Canopy nitrogen, carbon assimilation, and albedo in temperate and boreal forests: Functional relations and potential climate feedbacks

The availability of nitrogen represents a key constraint on carbon cycling in terrestrial ecosystems, and it is largely in this capacity that the role of N in the Earth’s climate system has been considered. Despite this, few studies have included continuous variation in plant N status as a driver of broad-scale carbon cycle analyses. This is partly because of uncertainties in how leaf-level physiological relationships scale to whole ecosystems and because methods for regional to continental detection of plant N concentrations have yet to be developed. Here, we show that ecosystem CO2 uptake capacity in temperate and boreal forests scales directly with whole-canopy N concentrations, mirroring a leaf-level trend that has been observed for woody plants worldwide. We further show that both CO2 uptake capacity and canopy N concentration are strongly and positively correlated with shortwave surface albedo. These results suggest that N plays an additional, and overlooked, role in the climate system via its influence on vegetation reflectivity and shortwave surface energy exchange. We also demonstrate that much of the spatial variation in canopy N can be detected by using broad-band satellite sensors, offering a means through which these findings can be applied toward improved application of coupled carbon cycle–climate models.

Terrestrial ecosystems influence the Earth’s climate through regulation of mass and energy exchange with the atmosphere. In recent years, much of the focus has been directed toward factors affecting the ~1- to 2-Pg carbon (C) sink that is believed to exist in the terrestrial biosphere (1). Candidate mechanisms include forest regrowth after agricultural abandonment (2) and growth enhancement from nitrogen (N) deposition (2a). The importance of C cycle effects vs. biophysical factors, typically in the context of biome conversions such as deforestation (13, 14). Although results differ among regions, these studies have demonstrated that changes in albedo can be as climatically important as the effects of altered C storage in terms of the overall impact of land cover change on climate (15). To date, most studies have treated albedo and the physiological factors that influence C assimilation as independent mechanisms, and few, if any, have examined the potential for linkages that occur within and among biomes.

Here, we present evidence that the well-known relationship between leaf photosynthesis and foliar N concentrations scales directly to maximum C assimilation over whole-forest canopies and that both variables are strongly and positively correlated with total shortwave surface albedo. Our findings are based on integration of field sampling, high-resolution imaging spectroscopy, broad-band remote sensing, and tower-based CO2 flux measurements from 12 forested research sites that are distributed across the conterminous U.S. and include a range of forest types (Table 1). We measured whole-canopy N concentrations at 181 field plots, determined as the mean of mass-based foliar %N over all species in each plot (weighted by the relative abundance of each), with samples from >1,700 trees in stands ranging from <15 to >500 years old. Measured %N data were combined in a

copies. Neither mass- nor area-based C expected given the considerable self-shading in multilayered canopies. Capacity is lower than that for individual leaves, which is estimated from global-scale satellite sensors. We allowed us to examine relationships between %N and reflectance-based imaging spectroscopy (12), the scope of our dataset estimate canopy %N over small landscapes by using aircraft-based measurements and is more relevant for models driven by remotely sensed data. The relationship between mass-based Cmax and %N is nearly parallel to the leaf-level photosynthetic capacity (Cmax) for the landscape represented by each tower. The model included a function describing the response of photosynthesis to incident photosynthetically active radiation (PAR) and a term for ecosystem respiration, which allowed partitioning of the maximum potential assimilation rate from the tower measurements of net CO2 exchange.

**Results**

Across all sites, Cmax was highly correlated with canopy %N (Fig. 1). The relationship was slightly stronger when Cmax was expressed per unit of canopy leaf mass (r² = 0.76) rather than per unit of ground area (r² = 0.65), although both trends were highly significant (P < 0.01). The mass-based relationship follows from well-established physiological relations (11), whereas expressing Cmax per unit of ground area relates more directly to tower-based measurements and is more relevant for models driven by remotely sensed data. The relationship between mass-based Cmax and canopy %N is nearly parallel to the leaf-level relationship between Amax and %N for woody plants worldwide (9; Fig. 1B). At any given %N, whole-canopy photosynthetic capacity is lower than that for individual leaves, which is expected given the considerable self-shading in multilayered canopies. Neither mass- nor area-based Cmax was correlated with LAI (P > 0.50 in both cases), likely because most of our study sites are closed canopy forests with relatively high LAI and near-complete interception of available light. Under these conditions, the photosynthetic potential per unit of leaf mass should be a better indicator of the efficiency with which intercepted light is used, rather than the total amount of foliage present. A significant positive relationship between light use efficiency (LUE) under full-sun conditions and canopy %N supports this idea (P < 0.01, r² = 0.59 [see supporting information (SI) Fig. S1 and S1 Text]).

