ABSTRACT: With model building applications in mind, we collect and develop basic techniques to analyze the landscape of D7-branes in type IIB compact Calabi-Yau orientifolds, in three different pictures: F-theory, the D7 worldvolume theory and D9-anti-D9 tachyon condensation. A significant complication is that consistent D7-branes in the presence of O7\textsuperscript{−} planes are generically singular, with singularities locally modeled by the Whitney Umbrella. This invalidates the standard formulae for charges, moduli space and flux lattice dimensions. We infer the correct formulae by comparison to F-theory and derive them independently and more generally from the tachyon picture, and relate these numbers to the closed string massless spectrum of the orientifold compactification in an interesting way. We furthermore give concrete recipes to explicitly and systematically construct nontrivial D-brane worldvolume flux vacua in arbitrary Calabi-Yau orientifolds, illustrate how to read off D-brane flux content, enhanced gauge groups and charged matter spectra from tachyon matrices, and demonstrate how brane recombination in general leads to flux creation, as required by charge conservation and by equivalence of geometric and gauge theory moduli spaces.
1. Introduction

Type IIB O3/O7 orientifold flux compactifications and their F-theory avatars currently appear to be the most promising corner of the string theory landscape for controlled, realistic model building. The virtues of this class of models include:

- Complex structure moduli, dilaton and D7-brane moduli can be stabilized classically at high mass scales by RR, NSNS and D7 worldvolume fluxes, and plausible stabilization mechanisms for the Kähler moduli based on quantum corrections have been proposed \[^1, 2\] and studied in detail, as reviewed in \[^3, 4, 5\].
• There is a very high degree of discrete tunability of physical parameters, which helps in producing controlled models. In particular the cosmological constant can in principle be discretely tuned to become extremely small, easily of the order of the measured cosmological constant or less [6, 7].

• The classical geometry of the compactification manifold remains Calabi-Yau after turning on fluxes, up to warping [8]. This means in particular that many of the powerful techniques from algebraic geometry can still be used to describe these vacua.

• Strongly warped throats of Klebanov-Strassler type [9] occur naturally, generating large scale hierarchies [8].

• Slow roll inflation can be accommodated, at least in fine tuned local models [10, 11, 12, 13].

• The F-theory description provides $g_s$ corrections to the geometry which smooth out the O7 singularities [14].

• There is a rich set of explicit D-brane constructions possible in these models, useful for particle physics model building; for an extensive resp. short review see [15, 16]. More recently, [17, 18] have initiated a program of model building in F-theory. This framework naturally incorporates GUTs and promises to be a powerful and elegant unifying geometrical framework for string phenomenology.

Despite all this, there are still significant gaps in our understanding of the landscape of type IIB orientifold vacua, in particular in our understanding of the landscape of D7-brane configurations and its interplay with moduli stabilization and other global issues.

Simple, flat, intersecting D7/D3-brane constructions are well understood by now in the context of toroidal orientifolds, as reviewed in [15], but these models are just a tiny subset of all possibilities, miss some desirable features such as warping and do not incorporate complete moduli stabilization.

The combinatorics of globally well defined D-brane models is systematically understood in the framework of boundary states of CFTs at Gepner points of general type II Calabi-Yau orientifold compactifications [19, 20, 21, 22, 23, 24, 25], but this analysis is by definition done at a special, nongeometric point in closed string moduli space and most of these studies did not yet address moduli stabilization and the parameter discretuum, as the tools to do this in this nongeometric regime have only been developed fairly recently [26].

Rather general geometrical D-brane setups have been studied systematically in “bottom up”, local, noncompact Calabi-Yau varieties decoupled from gravity (for example in [17, 18, 27, 28, 29, 30, 31, 32, 33]). Similarly, the models for slow roll inflation mentioned above are also essentially local models, with compactification effects only relatively crudely taken into account. The same is true for many recent models of dynamical supersymmetry breaking in string theory (such as [34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45]).

Eventually, all of these constructions need to be embedded in finite volume, fully moduli stabilized compactifications with broken supersymmetry, a tiny positive cosmological
constant, the correct spectrum of couplings and masses, effective scalar potentials admitting slow roll inflation, and so on. Completing local models to genuine string vacua reduces the number of possible constructions from a continuous infinity to a finite, discrete set, and may destroy the desired features the local or continuously tuned model was designed to have. For example, an almost flat potential on the moduli space of a local model, suitable for slow roll inflation, will generically develop steep slopes in the direction of additional moduli induced by the embedding. An intersecting brane model will often be forced into recombination by turning on moduli stabilizing background fluxes, breaking the desired gauge symmetries. Global tadpole cancelation constraints generically require the presence of additional D-branes, potentially intersecting the local construction and producing additional, unwanted matter fields charged under the standard model gauge group.

Beyond these immediate model building concerns, one would like to address questions such as how many — if any — string vacua compatible with observational constraints we can expect to exist, and, more ambitiously, what the proper notion of naturalness or even probability is in the context of the string theory landscape. In other words, we would like to know whether the requirement of the existence of a consistent UV (quantum gravity) completion is sufficiently constraining to be predictive at low energies. To analyze these questions, statistical methods have been proposed and developed [46, 47, 7, 48, 49, 50, 51, 52, 53, 54, 55, 56]. Statistical analysis crucially relies on global constraints and topological parameters, such as tadpole cancelation, brane charges and flux lattice dimensions. For example, the number of critical points \( DW = 0 \) of an ensemble of flux superpotentials, for IIB RR/NSNS, F-theory or D7 worldvolume fluxes compatible with D3 tadpole cancelation without adding anti-D3 branes, in a region \( \mathcal{M} \) of the appropriate moduli space, is estimated\(^1\) by a formula of the general form (see [5] section 6 for a derivation):

\[
N_{\text{vac}} \approx \frac{(2\pi Q)^{b/2}}{(b/2)!} \int_{\mathcal{M}} e(D),
\]

where \(-Q = -Q^{(F)}\) is the total curvature induced D3-brane charge of the compactification (in F-theory unit conventions, see footnote 2), \( b \) is the dimension of the flux lattice and \( e(D) \) is the euler density of the connection \( D \) appearing in the critical point condition \( DW = 0 \). Distributions of discrete D-brane data such as enhanced gauge groups and charged matter content have so far only been studied in very limited and simple ensembles. In particular, no systematic studies of the statistics of D-brane configurations in general Calabi-Yau orientifold flux vacua have been done. On the other hand, contrary to what is sometimes tacitly assumed, in typical IIB orientifold or F-theory compactifications, virtually all of the degeneracy of flux vacua actually comes from worldvolume fluxes in the D-brane sector (the “open string landscape” [57]). For instance in the example we will study throughout the paper, the IIB orientifold obtained as the weak coupling limit of F-theory on the elliptic fibration over \( \mathbb{CP}^3 \), we will see that \( Q = 972 \) and that the number of bulk (RR and NSNS) fluxes is \( b_{\text{bulk}} = 300 + 300 = 600 \), while the number of D7-brane worldvolume fluxes is

\(^1\)This estimate is reliable in the regime \( 4\pi eQ \gg b \), which is often not satisfied in unrestricted F-theory flux ensembles. For further discussion see [3] section 6.3.
$b_{\text{brane}} = 23320$. As a result, the above estimate gives $N_{\text{vac}} \sim 10^{500}$ for the bulk sector, but $N_{\text{vac}} \sim 10^{2000}$ for the D-brane sector!

