Abstract

The epicardium plays an important role in coronary vessel formation and Tgfbr3⁻/⁻ mice exhibit failed coronary vessel development associated with decreased epicardial cell invasion. Immortalized Tgfbr3⁻/⁻ epicardial cells display the same defects. Tgfbr3⁺/+ and Tgfbr3⁻/⁻ cells incubated for 72 hours with VEH or ligands known to promote invasion via TGFβ (TGFβ1, TGFβ2, BMP2), for 72 hours were harvested for RNA-seq analysis. We selected for genes >2-fold differentially expressed between Tgfbr3⁺/+ and Tgfbr3⁻/⁻ cells when incubated with VEH (604), TGFβ1 (515), TGFβ2 (553), or BMP2 (632). Gene Ontology (GO) analysis of these genes identified dysregulated biological processes consistent with the defects observed in Tgfbr3⁻/⁻ cells, including those associated with extracellular matrix interaction. GO and Gene Regulatory Network (GRN) analysis identified distinct expression profiles between TGFβ1-TGFβ2 and VEH-BMP2 incubated cells, consistent with the differential response of epicardial cells to these ligands in vitro. Despite the differences observed between Tgfbr3⁺/+ and Tgfbr3⁻/⁻ cells after TGFβ and BMP ligand addition, GRNs constructed from these gene lists identified NF-kB as a key nodal point for all ligands examined. Tgfbr3⁻/⁻ cells exhibited decreased expression of genes known to be activated by NF-kB signaling. NF-kB activity was stimulated in Tgfbr3⁺/+ epicardial cells after TGFβ2 or BMP2 incubation, while Tgfbr3⁻/⁻ cells failed to activate NF-kB in response to these ligands. Tgfbr3⁺/+ epicardial cells incubated with an inhibitor of NF-kB signaling no longer invaded into a collagen gel in response to TGFβ2 or BMP2. These data suggest that NF-kB signaling is dysregulated in Tgfbr3⁻/⁻ epicardial cells and that NF-kB signaling is required for epicardial cell invasion in vitro. Our approach successfully identified a signaling pathway important in epicardial cell behavior downstream of TGFβR3. Overall, the genes and
signaling pathways identified through our analysis yield the first comprehensive list of candidate genes whose expression is dependent on TGFβ3 signaling.

Introduction

The epicardium plays an important role in coronary vessel development (reviewed [1–3]). Formation of the epicardium occurs when a population of mesothelial cells, termed the proepicardium, attach to and migrate over the heart tube myocardium [4, 5]. Subsequently, a subpopulation of the epithelial, epicardial cells lose epithelial character, change shape, and invade the underlying matrix in a process termed epithelial-mesenchymal transformation (EMT). The resulting mesenchymal cells invade into the subepicardial space with some cells proceeding to invade into the myocardium as well (reviewed [6]). These epicardial-derived cells differentiate into distinct lineages [7–11], that include cardiac fibroblasts, pericytes, and vascular smooth muscle cells, and support the formation of coronary vessels. Several reports support epicardial contribution to the coronary endothelial cell lineage [12–14]. Numerous lines of evidence are now revealing the importance of these same developmental processes in cardiac repair and that the epicardium makes critical contributions to cardiac response to injury (reviewed [6]). Despite this, the signaling processes which regulate epicardial EMT are incompletely understood.

TGFβ3 deletion in mice leads to failed coronary vessel development [15]. Tgfbr3−/− hearts featured a discontinuous epicardium overlying an expanded subepicardial space. Further studies revealed a significant decrease in proliferation and invasion of epicardium and epicardially-derived mesenchyme [16]. Overall, these studies demonstrated that TGFβ3 plays an important and non-redundant role in epicardial behavior and coronary vessel development in vivo.

TGFβ3 binds TGFβ1, TGFβ2 and TGFβ3 and is uniquely required to bind TGFβ2 with high affinity [17, 18]. TGFβR3 is also capable of binding and signaling in response to BMP2 [19] and functions as a receptor for inhibin [20]. TGFβR3 presents ligand to TGFβR2 to promote both Smad-dependent and -independent signaling [21]. The highly conserved 43 amino acid intracellular domain of TGFβR3 is not required for ligand presentation [22] but may regulate other signaling events. Phosphorylation of the cytoplasmic domain of TGFβR3 by TGFβR2 at Thr841 is required for β-arrestin2 binding, leading to internalization of TGFβR3 and down-regulation of TGFβ signaling. The 3 C-terminal amino acids of TGFβR3, STA, are a Class I PDZ binding domain that binds the scaffolding protein GIPC which in turn stabilizes TGFβR3 on the plasma membrane to promote signaling [23].