Whereas previous studies have demonstrated the ability to estimate canopy %N over small landscapes by using aircraft-based imaging spectroscopy (12), the scope of our dataset allowed us to examine relationships between %N and reflectance data obtained from global-scale satellite sensors. We systematically degraded the spectral resolution of imaging spectrometer scenes from 10 nm to 20 nm, 30 nm and so on to 100 nm, and repeated the PLS analysis. This process yielded little loss of prediction accuracy, and the reflectance feature that emerged as the dominant source of variability with respect to %N at coarser resolutions was the height of the near-infrared (NIR) reflectance plateau (800–1,200 nm; Fig. 2). We also examined

All but two sites (marked with *) are part of the AmeriFlux research network. NA, not available.†NA, not available.
relationships between %N and common vegetation indices that use NIR to visible reflectance ratios, but none yielded as strong a correlation with measured %N as did NIR reflectance on its own (Fig. 2B). The relatively small size of our field plots prevented direct comparison of measured canopy %N with data from coarse-resolution satellite sensors. However, imaging spectrometer %N estimates for the much larger flux tower footprints were positively correlated with NIR reflectance measured at a compatible scale by the MODIS instrument (Moderate Resolution Imaging Spectroradiometer; \( r^2 = 0.87, P < 0.001 \)) (see Fig. S2).

As is typical of live vegetation, PAR reflectance (400–700 nm) was lower and less variable than NIR reflectance among all %N classes. At wavelengths \( >800 \) nm, however, there was a strong and consistent response of increasing reflectance with increasing %N (Fig. 2A). A consequence of this pattern is that canopy %N was significantly correlated with mean reflectance across the entire imaging spectrometer detection range of 400–2,500 nm \( (r^2 = 0.69, P < 0.001, n = 102) \). Because full-spectrum reflectance is functionally similar to shortwave albedo, we compared canopy %N with independent estimates of shortwave land surface albedo from MODIS (17) collected during the midgrowing season to match our field sampling. This comparison revealed highly significant relationships between albedo and both canopy %N (Fig. 2C) and \( C_{\text{Amax}} \) (Fig. 3). Canopies with high concentrations of N in foliage have both a greater capacity to remove CO2 from the atmosphere and absorb less incident shortwave radiation than their low-N counterparts. Addition of independent %N data and MODIS albedo values for similarly sized forest landscape units at 8 sites in Canada (18) gives further support to this conclusion and extends the geographic scope and range of values in our data (Fig. 2C). As expected, deciduous and evergreen forests tended to separate along high and low portions of the observed trend, respectively, but there is substantial variation within each type, and the %N–albedo relationship is significant for both forest types (deciduous \( r^2 = 0.52, P < 0.05 \), evergreen \( r^2 = 0.59, P < 0.01 \)), with no difference in slope or intercept (see SI Text for discussion of potential underlying mechanisms for this relationship). Although reflectance properties in forests can also be affected by leaf area and other structural attributes that influence absorbance and scattering within canopies (19), there was no relationship between albedo and either LAI or canopy height when compared individually or in multiple regressions with %N (\( P > 0.5 \) in all cases; Fig. S3).

Collectively, these results suggest that we already have a basis for detecting variation in %N and \( C_{\text{Amax}} \) of forest canopies at continental scales by using scaled relationships with albedo and/or simple measures of NIR reflectance obtained during the peak period of the growing season. We do not suggest that NIR reflectance and surface albedo are driven solely by canopy %N or related plant traits, but our results do indicate that, for closed

![Fig. 2.](image_url)

![Fig. 3.](image_url)
canopy temperate and boreal forests, NIR reflectance and albedo patterns are reliably correlated with canopy %N over a wide range of conditions with no underlying influence of variation in LAI. We therefore propose as an initial hypothesis that the dominant patterns of canopy %N and C_{A\text{max}} for North American forests can be estimated by combining the trends in Figs. 2C and 3B with a peak growing season coverage of MODIS shortwave albedo (Fig. 4). Although patterns related to dominant forest functional groups are evident (e.g., higher values in the eastern deciduous biome and lower values in northern evergreens), there is considerable variability within vegetation types, with the highest overall estimates in forests of the mid-Appalachian region. This region has been identified as having high foliar N concentrations relative to other temperate deciduous forests (20, 21), with some evidence that variation is linked to patterns of atmospheric N deposition (21). Additional field measurements can confirm or reject this hypothesis and determine whether or not similar trends can be applied over other regions and vegetation types.