For all of these reasons, it would seem desirable to develop a more systematic top-down, approach to the D-brane sector of generic, compact type IIB O3/O7 orientifold vacua in the geometric regime, in a way suitable for concrete model building including moduli stabilization and for statistical analysis. In fact most of the necessary ingredients for such an approach are already present in the literature, although often in a somewhat abstract and formally involved form. For example, there exists an extensive categorical framework for D-branes in Calabi-Yau manifolds [58, 59, 60, 61], and in principle the construction of vacua with certain desired properties is, at sufficiently large Calabi-Yau volume, a well defined problem in standard algebraic geometry. There have indeed been several model building studies already where fully compact geometries were considered for nontoroidal Calabi-Yau O3/O7 orientifolds, sometimes even including complete moduli stabilization. This includes (with varying degrees of thoroughness and with varying degrees of assumptions and modeling) [62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77]. In particular in [77] the interaction between the particle physics D-brane sector and moduli stabilization mechanisms was studied, and it was found that the two could not be considered independently, providing further motivation for a holistic (as opposed to modular) approach to D-brane model building.

However, as we will see, the generic D7-brane sector in general Calabi-Yau orientifold compactifications presents a number of complications and puzzles. By “generic” we mean a D7-brane with minimal possible gauge group — in the case at hand this means no continuous gauge group at all. This differs from the usual D7-image-D7 pairs or invariant multiple brane stacks, which do have nontrivial gauge groups. A single D7-image-D7 pair, which has gauge group $U(1)$, will typically be mutually intersecting. This leads to the possibility of recombination into a single component, generic D7, whereby the $U(1)$ gets Englert-Brout-Higgsed. One of the complications alluded to above is now that, as we will see, in the presence of an O7$^-$, such a generic D7 will be singular: Locally near the O7$^-$, the D7 is forced to retain the structure of a D7-image-D7 pair, but globally it becomes a single connected object, and this causes the occurrence of pinch point singularities. Locally, these singularities are modeled by the so-called Whitney Umbrella in $\mathbb{C}^3$ (defined in section 3.3 and illustrated in fig. 2).

We will confirm that generic D7-branes are locally Whitney Umbrellas in three independent ways: by taking the weak coupling limit of F-theory (also noted in [53]), by requiring Dirac quantization in perturbative IIB string theory, and from the shape of tachyon condensates of consistent D9-anti-D9 systems. As a result of the presence of these non-orbifold singularities, the usual index formulae computing the quantities appearing in (1.1) — the curvature induced D3-charge $-Q$, the number of D7 moduli $n$ and the worldvolume flux lattice dimension $b$ — fail. Going to nongeneric, nonsingular D-brane configurations does not help to compute these numbers, as these configurations are in fact typically in different physical components of the moduli space of the theory, with different (smaller) values for D3-charge, flux lattice dimension and number of moduli.

Another general problem is to match D-brane gauge theory degrees of freedom to
geometric moduli. A puzzle which arises here is that the number of gauge theory degrees of freedom of $N$ coincident branes scales as $N^2$, while the number of geometric moduli of a degree $N$ supersymmetric 4-cycle in general scales as $N^3$.

Dealing with the above issues has been a carefully sidestepped problem in much of the existing model building literature — for example in the “better racetrack” models of [66] the D7-brane sector was left largely unspecified and in [67] potential problems with D7-branes were circumvented by considering a rather special compactification in which all D7-branes were rigid and coincident with the O7-planes. To the best of our knowledge, in the existing model building literature, only nongeneric D7-branes such as brane-image-brane pairs and invariant, nonsingular stacks have been considered.

It is clear though that in order to discuss D7 moduli stabilization by fluxes, or do systematic studies of the landscape of IIB orientifold compactifications, statistical or otherwise, one must face and fully resolve these issues.

One approach would be to directly work in F-theory instead of in its weakly coupled IIB limit, computing for example the D3-tadpole $Q$ using techniques such as those employed in [80, 81, 5]. However, if one wants to just build type IIB orientifold models, it is often desirable not to have to make the detour of finding a suitable F-theory completion. One could also avoid IIB orientifolds altogether, but in strongly coupled F-theory compactifications there is no general canonical distinction between bulk and localized degrees of freedom such as in the weakly coupled IIB limit, making the identification of gauge theory content somewhat difficult in compact models. This to date remains to be fully understood for F-theory compactifications down to four dimensions. Furthermore, one cannot use string perturbation theory to compute for example quantum corrections to the Kähler potential, some of which play a crucial role in the moduli stabilization scenario of [2].

We believe it will therefore be useful to set up a concrete computational framework to systematically analyze the D7-brane sector in type IIB O3/O7 orientifolds in the weak coupling, large volume limit, collecting and developing various complementary approaches, in a maximally accessible way. This is the goal of this paper. Specifically, we use the F-theory, D7 and D9-anti-D9 tachyon condensation pictures to arrive at the following:

- We derive concrete formulae for topological physical quantities such as the curvature induced D3-charge, the number of moduli and the dimension of the flux lattice, for any component of the moduli space. These are in complete agreement with the F-theory results when the latter are available, and with “K-theory” results obtained from D9-anti-D9 annihilation. Using fixed point index theorems, we furthermore relate in an interesting way for example $Q$ and the numbers of various massless particles in four dimensions.

- Starting from the D9-anti-D9 tachyon condensation picture, we explain how to compute in general the worldvolume and flux content of the resulting D7-branes and how this can change under brane recombination, as required by charge conservation.

To do this we generalize and adapt to orientifolds the analysis and constructions of [78, 79], where flux configurations on space-localized D4-branes were studied in...
(non-orientifolding) toric Calabi-Yau manifolds and traced back to D6-anti-D6 bound states — a special case of the general D-brane bound state constructions formalized in [59] (and reviewed in [60]).