Tgfbr3+/+ epicardial cells undergo loss of epithelial character and invasion into collagen gels in vitro in response to TGFβ1, TGFβ2, and BMP2, ligands known to bind TGFβR3 [18, 24]. While loss of epithelial character was still observed after loss of TGFβ3, Tgfbr3−/− cells had reduced invasion in response TGFβ1, TGFβ2, and BMP2, a response that was rescued by the addition of TGFβR3 [15, 25, 26]. TGFβ1 and TGFβ2 promoted smooth muscle differentiation in Tgfbr3−/− and Tgfbr3−/− cells while BMP2 did not [26]. Surprisingly, other ligands known to be important in epicardial EMT also required TGFβR3 to promote invasion in epicardial cells (FGF2 [27, 28], High Molecular Weight HMW-HA [29, 30]). Impaired invasion of three-dimensional gels by epicardial-derived mesenchyme was not due to the permanent loss of invasive properties, as PDGFAA, PDGFBB and VEGFC still induced invasion in Tgfbr3−/− epicardial cells [16].

This ability of TGFβ3 to regulate epicardial cell behavior in response to an array of ligands may explain the severity of the in vivo phenotype of Tgfbr3−/− embryos when compared to the absence of a phenotype in mice lacking individual TGFβ ligands [31–33]. It is known that the
loss of cell invasion has effects on cardiovascular development outside of the loss of the direct contributions of these cells to the structure of the coronary vessels. The deletion of several genes, encoding proteins that perform an array of functions including transcription factors, adhesion molecules, and growth factor ligands or receptors, share a common phenotype of a thinned myocardium (reviewed in [3]). These data as well as experimental embryology experiments in avian embryos have been interpreted to demonstrate that epicardially-derived mesenchymal cells are necessary for growth of the compact zone of the myocardium (reviewed in [34]). Therefore, the formation of the epicardium and the resultant generation of mesenchyme is critical for the support of both coronary vessel formation and myocardial growth. For example, targeted deletion of ALK5 in the epicardium in mice in vivo results in interrupted epicardial attachment to the myocardium, loss of expression of specific adhesion molecules, thinned myocardium, and a loss of coronary smooth muscle [33]. These embryos survive until birth, suggesting that, unlike in embryos lacking TGFβR3, the coronary vessels function to some degree as mice lacking coronary vessels die at approximately E14.5–E16.5 [35–37]. These data suggest that TGFβR3 signaling regulates a common pathway accessed by several upstream regulators of cell invasion.

TGFβR3-dependent invasion stimulated by TGFβ1, TGFβ2, BMP2, HMW-HA, or FGF2 was shown to require the cytoplasmic domain of TGFβR3 in vitro [16]. Overexpression of TGFβR3 rescued invasion in Tgfb3−/− epicardial cells in vitro in response to TGFβ1, TGFβ2, BMP2, HMW-HA, or FGF2, whereas constructs expressing a TGFβR3 mutant lacking the 3 C-terminal amino acids required for GIPC binding fail to rescue invasion [16, 25, 26]. The importance of this interaction is further supported by the observation that GIPC is not only required for invasion in Tgfb3−/− epicardial cells, but GIPC overexpression can promote invasion in the absence of additional ligand. GIPC regulation of epicardial invasion depends on TGFβR3 since GIPC expression in Tgfb3+/+ cells fails to rescue invasion and inhibition of GIPC expression impairs the ability of TGFβR3 to rescue invasion in Tgfb3−/− cells [16]. Similar results were observed in endocardial cushions where the interaction of TGFβR3 with GIPC is required to promote TGFβ2- and BMP2-dependent invasion in vitro [38]. These data linking defects in invasion of Tgfb3−/− epicardial cells to the cytoplasmic domain of TGFβR3, which is not required for ligand presentation, suggests a unique, non-redundant role for TGFβR3 in regulating epicardial and endocardial EMT.

Here, we use a well defined in vitro system based on immortalized epicardial cells coupled with RNA-seq analysis to generate a transcriptional profile of Tgfbr3+/+ and Tgfbr3−/− cells incubated with ligands that stimulate TGFβR3-dependent invasion. The resulting transcriptional profiles have identified regulators of epicardial cell behavior downstream of TGFβR3 and provided the first description of genes downstream of TGFβR3.