**Discussion**

The strong linkages among canopy %N, shortwave albedo, and C_{A\text{max}} raise the possibility of an unrecognized feedback in the Earth’s climate system involving the N cycle as a factor influencing surface energy exchange, in addition to its known effects on C assimilation. As an example, warming trends in boreal and arctic regions result in warmer soils, accelerated decomposition, and increased nutrient mineralization (22). Expected consequences include an increase in the N nutrition of plant canopies (23) or a shift in species composition to those requiring higher N supplies and having higher N concentrations in foliage. Although the effects of changes in major plant functional groups have been included in coupled land surface–climate models (24), those associated with changes in N cycling or shifts in species composition within biomes have not. Based on our findings, these specific changes (i.e., increased N supply or altered composition, both resulting in higher canopy %N) should increase gross C assimilation [and presumably net C sequestration (4, 25)] and surface albedo, both representing negative feedbacks to warming. Similar effects can be expected from anthropogenic N deposition and widespread use of N fertilizers, which also serve to increase canopy %N (26). Conversely, leaf N concentrations in temperate forests are inversely related to mean annual temperature (27) and are driven down by rising CO2 (6–8), suggesting that temperature and CO2 increases could lead to reduced canopy albedo and a positive feedback to warming. Additional scenarios can be envisioned, but the overall implication is that alterations to plant N availability have important and unrecognized impacts on the climate system that warrant serious consideration (see SI Text for details on surface heating effects over the observed range of %N and albedo). This is particularly relevant in light of the degree to which human activities have altered the N cycle globally (28).

It would be premature to draw management implications from these results or to conclude that N fertilization, increased N pollutant emissions, or shifts from low-N to high-N tree species would help offset climate warming induced by greenhouse gas emissions. We also cannot assume that changes in C assimilation will always lead to a change in net C sequestration, given the potential for synergistic changes in ecosystem respiration. Moreover, interrelations among canopy %N, C_{A\text{max}} and albedo need to be evaluated in additional ecosystem types, particularly in tropical forests, agricultural systems, and ecosystems with low LAI or sparse vegetation cover, and assessing the full outcome

**Fig. 4.** Estimates of canopy %N and C_{A\text{max}} for forested areas of North America, along with the albedo values from which they were derived. Albedo data were from the midportion of the growing season and were converted to estimates of canopy %N and C_{A\text{max}} by using trends shown in Figs. 2C and 3B. Results were applied to forested grid cells only, identified by using the MOD44B continuous vegetation fields data product (41).
of competing feedbacks will require new analyses using coupled climate–vegetation models. Finally, our analysis did not address N-induced changes in transpiration or potential consequences for cloud formation, which could have important effects on the net change in energy budgets (15) but were beyond the scope of our study. Despite these uncertainties, the observation of strong N–C–albedo linkages in forests adds a new dimension to our understanding of the role played by ecosystems within the climate system and warrant consideration in climate projection efforts given the extent to which all of these variables are being altered by human activities.

Methods

Field Sampling. Canopy %N (g of N 100 g of dry leaf matter−1) was sampled between 2001 and 2006 on 181 plots across the 12 research sites used in this study. At each site, plots were chosen from within a 5 × 5-km area to capture ecological variability in forest composition and condition that occurred over the local landscape. At each plot, all dominant and codominant species were identified, and between 2 and 5 trees per species were selected for green leaf collection from several heights in the canopy by using 12-gauge shotguns. Samples were collected to coincide with the peak of the growing season and with overflights by NASA AVIRIS or Hyperion instruments. A benchtop visible and near-infrared spectrophotometer (Foss NIRSystems 6500) was used to determine leaf-foliar N concentrations of oven-dried, ground foliage. According to methods described by Bolster et al. (29). The relative abundance of each species in the canopy was determined by using a point intercept sampling technique that quantifies the vertical distribution of leaf mass by species in the canopy (12). Plot-level canopy N concentrations (whole-canopy %N) were calculated as the mean of leaf-foliar N concentrations among all species, weighted by the mass-based fraction of the canopy represented by each species.

Canopy N Remote Sensing. Hyperspectral remote sensing, or imaging spectroscopy, is a form of optical remote sensing in which surface reflectance is examined in narrow and contiguous spectral regions that allow analysis of specific absorption features on a pixel-by-pixel basis. At each site, hyperspectral remote sensing scenes were obtained from NASA’s AVIRIS or Hyperion [aboard the Earth Observing-1 (EO-1) satellite] sensors. AVIRIS measures upwelling radiance in 224 contiguous optical bands from 400 to 2,500 nm with a spectral resolution of 10 nm. AVIRIS was flown on an ER-2 aircraft at an altitude of 20,000 m, producing a spatial resolution of 17 m and a swath width of ~10 km. The Hyperion instrument is part of the NASA EO-1 satellite, which was launched in November, 2000. The Hyperion detection capabilities are similar to those of AVIRIS (220 spectral bands ranging from 400 to 2,500 nm, with a 10-nm spectral resolution) but with a spatial resolution of 30 m. The Hyperion instrument is part of the NASA EO-1 satellite, which was launched in November, 2000.