- We illustrate with simple examples how to concretely compute charges, moduli, gauge groups and matter content in the D9-anti-D9 picture, using only polynomial manipulations.

It was pointed out in [78] that the presence of fluxes induced by brane recombination resolves the apparent discrepancy between geometric and gauge theoretic moduli mentioned earlier, and indeed the equivalence of gauge theory and geometry is manifest in the tachyon condensation picture.

We also encounter some interesting subtleties, such as the necessity to have an even number of D9-image-D9 pairs in the presence of O7− planes, which turns out to be crucial to match the F-theory results.

- We give a method for explicit construction of D7 flux vacua using holomorphic curves, which is much more tractable than solving the superpotential critical point condition (which in our basic example involves extremizing a tadpole-respecting integral linear combination of 23320 3-chain periods over 3728 variables...). This is analogous to the constructions used in [78, 79, 82, 83] to build and enumerate flux configurations on D4-branes in non-orientifolded Calabi-Yau manifolds.

A summary of our results and some ready-to-use formulae can be found in section 6, which the reader may consult before going to the detailed discussion.

This paper is meant to be expository, and throughout we focus on a particular example to illustrate the main ideas, making some generalizations as we go, as well as separately in section 5. We will not try to be complete; for much more advanced and comprehensive K-theoretic and categorical descriptions of orientifolds we refer to the upcoming works [134, 135]. Our approach will be more elementary. All the geometrical tools we will rely on can be found in section 5 of the lecture notes [5], and we will frequently refer to it.

2. F-theory picture

2.1 Introduction

We start by briefly sketching the F-theory picture [84] and its relation to IIB string theory and M-theory. An extensive introduction to this can be found in the lecture notes [5].

F-theory can be defined as type IIB string theory continued away from its weak string coupling limit, just like M-theory can be defined as type IIA continued away from weak coupling. In practice it usually refers to type IIB compactifications on a manifold $B$ with dilaton-axion $\tau = C_0 + e^{-\phi}$ varying over $B$, described in the supergravity approximation and by giving $\tau$ the interpretation of the modular parameter of a 2-torus $T^2$ fibered over $B$. This interpretation gives an elegant and useful geometrization of such backgrounds: Supersymmetric configurations correspond to Calabi-Yau manifolds $Z$ elliptically fibered
(with section) over $B$, the $SL(2,\mathbb{Z})$ gauge symmetry of IIB string theory corresponds to the geometrical $SL(2,\mathbb{Z})$ reparametrization symmetry of the $T^2$, and $(p,q)$ 7-branes on $B$ correspond to degeneration loci on $B$ where a $(p,q)$ 1-cycle of the $T^2$ degenerates. The surprising effectiveness of this higher dimensional geometric picture is best explained by noting that M-theory on the same elliptically fibered manifold $Z$, in the limit of vanishing fiber size, is dual to type IIB on the base $B$ of the elliptic fibration. Indeed M-theory on a small $T^2$ equals weakly coupled IIA on a small circle, which is T-dual to type IIB on a large circle. Applying this fiberwise to $Z$ yields type IIB compactified on $B \times S^1$, with the $S^1$ decompactifying in the limit in which the original fiber is sent to zero size. This duality allows one to use the geometrical objects of M-theory to define and analyze F-theory compactifications.

Of particular interest to us are F-theory compactifications on Calabi-Yau fourfolds, i.e. type IIB on their three complex dimensional base manifolds. For genuine $SU(4)$ holonomy fourfolds, this gives rise to an effective $\mathcal{N} = 1$ supergravity theory in four dimensions. The scalars in the massless chiral multiplets in this theory arise from the Kähler moduli of $B$, the complex structure moduli of $Z$ (which includes the IIB dilaton-axion and 7-brane moduli), D3-brane moduli and various axions.

In the following, we will give some physically important topological numbers associated to a particular example of an F-theory fourfold compactification. This includes the curvature induced D3 tadpole, the number of D7-brane moduli in the weak IIB coupling limit, and the number of fluxes that can be turned on. In the next section we will use these results as guidance to infer rules on how to compute these numbers directly in the perturbative IIB orientifold picture, and in particular how to deal with the D7 worldvolume singularities complicating the analysis there.

### 2.2 Fourfold data and D3 tadpole

The starting point of our main example is F-theory on the Calabi-Yau fourfold elliptically fibered over $\mathbb{CP}^3$, which is described by the equation

$$Z : y^2 = x^3 + f(u) x z^4 + g(u) z^6 \quad (2.1)$$

with projective $\mathbb{C}^*$ equivalences

$$(u_1, u_2, u_3, u_4, x, y, z) \simeq (\lambda u_1, \lambda u_2, \lambda u_3, \lambda u_4, \lambda^8 x, \lambda^{12} y, z) \quad (2.2)$$

$$\simeq (u_1, u_2, u_3, u_4, \mu^2 x, \mu^3 y, \mu z), \quad (2.3)$$

where $(u_1, u_2, u_3, u_4) \neq (0,0,0,0)$ and $(x,y,z) \neq (0,0,0)$. Here $f(u), g(u)$ are homogeneous polynomials of degrees 16 resp. 24. Note that the projective equivalences define a $W\mathbb{CP}_{2,3,1}$ fiber bundle over $\mathbb{CP}^3$, the fiber being parametrized by $(x,y,z)$ and the base by $(u_1, u_2, u_3, u_4)$. At fixed $u$, (2.1) describes an elliptic curve in $W\mathbb{CP}^3_{2,3,1}$, hence this equation indeed defines an elliptic fibration over $\mathbb{CP}^3$. Moreover the elliptic fibration has a section, obtained by putting $z = 0$, which is up to projective equivalences the surface $(x,y,z) = (1,1,0)$ with $\bar{u} \in \mathbb{CP}^3$ arbitrary.
A derivation of the geometric data of this example using relatively basic methods can be found in sections 5.7 and 5.9 of [5], or can be extracted from the general and more advanced discussion in [80]. We quote here the relevant results.

The nontrivial Hodge numbers of $Z$ are

$$h^{1,1} = 2, \quad h^{2,1} = 0, \quad h^{2,2} = 15564, \quad h^{3,1} = 3878,$$

so the number of complex structure moduli is $h^{3,1} = 3878$ (which can also be computed directly by counting the number of coefficients of $f$ and $g$ modulo $GL(4, \mathbb{C})$ coordinate transformations: $(\frac{16+3}{3}) + (\frac{24+3}{3}) - 16 = 3878$), and

$$\chi = 23328, \quad b_4 = 23322.$$  

A particular basis for $H^{1,1}(Z, \mathbb{Z})$ is $\{K_1, K_2\}$, where $K_1$ is Poincaré dual to the divisor $[u_1 = 0]$, and $K_2$ to the divisor $[z = 0] + 4[u_1 = 0]$. This is in fact a basis for the Kähler cone, i.e. we can parametrize the Kähler form on $Z$ as $J_Z = \xi^1K_1 + \xi^2K_2$ with $\xi^1, \xi^2 > 0$.