Methods

Generation of cell lines

Tgfb3+/−:Immorto mice were generated as described [39] and maintained on a C57BL/6 SV129 mixed background. Tgfbr3+/−:Immorto and Tgfb3−/−:Immorto immortalized epicardial cell lines were generated from littersmates as described [39] from E11.5 embryos (Fig 1A and 1B). The original work that covered the generation of the embryonic epicardial cell lines used in these studies was carried out as approved on protocol M/13/156 (Joey Barnett, PI) by the Institutional Animal Care and Use Committee of Vanderbilt University.

Cell culture

To maintain the immortalized state, cells were grown at 33°C in DMEM containing 10% fetal bovine serum, 100 U/ml penicillin/streptomycin, Insulin–Transferrin–Selenium (ITS: 1 μg/ml
insulin, $5.5 \times 10^{-4} \, \mu g/ml$ transferrin, $0.677 \, \mu g/ml$ selenium), and 10 U/ml interferon $\gamma$ (INF$\gamma$).

For experiments, the T-antigen was inactivated by culturing at 37°C in the absence of ITS or INF$\gamma$. Cells were seeded at 200,000 cells per well of a 6-well tissue culture plate and allowed to adhere overnight at 37°C. The following day the medium was replaced with media containing...
either VEH, 250 pM TGFβ1, 250 pM TGFβ2, or 5 nM BMP2. After a 72 hour incubation period at 37°C, total RNA was isolated via standard phenol-chloroform extraction (TRIzol Invitrogen). RNA was purified (Qiagen mini-prep kit) following the manufacturer’s protocol. Quantity and quality of RNA was determined by an Agilent Bioanalyzer. One well of a 6-well plate yielded 10–20 μg of RNA.

**qRT-PCR**
Quantitative Real Time PCR qRT-PCR was performed as described [16]. Briefly, cDNA was generated from 1μg total RNA using oligo-dT primers and Superscript III polymerase (Invitrogen). Real-time PCR analysis was done with iQ SYBR Green Supermix (Bio-Rad) in the Bio-Rad iCycler for 40 cycles. Primer pairs forward (F) and reverse (R): GAPDH F-ATGACAATG AATACGGCTACAG, R-TCTCTTTGCTCAGTGTCCCTTG; Mylk F-CCAAGGACCGGATGA AGAAATA, R-CCCTGAGATCATGGCCATAGAG; Sema3d F-TGGGACATAGAAGCATT AG, R-AGAGGCTTGTGGGAGTTAGG; Sxc F-AGGGCCTATGAACAGAGAT, R-GTAC GAGAGCCAGCATGGAAAG; Cadml F-TCTGTAGGCGGCTCAGTATAG, R-CTCACAT GTGCGGCTGTTTAG; Krt8 F-GGCCAACCTTAGGAGGAATTT, R-GAGCCAGCTGAGCTT ATT; Versican F-CAGGCTATCAGGCCAGATTAG, R-CAGAAGCCAGGAGTCACTTA.

**RNA-seq**
The generation of RNAseq libraries without normalizations or RNA/cDNA fragmentation were performed as described [40]. Libraries were sequenced as 50bp paired end sequences on a single lane of the Illumina HiSeq2000. TOPHAT [41] (http://tophat.cbcb.umd.edu/) was used to align HiSeq 2000 reads to produce bam files. Reads were normalized to total mRNA (total aligned reads per gene-loci per million). Gene expression profiles were generated as described [42] using a Bayesian p-value (S1 and S2 Figs). Data deposited at the Cardiovascular Development Consortium (CvDC) Data Repository (https://hci-bio-app.hci.utah.edu/gnomex/), external experiment number 38R1 (https://b2b.hci.utah.edu/gnomex/gnomexGuestFlex.jsp?requestNumber=38R1).

**SEAP Reporter System**
The pNF-kB-SEAP (Clontech) reporter was used to determine NF-κB activity in cells as described [43, 44]. Briefly, cells were co-transfected with pNF-kB-SEAP and β-galactosidase expression vector (p-CMVβ) and after 24 hours incubated with ligand (250pM TGFβ1, 250 pM TGFβ2, or 5nM BMP2). 24 hours after ligand addition the supernatant was assayed for alkaline phosphatase. β-galactosidase activity was used to normalize alkaline phosphatase activity.