Flux Data and Derivation of Cmax and LUE Estimates. At each flux tower site, the eddy covariance method (30) was used to obtain continuous measurements of the surface–atmosphere exchange of CO2, H2O, and energy. Three years of flux measurements and ancillary meteorological data were used for each site. We used daytime measurements of the net ecosystem exchange of CO2 (NEE, μmol m−2 s−1) to estimate 3 parameters of a simple “big leaf” Michaelis–Menten light response model of gross canopy photosynthesis driven by incident solar photosynthetic photon flux density (I, μmol m−2 s−1),

\[
P_{\text{gross}} = \text{NEE} - R_{\text{eco}} = \frac{CA_{\text{sat}} I}{I + K_m} + R_{\text{eco}}
\]

where \(CA_{\text{sat}}\) is the theoretical, whole-canopy light-saturated rate of photosynthesis, \(K_m\) is the half-saturation value of I for the light response function, and \(R_{\text{eco}}\) is ecosystem respiration. Maximum likelihood parameter estimates were fit separately for each site, using 3 years of flux data and a 14-day moving window, following methods described by Press et al. (31) and by using flux uncertainty estimates presented by Richardson et al. (32). This approach to partitioning NEE to photosynthetic and respiratory component fluxes was recently evaluated and was found to yield results comparable to those of a range of other partitioning methods (33). Because of potential correlation between \(CA_{\text{sat}}\) and \(K_m\) parameters, which could result in unrealistically high values for the theoretical light-saturated rate of uptake, we instead focused on subsequent analyses on \(C_{\text{max}}\), the maximum rate of assimilation when \(I = 2,000 \mu\text{mol} m^{-2} s^{-1}\), i.e., under reasonable “full-sun” conditions, and when other environmental variables are least limiting. Resulting values for \(CA_{\text{sat}}\) and \(C_{\text{max}}\) were highly correlated (\(r^2 = 0.89, P < 0.0001\)), and use of either variable in the analyses produced the same overall conclusions. The \(C_{\text{max}}\) values used for comparison with other variables in the study were means of the peak value achieved during each growing season of the 3-year record.

LAI and Maximum LUE. LAI values were obtained from a combination of published values and measurements taken during the time of our field sampling (34–38). All LAI data were from site-specific, midgrowing season measurements conducted with optical-based methods, primarily by using the Li-Cor LAI-2000 (Li-COR Biosciences) instrument. Estimates based on leaf litterfall collections or allometry were also available for some sites. Although small discrepancies among LAI sampling methods have been noted (39), we used data collected from optically based methods to maintain consistency across sites.

Maximum canopy LUE (mol of C assimilated per mol of absorbed photons) was determined by dividing area-based \(C_{\text{max}}\) by the quantity of absorbed photosynthetically active radiation (APAR) when \(I = 2,000 \mu\text{mol} m^{-2} s^{-1}\). APAR was estimated by using a simplified model of transmission and scattering of light in plant canopies, applied by using measured LAI values for each site (40).

MODIS Albedo and Surface Reflectance. MODIS reflectance and shortwave albedo data (collection 4, MOD43B4 and MOD43B3), respectively) were obtained from the MODIS subset data server for each of the study sites (17). Individual image datasets are 16-day composites of atmospherically corrected surface reflectance, derived by using cloud-free images only. The reflectance product is nadir BRDF-adjusted reflectance (NBAR) and represents reflectance at the mean solar zenith angle. We used reflectance and albedo data from DOY 177 through 241 for years 2001–2006 to calculate mean growing season values that would be compatible with field measurements and hyperspectral imagery. Data completeness for this time period averaged 93% with gaps caused by cloudiness and other data quality issues. Data gaps were distributed randomly in time. Shortwave albedo is calculated across a spectral range of 300–5,000 nm and was available as black-sky, white-sky, and actual albedo (17). Data shown in Fig. 2C and 3 are actual albedo, although use of other albedo variables produced nearly identical results (e.g., black-sky values were within 2% of actual albedo, and a regression of the 2 across the study sites produced a relationship with \(r^2 = 0.997\) and a slope and intercept not significantly different from 1 and 0, respectively).