In the F-theory limit, the size of the base is $(\xi^1)^3/6$ and the size of the elliptic fiber is $\xi^2 \to 0$.

The curvature induced D3-tadpole\(^2\) is $-Q^{(F)}_c$, with

$$Q^{(F)}_c = \frac{\chi(Z)}{24} = 972.$$  

This together with the charge of mobile D3-branes and 4-form fluxes $G$ must add up to zero:

$$-Q^{(F)}_c + N_{D3} + \frac{1}{2} \int_Z G \wedge G = 0.$$  

Reproducing this number $Q^{(F)}_c$ from the perturbative IIB orientifold picture will be our first task in the next section.

### 2.3 Weak coupling orientifold limit and D7 moduli

The IIB dilaton-axion $\tau$ is identified with the modular parameter of the elliptic fiber, and determined by

$$j(\tau) = \frac{4 \cdot (24f)^3}{\Delta}, \quad \Delta := 4f^3 + 27g^2 = 0,$$

where $j(\tau)$ is Klein’s modular invariant function $j(\tau) = e^{-2\pi i \tau} + 744 + \mathcal{O}(e^{2\pi i \tau})$. The 7-branes are localized where the fibration degenerates, i.e. at

$$\Delta(u) = 0.$$  

\(^2\) There is a difference in standard conventions used in F-theory and in type IIB orientifolds. In F-theory, one mobile D3 has one unit of D3-charge. In the corresponding IIB description, this corresponds to a D3 together with its orientifold image on the Calabi-Yau double cover of the base of the elliptic fibration, and this usually gets assigned charge 2. Thus $Q^{(IIB)}_c \equiv 2Q^{(F)}_c$. We furthermore define the sign of D3-charge such that D7 and $+\text{D3}$ branes are mutually supersymmetric.
To make contact with the weak coupling perturbative IIB orientifold picture, we follow Sen’s procedure \[14, 86\]. We parametrize, without loss of generality,

\[
\begin{align*}
    f &= -3h^2 + \epsilon \eta, \\
    g &= -2h^3 + \epsilon \eta - \epsilon^2 \chi/12,
\end{align*}
\]

(2.10)

where \( h, \eta \) and \( \chi \) are a homogeneous polynomials of degrees 8, 16 and 24 in the \( u_i \), and \( \epsilon \) is a constant. When \( \epsilon \to 0 \) keeping everything else fixed, one finds

\[
\Delta \approx -9\epsilon^2 h^2(\eta^2 - h\chi), \quad j(\tau) \approx \frac{(24)^4}{2} \frac{h^4}{\epsilon^2(\eta^2 - h\chi)},
\]

(2.11)

Thus, in this limit, \( g_s = \frac{1}{2\pi \tau} \sim -\frac{1}{\log |\epsilon|} \to 0 \) everywhere except near \( h = 0 \), and the \( \epsilon \to 0 \) limit can therefore be interpreted as a IIB weak coupling limit. A monodromy analysis \[86\] reveals that in this limit the two components of \( \Delta = 0 \) should be identified with an \( O7 \)-plane and a \( D7 \)-brane in a Calabi-Yau orientifold as follows:

\[
O7 : h(u) = 0, \quad D7 : \eta(u)^2 = h(u) \chi(u),
\]

(2.12)

where the Calabi-Yau 3-fold is given by the equation

\[
X : \xi^2 = h(u)
\]

(2.13)

with \( \mathbb{C}^* \) equivalence \( (u_1, u_2, u_3, u_4, \xi) \simeq (\lambda u_1, \lambda u_2, \lambda u_3, \lambda u_4, \lambda^4 \xi) \), orientifolded by the involution

\[
\sigma : \xi \to -\xi.
\]

(2.14)

The CY threefold \( X \) is a double cover of \( \mathbb{CP}^3 \) branched over \( h(u) = 0 \); moding out by \( \sigma \) gives back \( \mathbb{CP}^3 \). It has \( h^{2,1} = 149 \) complex structure deformations, given by the coefficients of \( h \) modulo \( GL(4, \mathbb{C}) \) coordinate transformations, and \( h^{1,1} = 1 \) Kähler deformation. In addition to this, there are \( D7 \)-brane moduli, counted by the number of inequivalent deformations of \( (2.12) \), i.e. \( \binom{16+3}{3} + \binom{24+4}{3} - \binom{8+3}{3} - 1 = 3728 \). The first subtraction comes from the fact that we can shift \( \eta \to \eta + h\psi \) with \( \psi \) an arbitrary degree 8 polynomial and shift \( \chi \) accordingly, without changing the form of the equation \( (2.12) \), and the last subtraction corresponds to overall rescaling of the coefficients. As a check note that indeed the number of \( D7 \) moduli plus the number of 3-fold complex structure moduli plus one for the dilaton-axion equals 3878, the number of fourfold complex structure moduli.

In conclusion, we find that the number of \( D7 \) moduli is

\[
\dim \mathcal{M}_{D7} = 3728.
\]

(2.15)

Reproducing this number from IIB orientifold data will be our second task in the next section.
2.4 Fluxes

In M-theory one can turn on general 4-form fluxes $G \in H^4(Z,\mathbb{Z})$ on $Z$. At first sight one would therefore conclude that the number of F-theory fluxes is $b_4$. However, this is not quite correct. Because the M-F duality described in section 2.1 turns one M-theory elliptic fiber direction into a IIB 4d spatial direction, not all $G$-fluxes dualize to 4d Poincaré invariant fluxes in IIB. Roughly speaking we need one and only one leg of the flux to be on the elliptic fiber. A more precise way of thinking about this is in terms of the domain walls that source the fluxes (see also [5]). In M-theory these are M5 branes wrapping 4-cycles $S$ in $Z$ — this will produce a flux $G$ Poincaré dual to $S$. Now if $S$ wraps the complete elliptic fiber and a complex curve $C$ in the base, then in IIA this becomes a D4 wrapping $S$ and the $S^1$ which gets T-dualized to go to IIB, resulting in a D3 wrapping $C$. This is a string in the four noncompact dimensions, and will clearly not produce a Poincaré invariant flux. Similarly, if $S$ is completely transversal to the elliptic fiber, then we end up with a IIB KK monopole wrapped on $S$, which is again a stringlike object in four dimensions. If on the other hand $S$ wraps only a 1-cycle of the elliptic fiber, we end up with a 5-brane domain wall in IIB, which sources appropriate Poincaré invariant fluxes.