**Transwell Invasion Assay**
Invasion assay performed using a collagen pad in a transwell as described in [16].

**Results**
Transcriptional profiles of Tgfbr3+/+ and Tgfbr3−/− cells confirm epicardial cell identity and ligand response
We undertook a transcriptional profiling approach to examine the genes downstream of TGFβ3 in epicardial cells in vitro. This system was chosen since it provides defined phenotypic endpoints to contrast between genotypes and different ligand incubation groups (Fig 2A).
Tgfbr3+/+ and Tgfbr3-/− epicardial cells were incubated for 72 hours with VEH or ligands known to drive TGFβR3-dependent invasion (TGFβ1, TGFβ2, BMP2) [25]. After incubation RNA was harvested and analyzed by RNA-seq as described. More than 24 million reads were obtained for each group (VEH, TGFβ1, TGFβ2, BMP2) in each genotype (Fig 2B–Genes). Over 13,900 genes were significantly expressed (Reads > 10) in each dataset (Fig 2B–Reads). Of these genes, we observed that markers of embryonic epicardial cells (Wt1 [45], Tbx18 [46], Sema3d [14], Scx [14]) were expressed in all data sets (Fig 3A) but markers of endothelial (Cdh5 [47], Pecam1 [48], Tie1 [49]) or myocardial (Tnni2 [50, 51], Tnni3 [51, 52]) lineages were not (Fig 3). Sema3a and Scx expression were confirmed with qRT-PCR (S3 Fig). The expression profile observed confirms the epicardial identity of these cells.

We have previously reported that TGFβ1 and TGFβ2 promote loss of epithelial character, invasion, and smooth muscle differentiation defined as the increased expression of the smooth muscle markers α-Sma, Sm22α, and Cnn1 (reviewed [53]) in Tgfr3+/+ and Tgfr3−/− epicardial cells (TGFβ2 depicted in Fig 1C). BMP2 promotes loss of epithelial character and invasion but not smooth muscle differentiation [26]. RNA-seq data sets demonstrated that the level of expression of α-Sma, Sm22α, and Cnn1 were >2-fold higher in TGFβ1- and TGFβ2-incubated cells of each genotype (Fig 3B). BMP2 incubation resulted in a considerably lower induction of smooth muscle markers (Fig 3B). Hundreds of genes had >2-fold increased or decreased expression after TGFβ1 or TGFβ2 incubation (Fig 3B). Far fewer genes were >2-fold differentially expressed after BMP2 incubation (Fig 3B) which may be at least partially due to the inability of BMP2 to induce smooth muscle differentiation. Of note, fewer genes were induced with TGFβ1 or TGFβ2 incubation in Tgfr3+/+ cells when compared to Tgfr3−/− cells, while the opposite was found with BMP2 incubation. This transcriptional profile of Tgfr3+/+ and

Tgfbr3-/-
epicardial cells confirms both the epicardial identity and the known response of these
cells to ligand. Therefore, we used these data sets for further analysis towards delineating the
downstream signaling pathways of TGFβR3 in the epicardium.

Dysregulation of gene expression in epicardial cells lacking TGFβR3

To ascertain the genes differentially regulated after the loss of Tgfbr3, we compared the expression
profiles of Tgfbr3+/+ and Tgfbr3-/- epicardial cells incubated with VEH, TGFβ1, TGFβ2, or
BMP2. We observed hundreds of genes >2-fold (p<0.001) differentially regulated between
genotypes in cells incubated with VEH (604), TGFβ1 (515), TGFβ2 (553), or BMP2 (632) (Fig
4A; S1–S4 Tables). The overlap between these >2-fold differentially expressed gene lists were
plotted (Fig 4B) identifying 129 genes similarly dysregulated across all groups. This list of
genes is defined as those that are differentially expressed after the loss of Tgfbr3 regardless of
ligand incubation. To gain a better understanding of the biological processes these genes may
be associated with, Gene Ontology (GO) analysis was undertaken using Database for
Annotation, Visualization, & Integrated Discovery (DAVID) software [54]. GO analysis identified enriched biological processes (p < 0.0001) associated with cell adhesion and extracellular structure organization indicating a potential defect in cell interaction with the ECM, a vital component of cell invasion (Fig 4C–Top). In order to understand how these genes may interact, Ingenuity Pathway Analysis (IPA) software (www.ingenuity.com) was used to perform Gene Regulatory Network (GRN) analysis. An example network is depicted (Fig 4C–Bottom) which revealed TGFβ and Notch signaling pathways [55], both known important regulators of epicardial cell behavior and subsequent coronary vessel development. We also identified signaling pathways previously unexamined in epicardial development. For example, NF-κB signaling emerged as a central node in this analysis providing a candidate for further evaluation.

