text{phys}(\mathbf{r},\epsilon)$. Due to the symmetry properties of $f^\text{per}$, $\rho'$ is simply related to $\rho^\text{lattice}$ through a modified structure factor

$$\rho'_q(\epsilon) = S_q \rho^\text{lattice}_q(\epsilon)$$

$$S_q' = \int d^2 \mathbf{r} f^\text{per}(\mathbf{r}) |\phi(\mathbf{r})|^2 e^{i\mathbf{q} \cdot \mathbf{r}}.$$

Expressing $g^\text{meas}(\epsilon)$ in terms of $\rho'$,

$$g^\text{meas}_q(\epsilon) = \rho'_q(\epsilon) - \int \frac{d^2 k}{(2\pi)^2} H_{\mathbf{k} \cdot \mathbf{q}} \rho'(\mathbf{k}^*) \epsilon,$$

we see that $g^\text{meas}_q(\epsilon)$ gets “direct” contributions from structure in the LDOS at wave vector $\mathbf{q}$, as well as “shadow” contributions from structure in the LDOS at other wave vectors $\mathbf{k}$, whenever $H_{\mathbf{k} \cdot \mathbf{q}}$ is nonzero. Whereas Eq. (15) is an exact relation, it is useful to truncate it to order $V_0^2$ by keeping in the second term only those contributions coming from the neighborhood of the reciprocal vectors $\mathbf{k} \approx \mathbf{G}$,

$$g^\text{meas}_q(\epsilon) = \rho'_q(\epsilon) - \alpha_q \rho^\text{lattice}_{k=0}(\epsilon) + O(V_0^4),$$

where

$$\alpha_q = \sum \frac{H_{\mathbf{k} \cdot \mathbf{q}} S_{\mathbf{k}, \mathbf{G}}'}{S^\text{meas}_q(\epsilon)}.$$

In this approximation the shadow contribution to $g^\text{meas}_q(\epsilon)$ factorizes into the space-dependent factor $\alpha_q$ and the space-averaged density of states $\rho^\text{lattice}_{k=0}$. From Eqs. (16) and (17) we can verify an important property of the tunneling spectra

$$g^\text{meas}_{\mathbf{q} + \mathbf{G}}(\epsilon) = g^\text{meas}_{\mathbf{q}}(\epsilon)$$

when $\mathbf{G}$ is a vector of the reciprocal lattice and $\mathbf{q}$ is not. Hence, we expect $g^\text{meas}_{\mathbf{q}}(\epsilon)$ and $g^\text{meas}_{\mathbf{q} + \mathbf{G}}(\epsilon)$ to have peaks at the same energies but in general with different overall amplitudes.

An interesting question to ask is whether it is possible to analyze experimental data in a way that would allow to separate direct and shadow contributions to $g^\text{meas}_q(\epsilon)$. Below we demonstrate that this is possible using an exact sum rule obeyed by $\rho^\text{lattice}_q(\epsilon)$. Regardless of the model used and the nature of the symmetry breaking perturbation, the sum over all frequencies of $\rho^\text{lattice}_q(\epsilon)$ should be identically zero for all $\mathbf{q}$ different from the reciprocal lattice vectors $\mathbf{G}$:

$$\int_{-\infty}^{\infty} d\epsilon \rho^\text{lattice}_q(\epsilon) = \frac{1}{N} \sum_{\mathbf{k}\epsilon} \langle 0 \mid \hat{c}_{\mathbf{k}+\mathbf{q}r} \hat{c}_{\mathbf{k}}^\dagger \rangle \langle 0 \rangle$$

$$= 2 \sum_{\mathbf{G}} (2\pi)^2 \delta(\mathbf{q} - \mathbf{G}).$$

In principle, this identity can be used to remove the shadow contribution in Eq. (15). In particular, for $\mathbf{q} \neq \mathbf{G}$, combining...
the approximate result (16) and our knowledge of \( \rho_{k=0}^{lattice}(\epsilon) \) from experiment, we can fix \( \alpha_{q} \) by requiring the sum rule to be obeyed:

\[
\rho_{q}^{I}(\epsilon) = g_{\text{meas}}^{\text{meas}}(\epsilon) \frac{\int_{-V_{\text{max}}}^{V_{\text{max}}} g_{q}^{\text{meas}}(\epsilon)d\epsilon}{\int_{-V_{\text{max}}}^{V_{\text{max}}} (g_{\text{meas}}^{\text{meas}}(\epsilon))d\epsilon}.
\]

(18)

Here \( V_{\text{max}} \) should be chosen sufficiently large so that the ratio of the two integrals is close to its saturated value, yet it should be small enough that we are still justified in using a single band model and a local picture of electron tunneling.