Now, when $S$ is the intersection of two regular divisors in $Z$, it will always be of one of the two unacceptable types. Since divisor classes are in $H^{1,1}$, fluxes Poincaré dual to these are elements of $H^{1,1} \wedge H^{1,1}$. Therefore, to get good F-theory flux vacua, we should take our fluxes $G \in H^4$ to be perpendicular to $H^{1,1} \wedge H^{1,1}$, i.e. be contained in

$$H^4(Z,\mathbb{Z}) = \{ G \in H^4(Z,\mathbb{Z}) \mid \int_Z G \wedge K_A \wedge K_B = 0 \ \forall A,B \}, \quad (2.16)$$

where $\{ K_A \}_A$ is a basis of $H^{1,1}(Z)$.

Naively this reduces the lattice of allowable fluxes by three in our example, but there is in fact a quadratic relation $K_2^2 = 4K_1K_2$ for the basis introduced above (as derived in [5] section 5.7), so we get a reduction by two instead. In conclusion, the dimension of the lattice of allowable F-theory fluxes is

$$b = b'_4 = b_4 - 2 = 23320. \quad (2.17)$$

In the weak coupling perturbative IIB picture, part of these fluxes correspond to bulk NS-NS and R-R fluxes, and the remainder to D7 $U(1)$ worldvolume fluxes. Reproducing the number $b$ above from IIB orientifold data will be our third task in the next section.

3. Weak coupling geometric IIB picture

3.1 The orientifold and the D7 double intersection property

As we saw in the previous section, the weak coupling orientifold description of our example starts from a Calabi-Yau $X$ given by the equation $\xi^2 = h(u)$ in $\mathbb{CP}^4_{1,1,1,4}$, where $h$ a

---

3In the present example $c_2(Z)$ is even, so there is no half integral shift of $G$.

4If $Z$ has reduced holonomy or has singularities such as those giving rise to enhanced gauge symmetries, the situation is more subtle. We will not analyze these cases here.
homogeneous polynomial of degree 8. Note that the most general degree 8 hypersurface in this space can indeed be brought in this form, since terms linear in $\xi$ can be absorbed by a coordinate transformation shifting $\xi$. The Hodge numbers of $X$ are $h^{1,1} = 1, h^{2,1} = 149$. The space of D7 charges $H^2(X, \mathbb{Z})$ is generated by the hyperplane class $H = [a_i u_i = 0]$. It satisfies $H^3 = 2\omega$ where $\omega$ is the unit volume element on $X$. The second Chern class of $X$ is $c_2(X) = 22 H^2$.

The Hodge numbers of $X$ are $h^{1,1} = 1, h^{2,1} = 149$.

The orientifold involution is

$$\sigma : \xi \rightarrow -\xi.$$  \hspace{1cm} (3.1)

This is combined with $(-1)^{F_L}\Omega$ acting on string states, where $\Omega$ is worldsheet orientation reversal and $F_L$ is the spacetime fermion number in the leftmoving sector.

There is an O7-plane at $\xi = 0$, whose Poincaré dual cohomology class is $[O7] = 4H$. We choose the orientifold projection such that it produces $SO$ groups for D7-branes coincident with the O7, so the O7 is an $O7^-$. To cancel the D7 charge tadpole induced by the O7, we need to add D7 branes for a total of D7 charge $[D7] = 32H$. Such a D7 can be described as the zero locus of a homogeneous polynomial equation of degree 32. To respect the orientifold $\mathbb{Z}_2$ symmetry $\sigma$, only even powers of $\xi$ can occur, which in turn can be eliminated by (2.13). Hence the most general $\mathbb{Z}_2$ symmetric holomorphic surface in the class $32H$ is described by an equation of the form $P_{32}(u) = 0$, where $P_{32}(u)$ is a homogeneous polynomial of degree 32 on $\mathbb{C}P^3$, and naively we might be tempted to conclude the space of possible supersymmetric D7 embeddings to be given by

$$D7 : P_{32}(u) \quad \text{(naive)}.$$  \hspace{1cm} (3.2)

Recall however that in the weak coupling limit of F-theory, we found the D7 equation to be of the form (2.12):

$$D7 : \eta^2(u) = \xi^2 \chi(u) \quad \text{(F-theory)},$$  \hspace{1cm} (3.3)

where $\eta$ and $\chi$ are homogenous polynomials of degree 16 and 24. This is certainly not the most general degree 32 equation, as can be seen for example by counting parameters: as we saw in section 2.3, the number of distinct deformations of (3.3) is 3728, while the most general $\sigma$-symmetric surface $P_{32}(u) = 0$ has 6544 deformations. Moreover, as will become clear below, a generic $\mathbb{Z}_2$-symmetric surface would give a contribution to the D3 tadpole and would allow a number of worldvolume fluxes which would both be in gross disagreement with the F-theory results.

What characterizes the D7 worldvolumes described by (3.3) is that for generic $\eta$ they all have double point intersections with the O7-plane: when we put $\xi = 0$, (3.3) reduces to $\eta^2 = 0$, so all zeros are double zeros. Another way of saying this is that locally (away from $\chi = 0$), the D7 looks like a D7-image-D7 pair, as is manifest by writing the equation

\[ P_{32}(u) = 0. \]

\[ D7 : P_{32}(u) \quad \text{(naive)}. \]

\[ D7 : \eta^2(u) = \xi^2 \chi(u) \quad \text{(F-theory)}. \]

\[ \sigma : \xi \rightarrow -\xi. \]

\[ \eta \text{ and } \chi \text{ are homogenous polynomials of degree 16 and 24.} \]

\[ \text{This is certainly not the most general degree 32 equation, as can be seen for example by counting parameters:} \]

\[ \text{as we saw in section 2.3, the number of distinct deformations of (3.3) is 3728, while the most general } \]

\[ \sigma \text{-symmetric surface } P_{32}(u) = 0 \text{ has 6544 deformations. Moreover, as will become clear below, a } \]

\[ \text{generic } \mathbb{Z}_2 \text{-symmetric surface would give a contribution to the D3 tadpole and would allow a number of worldvolume fluxes which would both be in gross} \]

\[ \text{disagreement with the F-theory results.} \]

\[ \text{What characterizes the D7 worldvolumes described by (3.3) is that for generic } \eta \text{ they all have double point} \]