To gain a more detailed understanding of the genes dysregulated after loss of TGFβR3, we examined genes with dysregulated expression in specific ligand incubation groups. When considering the overlap between genes in at least any two groups (VEH, TGFβ1, TGFβ2, or BMP2) that are similarly >2-fold differentially expressed between genotypes (Fig 4B), we observed that there are many more genes shared between TGFβ1-TGFβ2 (198) and VEH-BMP2 (191) than any other comparison (for example; VEH-TGFβ1 (10), BMP2-TGFβ2 (22)). This may reflect the fact that both TGFβ1 and TGFβ2 induce smooth muscle differentiation. GO analysis

doi:10.1371/journal.pone.0159710.g004
of the 198 genes uniquely dysregulated in Tgfbr3−/− cells after TGFβ1 and TGFβ2 incubation identified vasculature development as the most enriched biological process (p < 0.001) (Table 1). This analysis is consistent with altered vascular development in the epicardium after loss of Tgfbr3. However, processes associated with vascular development were not found to be significantly enriched by GO analysis in the 191 genes uniquely >2-fold dysregulated between genotypes with VEH and BMP2 incubation or in the 221 genes uniquely dysregulated with BMP2 incubation (Table 1).

Although we have reported that TGFβ2 promotes loss of epithelial character and smooth muscle differentiation via ALK5 signaling and BMP2 promotes only the loss of epithelial character via ALK3 signaling, both ligands require TGFβR3 to mediate invasion [26]. To gain a better understanding of how TGFβ and BMP signaling are impacted by the loss of Tgfbr3, we examined genes >2-fold differentially expressed between Tgfbr3+− and Tgfbr3−/− epicardial cells incubated with TGFβ2 or BMP2. GO analysis identified that biological processes associated with blood vessel development and angiogenesis were enriched (p < 0.001) in TGFβ2 but not BMP2 gene lists (genes including Fgf2 and Vegfc) (Fig 5A). Thus, while TGFβ induces smooth muscle differentiation in Tgfbr3+/− cells, there remain defects in the signaling networks associated with formation of the vasculature. Biological processes enriched in both of these TGFβ2 and BMP2 gene lists include processes associated with cell adhesion, extracellular matrix (ECM) organization, and proliferation (Fig 5A and 5B). These results are consistent with the known epicardial phenotype of Tgfbr3−/− embryos [15, 16].

To reveal interactions, genes >2-fold differentially expressed between genotypes after TGFβ2 or BMP2 incubation were used to generated GRNs using IPA software. Example networks are depicted in Fig 5C and 5D. The TGFβ2 network features predicted proteins known to be located in the ECM that regulate cell-ECM interactions. Several of these genes have lower levels of expression in Tgfbr3+/− cells compared to Tgfbr3−/− cells (green nodes). Also present are several genes encoding cytoplasm and plasma membrane proteins that are expressed at higher levels in Tgfbr3+/− epicardial cells compared to Tgfbr3−/− cells (red nodes). These genes

Table 1. GO Analysis of Genes >2-fold Differentially Expressed Between Genotypes Unique to Specific Ligand Incubation Groups.
are associated with epithelial sheet stability and adhesion, for example Krt18 and Krt8, whose expression pattern was confirmed using qRT-PCR (S3 Fig). The BMP2 network also features genes that are expressed at higher levels in Tgfbr3+/+ cells whose proteins are known to associate with the plasma membrane to regulate cell adhesion and cell migration (Lin7a [56], Amot...
Nodes associated with ECM protein synthesis (Csgalnact1) or post translation modification of receptors that interact with ECM (Chst7) were also observed in the BMP2 network and the induction of Chst7 in immortalized epicardial cell was confirmed using qRT-PCR (S3 Fig). These networks indicate a deficit in the ability of cells to interact with the ECM and a potential defect in cell motility. NF-κB was a central node in not only the TGFβ2 and BMP2 networks (Fig 5C and 5D Orange circle), but also in GRNs derived from genes differentially expressed between genotypes with VEH or TGFβ1 incubation (S4 Fig). We identified several genes known to be downstream of NF-κB signaling that were differentially regulated in each ligand incubation group (S5A–S5D Fig) when compared between genotypes. A table depicting the overlap between these genes is shown (Fig 6A Top). GRN analysis indicates that NF-kB signaling may be dysregulated with loss of TGFβR3 in epicardial cells. The dysregulated NF-kB signaling in both TGFβ2 and BMP2 gene lists, where a common phenotype is loss of invasion, suggests that NF-kB signaling may regulate cell invasion in response to these ligands.