For completeness, we also list two other sum rules obeyed by tunneling spectra. By construction, at every wave vector \( q \neq 0 \) the function \( g_{\text{meas}}^{\text{meas}}(\epsilon) \) must satisfy the normalization condition

\[
\int_{0}^{eV_{f}} d\epsilon g_{q}^{\text{meas}}(\epsilon) = 0.
\]

One can derive an independent sum rule if we restrict the class of symmetry breaking Hamiltonians to effective one-particle operators \( \langle 0|\{c_{k+q\sigma}, H\}, c_{k\sigma}\rangle|0\rangle \rangle \).

\[
\int_{-\infty}^{\infty} d\epsilon \epsilon \rho_{q}^{\text{lattice}}(\epsilon) = \frac{1}{N} \sum_{k\sigma} \langle 0|\{c_{k+q\sigma}, H\}, c_{k\sigma}\rangle|0\rangle \rangle = \frac{2}{N} \sum_{k\sigma} V_{k,q}.
\]

For the basis functions discussed in Sec. II we find that only the \( V_{k,q} \) describing simple CDW gives finite contributions after summing over \( k \). Hence,

\[
\int_{-\infty}^{\infty} d\epsilon \epsilon \rho_{q}^{\text{lattice}}(\epsilon) = 2 V_{\text{CDW}}.
\]

It is important to point out that this sum rule will be spoiled by shadow contributions in Eq. (15), and is only of use if these have been previously removed, using for example procedure in equation Eq. (18).

As a useful consistency check of our formalism, one can easily verify that expressions (7), (8), and (9) satisfy both sum rules. We emphasize, however, that although these expressions are only correct to linear order in perturbation strength, the sum rules are nonperturbative and therefore hold to all orders in perturbation theory. Furthermore, their validity is not affected by the introduction of finite quasiparticle lifetimes as, for any normalized symmetric distribution \( g(\epsilon) \), \( \int d\epsilon (\alpha + \beta \epsilon) g(\epsilon - \epsilon_{0}) = \alpha + \beta \epsilon_{0} \). By contrast, the average of \( \rho_{q}(\epsilon) \) weighted by any other power of \( \epsilon \) is sensitive to details of quasiparticle smearing. Unfortunately, these sum rules are of limited immediate use, since the bulk of the integration comes from large energies, whereas current experiments only probe a relatively narrow range of biases about the chemical potential.

VI. PHOTOMISSION

Before concluding, we would like to propose a way of identifying weak charge ordering in photoemission experiments that could supplement current STM studies. A common signature of a strong charge ordering in the angle resolved photoemission microscopy experiments is the presence of shadow bands: the electron spectral function at momentum \( k \) acquires an additional peak at the energy of the quasiparticle at momentum \( k + Q \). For weak charge order the shadow bands may be difficult to observe: when the energy difference between \( E_{k} \) and \( E_{k+Q} \) is large, mixing between quasiparticles is negligible and the intensity of the shadow peaks is vanishingly small. Strong mixing only occurs when states \( k \) and \( k + Q \) are nearly degenerate, although in this case the two peaks are hard to distinguish since they are close in energy. Thus we expect to observe an increase of the apparent linewidth of quasiparticles when the latter satisfy the degeneracy condition \( E_{k} = E_{k+Q} \) and are strongly affected by the charge order. For example, in the case of the \( \text{Bi}_{2}\text{Sr}_{2}\text{CaCu}_{2}\text{O}_{8+x} \) band structure shown on Fig. 3 we expect an anomalous increase in the apparent quasiparticle linewidth at the points \( A, A', B, \) and \( B' \) on the Fermi surface.

VII. CONCLUSIONS

To summarize, we considered the effects of weak translational symmetry breaking on the \( d \)-wave superconducting state of the cuprates. For systems with periodic charge order we derived an explicit formula for the energy dependence of the Fourier component of the local density of states for several types of order, including simple charge density wave, electron kinetic energy and superconducting gap modulations. We argued that within a one band model the STM spectra observed in Refs. 13–15 cannot be explained by a simple charge density wave but require the existence of some form of (anomalous) dimerization, i.e., modulation in the electron hopping or in the superconducting pairing amplitude. We discussed a situation in which charge order has finite correlation length due to pinning by impurities. In this case the LDOS has Fourier components for a range of momenta around the ordering wave vector \( Q \). For different wave vectors \( q \), peaks in \( \rho_{q}(\epsilon) \) will occur at different energies, although the peak dispersion is weak, in agreement with Refs. 16,15. We also considered systems in which translational symmetry breaking comes not from charge ordering but from impurities. We found that the Fourier components of the LDOS in this case have peaks for a wide range of wavevectors and strong dispersion of these peaks is consistent with the STM experiments of Refs. 16,17.

TRANSLATIONAL SYMMETRY BREAKING IN THE . . .

28. The distinction between site and bond-centered orders is only defined for translational symmetry breaking commensurate with the lattice, i.e., when the wave vector is $Q = 2\pi/n$ with $n$ integer.
31. We only consider spin singlet interactions in Eq. (10), since these are the only ones contributing to $\rho_{Q}$ to linear order in perturbation theory.