\[ \text{intersections with the O7-plane: when we put } \xi = 0, (3.3) \text{ reduces to } \eta^2 = 0, \text{ so all zeros are double zeros. Another way of saying this is that locally (away from } \chi = 0, \text{ the D7 looks like a D7-image-D7 pair, as is manifest by writing the equation} \]

\[ \text{\footnote{\text{See section 5.5 of [5] for a review on how to compute Chern classes of complete intersections in toric} \]

\[ \text{varieties}} \]

\[ \text{\footnote{\text{We define an O}p^- \text{ in general to be an O}p\text{-plane such that stacks of D}p \text{ branes coincident with it have} \]

\[ \text{orthogonal gauge groups and O}p^+ \text{ for the case in which the gauge group is symplectic. The gauge groups for} \]

\[ \text{lower dimensional branes follow from this; for example we get symplectic groups for D3-branes coincident with an O7^- and again orthogonal groups for D(-1) branes on an O7^- [5].} \]
as $\xi = \pm \eta/\sqrt{\chi}$. Globally however we generically have a single connected brane, and (3.3) is in fact the only possible globally well-defined equation which has this local property.

\[ \xi = \pm \eta/\sqrt{\chi}. \]

This double intersection property was independently noted in [88].

### 3.2 Perturbative IIB explanation of the double intersection

How can we see the necessity of such double intersections with $\xi = 0$ directly within the perturbative type IIB picture? Put differently, what is wrong with single D7-O7 intersections? The answer, it turns out, is that such single intersections violate Dirac quantization! To see this, first consider a D($-1$) probe at a point $p$ near the D7 away from the O7. Its path integral phase is $e^{2\pi i C_0(p)}$. When parallel transporting it on a loop $C$, it will pick up an additional phase $e^{2\pi i n_7}$, where $n_7$ is the number of D7-branes enclosed in the loop. Since $n_7$ is integral, this equals 1, so the phase $e^{2\pi i C_0(p)}$ is unambiguous, as it should. We can move the D($-1$) to the O7, where it will coincide with its orientifold image, with the same result. However, for the O7- orientifold projection we have chosen, this is not the minimal D($-1$) there exists on the O7: as we recalled in footnote \[6\], D($-1$) branes coincident with the O7 give orthogonal gauge groups; a brane-image brane pair corresponds to $O(2)$, but $O(1)$ is possible too: this represents a D($-1$) stuck on the O7, with charge half of that of the bulk D($-1$) we have been considering so far. When taken around a loop, such a “half” D($-1$) will thus pick up a phase $e^{\pi i n_7}$. Hence for the phase of the D($-1$) to be unambiguous, $n_7$ must be even, that is, the D7 must intersect the O7 only in double points.\[^7\]

\[^7\]As usual, probe arguments of this sort are a little slick: one can always object that it might just be the probe which is inconsistent, not the background. A more direct argument can presumably be given along the lines of the analysis of \[5\], where the relation between Dirac quantization and certain kinds of brane
The choice of orientifold projection was crucial for this argument. Had we chosen the O7\(^+\) projection, which gives respectively gauge groups USp, O and USp for D7, D3 and D(−1) branes coincident with the O7\(^+\), there would be no half D(−1) branes living on the O7 (since the minimal USp group is USp(2) = SU(2)), and therefore no need for double intersections. This choice of orientifold projection would have given positive D7-charge to the O7, so this would not have corresponded to the F-theory case we started off with, and in fact it would have been incompatible with supersymmetry and D7-tadpole cancelation.

(Very) special cases of consistent D7 brane embeddings are global brane-image-brane configurations, obtained by taking \( \chi = \psi^2 \) with \( \psi \) a degree 12 polynomial in equation (3.3). The D7 and its image are then given by D7\(_\pm\): \( \eta = \pm \xi \psi \), and both components are generically smooth. However this is only a dimension 1423 subvariety of the full 3728 dimensional moduli space, and moreover as we will see such configurations do not reproduce the (zero flux) F-theory D3-tadpole. Thus if we want to explore more than a tiny fraction of the landscape of this compactification, we are forced to consider the most general consistent D7 embedding, and deal with its singularities.

### 3.3 Singularity structure of the D7

From the previous discussion we take that the only allowed D7-worldvolumes \( S \) in \( X \) of D7-charge \( 2mH \) are described by equations of the form

\[
S : \quad P_{2m} := \eta^2 - h\chi = 0,
\]

inside \( X : P_X := \xi^2 - h = 0 \). Here \( (h, \eta, \chi) \) are polynomials of degree \( (8, m, 2m - 8) \) on \( \mathbb{CP}^3 \). To saturate the D7-tadpole, one can add a number of such D7-branes with charges \( 2m_iH \), given by equations \( P_{2m_i} = 0 \), satisfying \( \sum_i 2m_i = 32 \). Such a combined system is described by replacing the equation above with \( \prod_i P_{m_i} = 0 \), and can be rewritten in the form \( \tilde{\eta}^2 - \xi^2 \tilde{\chi} = 0 \), with \( \tilde{\eta} \) and \( \tilde{\chi} \) suitable degree 16 and 24 polynomials, consistent with the F-theory result. For many purposes we can however forget about the D7 tadpole constraint and just consider (3.4) with arbitrary \( m \). Unless stated otherwise, we will moreover assume \( m > 4 \). The advantage of allowing general \( m \) is that it allows sharper matching of topological data in the various pictures we will present.

The singularities of the algebraic surface \( S \) are those points for which the rank of the gradient matrix \( (dP_{2m}, dP_X) \) deviates from its generic value 2. It is not hard to see that for generic polynomials \( (h, \eta, \chi) \), this happens precisely at the intersection of the D7 with the O7, i.e. on the curve

\[
C : \quad \eta = 0 \quad \cap \quad h = 0 \quad \cap \quad \xi^2 - h = 0.
\]

These are of course nothing but the double point intersections we discussed earlier: away from \( \chi = 0 \) the D7 looks locally like a D7 and its \( \mathbb{Z}_2 \) image: \( \xi = \pm \eta/\sqrt{\chi} \). Globally this is generically not the case because the sheets get interchanged when circling around \( \chi = 0 \).
The projection $S_B$ of $S$ to the $\mathbb{CP}^3$ base, given by the first equation in (3.4), does not have singularities at generic points of the projection of $C$ to the base. However it does have double point singularities, locally isomorphic to the singularity $x^2 + y^2 + z^2 = 0$ in $\mathbb{C}^3$, in the $8m(2m - 8)$ isolated points

$$pp : h = \eta = \chi = 0.$$  \hspace{1cm} (3.6)

These singular points lift to pinch point singularities on $S$, locally isomorphic to the so-called (complexified) “Whitney umbrella”:

$$x^2 = zy^2$$  \hspace{1cm} (3.7)

in $\mathbb{C}^3$ (we identified $x = \eta, y = \xi, z = \chi$, so the O7 is at $y = 0$). This can alternatively be seen as the embedding of $\mathbb{C}^2$ into $\mathbb{C}^3$ given by $(s, t) \mapsto (st, s, t^2)$. The Whitney umbrella has a curve of double points at $x = y = 0$ pinching off at $x = y = z = 0$. Its projection to $\mathbb{R}^3$ is illustrated in fig. 2. A detailed analysis of such surfaces can be found in [97] p. 618-621, and [98] currently gives an aesthetically pleasing and succinct description.