NF-kB signaling is dysregulated in Tgfbr3−/− epicardial cells in vitro

To test the hypothesis that TGFβR3 promotes NF-kB signaling to regulate epicardial cell invasion we examined if NF-kB activity was induced by TGFβ2 or BMP2 ligand incubation in...
epicardial cells in vitro (Fig 6B). Immortalized epicardial cells incubated with TGFβ2 or BMP2 increased NF-kB activity compared to VEH in Tgfbr3+/+ epicardial cells as described [44]. TGFβ2 or BMP2 ligand incubation failed to induce NF-kB activity in Tgfbr3−/− cells (Fig 6B). To determine if NF-kB signaling was required for epicardial cell invasion in vitro, we performed a collagen pad, transwell invasion assay with TGFβ1, TGFβ2, and BMP2 in the presence or absence of the NF-kB inhibitor, BMS345541. BMS345541 (10 μm) significantly decreased TGFβ1-, TGFβ2-, or BMP2-induced invasion in Tgfbr3+/+ cells when compared to VEH (Fig 6C). Together these data demonstrate that NF-kB signaling is dysregulated in Tgfbr3−/− epicardial cells and that NF-kB is required for epicardial cell invasion in vitro. These data support the hypothesis that TGFβ3 promotes NF-kB activity to regulate epicardial cell invasion.

Discussion

Transcriptional profiling of epicardial cells

We developed a transcriptional profiling strategy using immortalized, embryonic epicardial cells in vitro to identify genes and signaling pathways downstream of TGFβ3 that regulate cell invasion. Previous studies have profiled gene expression in adult epicardial cells [60, 61], the proepicardium [62], and primary epicardial cells (E12.5) [63] using microarrays, but a comprehensive transcriptional profiling of embryonic epicardial cells has been lacking. Additionally, our choice of this system allows for a first systematic examination of the genes and signaling pathways regulated by TGFβ3.

Tgfbr3−/− epicardial cells have altered expression of ECM associated genes

GO and GRN analysis of genes whose expression was >2-fold dysregulated between Tgfbr3+/+ and Tgfbr3−/− cells for each ligand incubation group revealed biological processes associated with ECM production, ECM binding, cell adhesion, and invasion. The dysregulation of gene expression associated with these processes is consistent with the known defects identified after loss of Tgfbr3 in vivo and in vitro. Epicardial cell abnormalities in Tgfbr3−/− embryos include expansion of the subepicardial space and a hyperplastic, irregular epicardium, both of which suggest defects in epicardial cell interactions with the ECM [15]. Invasion of epicardial cells is also defective in vivo and in vitro in cells lacking TGFβ3 [16]. Consistent with a defect in cell interaction with the ECM, we observe that epicardial cells in vitro fail to invade in response to high molecular weight HA [16, 64], a major ECM component of the subepicardial space [65]. CD44 is the cell surface receptor which binds HA and this interaction is important for epicardial invasion [44]. Upregulated expression of the chondroitin sulfotransferase, Chst7, is associated with increased chondroitin sulfation of CD44 and decreased CD44-HA binding in multiple cell types [59, 66, 67]. Chst7 had markedly increased expression (>4-fold) in Tgfbr3−/− cells when compared to Tgfbr3+/+ cells across all ligand incubation groups. These data suggest that the inability of Tgfbr3−/− cells to undergo invasion in respond to HA may result from increased chondroitin sulfation of CD44.

The myocardium and proepicardium both contribute to the ECM contained in the subepicardial space [65, 68], yet the exact makeup and source is unknown. Tgfbr3−/− epicardial cells show dysregulated expression of genes encoding proteins found in the ECM, suggesting that epicardial contributions to the ECM are altered after loss of TGFβ3. Mgp, Eln, and Tnc have decreased expression in Tgfbr3−/− cells when compared to Tgfbr3+/+ cells, while Matn4 and Eml1 have increased expression irrespective of ligand. Alterations in the expression of specific
genes were also found to be ligand-specific. *Versican* is an ECM component contained in the supepicardial space [69] that promotes cell invasion in some cancer cells (reviewed [70]) and is required for endocardial cushion formation and subsequent EMT [71, 72]. *Versican* has >2-fold higher expression after ligand (TGFβ1, TGFβ2, BMP2) incubation when compared to VEH in Tgfbr3+/− cells. Ligand induction of *Versican* expression is decreased in Tgfbr3−/− cells (S3 Fig), demonstrating that *Versican* expression is dependent on Tgfbr3-ligand interaction. Together, these data suggest the defects in coronary vessel development are due to both the altered response to, and expression of, ECM components by epicardial cells following the loss of Tgfbr3.

**TGFβ- and BMP-mediated gene expression programs are dysregulated in Tgfbr3−/− epicardial cells**

Distinct differences were observed in dysregulated gene expression between epicardial cells incubated with BMP and TGFβ ligands after loss of TGFβR3. Analysis of the genes dysregulated between Tgfbr3+/+ and Tgfbr3−/− epicardial cells revealed potentially different mechanisms between BMP2 and TGFβ1 or TGFβ2 mediated-GRNs that may underlay a defect in cell invasion. BMP2 is important in the specification and maintenance of proepicardial cell identity [73], directed proepicardial cell migration [74], and epicardial cell loss of epithelial character and invasion [25]. GRNs generated from the genes dysregulated between genotypes after BMP2 incubation revealed a grouping of genes encoding PDZ domain-containing proteins that had decreased expression in Tgfbr3−/− epicardial cells when compared to Tgfbr3+/+ cells (Anot, Cadm1, Cnksr3, Lin7a, Mpp6). Several of these genes (Anot [57, 75, 76], Cadm1 [77], Cnksr3 [78], Lin7a [56, 79]) have been previously reported to promote cell migration but a role in the epicardium has not been described. These observations are consistent with the known role in BMP2 in directing epicardial migration and the decrease of invasion observed in Tgfbr3−/− epicardial cells. These data also provide an intriguing set of candidate genes as the PDZ domain of TGFβR3 and a protein that interacts with this domain, GIPC, are required for TGFβR3-mediated invasion *in vitro* [16]. GRNs generated from the genes dysregulated between genotypes after TGFβ1 or TGFβ2 incubation had different features from the BMP2 network. A large grouping of genes whose expression was reduced after loss of TGFβR3 was localized to the extracellular space in the TGFβ1 and TGFβ2 networks. These genes were involved in the production of ECM components (Eln), matrix degradation (Mmp3, Elastase), and ECM organization (Mfap2). A different grouping of genes expressed at higher levels after loss of TGFβR3 localized to the cytoplasm were associated with epithelial sheet stability and non-motile cells (Krt8, Krt18). The GRNs are consistent with a population of cells with dysregulated ECM interaction and reduced motility. In addition, genes in signaling pathways associated with vascular development and angiogenesis were dysregulated between genotypes with TGFβ1 and TGFβ2 but not BMP2 incubation. This finding is particularly interesting as factors secreted by the epicardium after injury to the heart are hypothesized to promote the formation of new vessels in the impacted area [80]. To support proper coronary vessel development signaling events must be tightly regulated in the epicardium *in vivo*. Our data demonstrates TGFβR3 is an important component of the regulatory machinery that integrates TGFβ and BMP signaling in epicardial cells.

**Loss of TGFβR3 disrupts NF-κB signaling in embryonic epicardium**

TGFβR3 is required for invasion promoted by TGFβ1, TGFβ2 and BMP2, suggesting that a TGFβR3-dependent signaling mechanism that regulates invasion is shared between these ligands. Our data predicts NF-κB signaling is dysregulated in Tgfbr3−/− epicardial cells. GRN’s
generated from genes >2-fold differentially expressed between Tgfb3+/+ and Tgfb3−/− epicardial cells across each ligand incubation group (VEH, TGFβ1, TGFβ2, BMP2) identified NF-kB signaling as a central node. In support of a role for NF-kB signaling, genes known to be regulated directly or indirectly downstream of NF-kB were also dysregulated. Incubation of epicardial cells with TGFβ or BMP2 increased NF-kB activity in Tgfb3+/+ but not in Tgfb3−/− cells, demonstrating that TGFβR3 is required for NF-kB activity in epicardial cells. Several mechanisms may account for the ability of TGFβR3 to regulate NF-kB signaling. Previous studies have found that TGFβR3 can suppress NF-kB signaling via interaction with β-arrestin2 [81]. IL-1β, an upstream regulator of NF-kB signaling, can suppress TGFβR3 signaling by binding to TRAF6 which subsequently sequesters TGFβR3 from TGFβR2 [82]. Here, reduced NF-kB activity may result from a >2-fold reduction in the expression of an important upstream regulator of NF-kB signaling, Il-1r (reviewed [83]), in Tgfb3+/+ cells compared to Tgfb3−/− cells. Reduced NF-kB activity may also result from decreased expression in Tgfb3−/− cells of Myosin Light Chain Kinase (Mylk) as seen in RNA-seq (S1–S4 Tables) and by qRT-PCR (S3 Fig). MYLK has recently been shown to promote activation of NF-kB signaling [84]. MYLK kinase activity is required for MyD88 and IRAK4 complex formation, which in turn is required to activate NF-kB downstream of lipopolysaccharide [85, 86], in lung endothelial cells [84]. Given the known roles of Mylk in regulating smooth muscle behavior [87], cell migration [88], and a link to coronary artery disease [89], the elucidation of the regulatory interactions between MYLK, TGFβR3, and NF-kB in epicardial cells may provide key insights into coronary vessel development.