Due to the presence of these singularities, computing topological quantities such as charges, deformation moduli and flux lattice dimensions from topological data such as Hodge numbers becomes significantly more subtle than in the smooth case. We now turn to these issues.

### 3.4 RR charges

#### 3.4.1 Generalities

We start by reviewing the known formulae for RR charges of smooth D-branes and O-planes. For future reference we will be more general than necessary to treat our example. However, we will be far from completely general; in particular we will not use the proper K-theoretic framework, which is fine for our purposes. For a comprehensive treatment of the geometry and topology of orientifolds, we refer to [134].

We normalize worldvolume, NSNS and RR potentials such that their fluxes are integrally quantized (up to possible overall shifts), or equivalently such that large gauge transformations act by integral shifts on period integrals of flat potentials. Then a D-brane with worldvolume $W$ carrying (possibly nonabelian) flux $F$ couples to the total RR potential $C = C_0 + C_2 + C_4 + C_8 + C_{10}$ as [89, 90, 91, 92]

$$S^{\text{Dbrane}}_{W, C} = 2\pi \int_W C \wedge e^{-B} \text{Tr} e^F \sqrt{\frac{\hat{A}(TW)}{\hat{A}(NW)}},$$  \hspace{1cm} (3.8)

where $\hat{A}$ is the A-roof characteristic class defined e.g. in section 5.5 of [3] and $TW$ and $NW$ are the tangent resp. normal bundles of $W$. We work in units with $\ell_s := 2\pi \sqrt{\alpha'} = 1$. 

Figure 2: The Whitney umbrella in $\mathbb{R}^3$. 

- 14 –
The flux $F$ obeys integral quantization conditions shifted by what can be thought of as a half integral diagonal $U(1)$ flux $\Delta F$ which reduces modulo $\mathbb{Z}$ to $w_2(N_W)\ [12, 13]$. More generally for a sheaf $E$, $\text{Tr}e^F$ is replaced by $\text{ch}(E)$.

For spacetime filling D-branes translationally invariant in the $\mathbb{R}^{1,3}$ directions this coupling defines a cohomology class $\Gamma \in H^*(X)$, which we will call the charge of the D-brane, by requiring that for all closed $B, C$ we have

$$S^\text{Dbrane}_{W,C} = 2\pi \int_{\mathbb{R}^{1,3} \times X} C \wedge e^{-B} \Gamma. \quad (3.9)$$

In the case at hand, this identifies $(D9,D7,D5,D3)$ charges with elements in respectively $(H^0(X), H^2(X), H^4(X), H^6(X))$.

More concretely, using the fact that $X$ is Calabi-Yau, one gets for a D9-brane stack carrying a holomorphic vector bundle $E$

$$\Gamma_{D9} = \text{ch}(E) \left( 1 + \frac{c_2(X)}{24} \right), \quad (3.10)$$

and for a stack of $N$ D7-branes wrapped on a smooth surface $S$ carrying a holomorphic vector bundle $E$

$$\Gamma_{D7} = N[S] + \left( \int_S D_A \wedge \text{ch}_1(E) \right) \tilde{D}^A + \left( \frac{N \chi(S)}{24} + \int_S \text{ch}_2(E) \right) \omega \quad (3.11)$$

where $[S] \in H^2(X)$ is Poincaré dual to the homology class of $S$, $D_A$ is a basis of $H^2(X)$ and $\tilde{D}^A$ the dual basis of $H^4(X)$, $\chi(S)$ is the Euler characteristic of $S$, and $\omega$ the unit volume element of $X$, which serves as a basis of $H^6(X)$. Thus the first term represents D7 charge, the second D5 charge and the last one D3 charge.

The Euler characteristic of a smooth surface $S$ in a Calabi-Yau $X$ can be computed from the adjunction formula as

$$\chi(S) = \int_X S^3 + c_2(X) S. \quad (3.12)$$

In our example this becomes for $S = nH$, $\chi(nH) = 2n^3 + 44n$.

For a stack of $N$ D5-branes wrapped on a curve $C$ carrying a holomorphic vector bundle $E$ we have

$$\Gamma_{D5} = N[C] + \left( \int_C c_1(E) \right) \omega. \quad (3.13)$$

Finally, for a single D3-brane (as opposed to an anti-D3-brane) we take the convention

$$\Gamma_{D3} = -\omega. \quad (3.14)$$

Note the minus sign, which we chose such that D3-brane probes preserving the supersymmetry of the orientifold backgrounds of interest to us have positive D3-charge, as is common in the model building literature. In other words, we will take the basis element of $H^6(X)$ with respect to which we express D3-charge to be $-\omega$. (The other choice of sign
is actually more natural for a variety of reasons (for example requiring T-duality to map positive branes to positive branes), but we will stick to the above choice.)

An $O_p$-plane on $V$ couples to the RR potentials as

\[ S_{V,C}^{O^p} = \pm 2\pi \int_V C \wedge 2^{p-4} \sqrt{\frac{L(\frac{1}{4}TV)}{L(\frac{1}{4}NV)}}, \]  

(3.15)

where $L$ is the Hirzebruch $L$-genus (again defined e.g. in section 5.5 of [5]). Again we define a charge $\Gamma$ by pairing with closed forms:

\[ S_{V,C}^{O^p} = 2\pi \int_{\mathbb{R}^{1,3} \times X} C \wedge \Gamma. \]  

(3.16)

In particular for an $O7^-$ wrapping a single component smooth divisor $U$, as in our example, one gets, using the adjunction formula and the fact that $X$ is Calabi-Yau:

\[ \Gamma_{O7^-} = -8[U] + \frac{\chi(U)}{6} \omega. \]  

(3.17)

where we recall $\chi(U) = U^3 + c_2 U$.