While TGFβR3 signaling has been previously reported to both inhibit [81, 90] and promote [91] NF-kB signaling, a consistent fact in all of these studies is that a decrease in NF-kB activity was coincident with decreased invasion. Here we used a small molecule inhibitor and showed that NF-kB activity was required for epicardial cell invasion. In a recent, separate study [92], we confirmed that invasion is dependent upon NFκB signaling and that Tgfb3−/− cells lack both invasion and NFκB activation. Overexpression of TGFβR3 in Tgfb3−/− cells rescues ligand-dependent invasion that is sensitive to NFκB inhibitors. Further, endocardial cell invasion, a TGFβR3-dependent process [93], is decreased by the inhibition of NFκB activity. These data suggest that NF-kB is a shared signaling pathway downstream of ligand and that TGFβR3 interaction is required for cell invasion. Therefore, we propose that the disruption of TGFβR3 regulated NF-kB signaling is a mechanism responsible for the loss of invasion in epicardial cells and ultimately failed coronary vessel development in Tgfb3−/− embryos.

Supporting Information

S1 Fig. Variability of RNA-seq data sets. The reads for the two biological replicates (n = 1, n = 2) for each group (VEH, TGFβ1, TGFβ2, BMP2) in Tgfb3+/+ (A-D) or Tgfb3−/− (E-H) were plotted against each other. There was a high degree of agreement in Tgfb3+/+ (A-D) (R>0.87) or Tgfb3−/− (E-H) (R>0.89) datasets. These comparisons support a high degree of agreement between biological replicates.

(TIF)

S2 Fig. Comparison of differential gene expression between biological replicates. Plots mapping the fold (log base 2) difference >2-fold in expression between VEH and ligand incubated groups in Tgfb3+/+ (A) or Tgfb3−/− (B) in biological replicates (X-axis: n = 1, Y-axis: n = 2) shown. Genes that have agreement, defined as having >2-fold (p<0.001) increased or decreased expression in a specific comparison in both replicates, are mapped to quadrants I (upper right) or III (lower left) of a plot. Genes that show disagreement, defined as having >2-fold (p<0.001) increased expression in a tissue in one replicate and decreased in another
(or vis versa), are mapped to quadrants II (upper left) or IV (lower right). There was a high degree of agreement in Tgfbr3+/+ (A) (R > 0.85) or Tgfbr3+/− (B) (R > 0.89) datasets across all comparisons [94]. Variability between biological replicates was determined.

S3 Fig. Genes with dysregulated expression in Tgfbr3+/− epicardial cells. Differential gene expression between Tgfbr3+/+ and Tgfbr3+/− epicardial cells observed in RNA-seq data was evaluated using qRT-PCR analysis (n = 3). Expression was normalized to the constitutive expression level of GAPDH RNA and the ratio of transcriptional abundance found in Tgfbr+/+ to Tgfbr−/− is depicted.

(TIF)

S4 Fig. Gene regulatory network analysis identifies NF-κB signaling as a central node. Genes >2-fold (p < 0.001) differentially expressed between Tgfbr3+/+ and Tgfbr3+/− epicardial cells incubated with either TGFβ1 (A) or VEH (B) were subjected (A) to gene ontology analysis (using DAVID software, p < 0.0001). (C-D) NF-κB signaling (orange circle) is a central node in representative networks generated by gene regulatory network analysis (using Ingenuity Pathway Analysis software). Green- expressed higher in Tgfbr3+/+, Red- expressed higher in Tgfbr3−/−.