With these definitions, the RR tadpole cancelation condition for backgrounds with flat B-field can be formulated as

\[ e^{-B\Gamma_D + \Gamma_O} = 0, \]  

(3.18)

where $\Gamma_D$ denotes the total charge of all D-branes and $\Gamma_O$ the total charge of all O-planes.

For non-flat B-fields or B-fields with torsion these formulae need to be modified [134].

### 3.4.2 Orientifold actions

An $O3/O7$ orientifold is produced by a holomorphic involution $\sigma$ combined with $\Omega(-1)^F L$. The action on the massless closed string fields is

\[ C_{0,4,8} \rightarrow \sigma^* C_{0,4,8}, \quad C_{2,6,10} \rightarrow -\sigma^* C_{2,6,10}, \quad B \rightarrow -\sigma^* B, \quad g \rightarrow \sigma^* g. \]  

(3.19)

The action on a worldvolume gauge field living on an orientifold-invariant D3- or D7-brane stack is

\[ A \rightarrow -M\sigma^* A^t M^{-1}, \]  

(3.20)

where $M$ is a symmetric or antisymmetric constant unitary matrix, depending on the choice of orientifold projection and the stack under consideration.\(^8\) If symmetric, the surviving four dimensional gauge group is orthogonal, and if antisymmetric it is symplectic. If $M = M^t$ one can choose a Chan-Paton basis such that $M = 1$ or alternatively if the rank of the stack is even $M = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$. If $M = -M^t$ one can choose a basis such that

---

\(^8\)For a D$(p - 4k)$-brane stack coincident with an $O_p^\pm$-plane we have $M^t = \pm (-1)^k M$, and for a D7 stack wrapping a smooth 4-cycle transversal to an $O7^\pm$, we have $M^t = \pi M$. For a stack wrapped on a generic $O7^-$-transversal cycle of the singular kind we discussed in section 3.3, we get $M^t = M$. These rules are most easily and universally derived in the tachyon condensation picture, as will be discussed in section 4.2.4.
$M = \begin{pmatrix} 0 & i1 \\ -i1 & 0 \end{pmatrix}$. Here $I$ is a unit matrix of the appropriate dimension. For a $Dp$-$Dp'$ pair where $Dp' = \sigma(Dp)$, the action can be taken to be

$$A \rightarrow -\sigma^* A^t.$$  

(3.21)

This leads to unitary gauge groups.

Consistent with the above actions on the fields, the charge vectors $\Gamma$ transform as

$$\Gamma \rightarrow -\sigma^* \Gamma^*,$$

i.e. $\Gamma^{(2k)} \in H^{2k}(X) \rightarrow (-1)^{k+1} \sigma^* \Gamma^{(2k)}$.  

(3.22)

Here $\Gamma^*$ is obtained from $\Gamma$ by flipping the sign of the 2- and 6-form components, i.e. $\Gamma^* := \sum_k (-1)^k \Gamma^{(2k)}$ where $\Gamma^{(2k)}$ is the $(2k)$-form component of $\Gamma$. Thus the lattice of invariant charges is

$$(D9 \oplus D7 \oplus D5 \oplus D3)_{\text{invar}} = 0 \oplus H^2_\mp \oplus H^4_\pm \oplus H^6$$

(3.23)

where $H^{2k}_\pm$ is the $\pm 1$ eigenspace of $\sigma^*$ on $H^{2k}$. In our example $H^2_+ = H^2$ and $H^4_- = 0$.

### 3.4.3 Failure of naive charge formula for generic consistent D7-branes

We now return to the example. Our goal is to guess a formula for the D3 charge of the generic consistent D7-branes described by (3.4), by comparing to the known F-theory tadpole cancelation condition (2.7) at zero flux $G$. Reasonably assuming that zero flux in F-theory corresponds to zero worldvolume and bulk fluxes in IIB, we see that a configuration without any worldvolume or bulk flux and 972 mobile D3-branes plus their orientifold images must be tadpole free. In other words, minus the curvature induced D3 charge on the O7 and the degree 32 D7 should add up to $2 \times 972 \omega = 1944 \omega$.

Since the O7 is smooth for generic $h$, the charge of the O7 is given directly by (3.17) and (3.12), using $U = 4H$, $H^3 = 2\omega$ and $c_2(X) = 22H^2$:

$$\Gamma_{O7} = -32H + \frac{152}{3} \omega.$$  

(3.24)

Now, if we recklessly ignored the fact that the degree 32 surface $S$ wrapped by the D7 is singular, we would find, using (3.12), that $\chi(S) = 66944$ and thus from (3.11) with $N = 1$ and $E$ trivial$^9$,

$$\Gamma_{D7} = 32H + \frac{8368}{3} \omega,$$

(3.25)

and

$$\Gamma_{D7} + \Gamma_{O7} = 2480 \omega.$$  

(3.26)

This overshoots the F-theory value 1944 $\omega$. One could contemplate the possibility that this type (supersymmetric) IIB configuration actually secretly corresponds to an F-theory vacuum with nonzero $G$-flux, but one quickly sees that this is not possible since the equations of motion imply $G = *G$ [41, 42, 8], so flux always adds positively to the D3-charge in

$^9$Note that we can indeed take $E$ trivial because the degree of $S$ is even, so $w_2(N_S) = c_1(N_S) \mod 2 = [S] \mod 2 = 0$. 

(2.7), which would make the discrepancy even worse. Thus we conclude that we have been too reckless indeed in ignoring the singularity of \( S \), in particular by using (3.12).

On the other hand, if we take our D7 to be of the special global brane-image-brane type discussed at the end of section 3.1, i.e. \( \chi = \psi^2 \), we can reliably compute the charge, since the two component surfaces are generically smooth divisors in the class \( 16H \), and the total charge is just the sum of the charges of these components. This gives

\[ \Gamma_{D7} + \Gamma_{O7} = 792 \omega, \]

undershooting the F-theory value. This is not inconsistent, but suggests that the sector in the moduli space of D7-branes physically connected to this configuration maps in F-theory to a sector with nonzero \( G \)-flux. We will later on show that this interpretation is indeed correct. But this computation also shows that we cannot compute the charge of the generic D7 by going to this particular, well-controlled brane setup; we must deal with the singular generic D7 directly.

### 3.4.4 Modified charge formula

To formally preserve the usual charge formula (3.11) also for the generic, singular D7 in the orientifold, we need to come up with a physical definition of the Euler characteristic of \( S \) which reproduces the correct D3 charge. We will denote this modified Euler characteristic by \( \chi_o(S) \), where the subscript \( o \) is for orientifold, i.e. we define \( \chi_o(S) \) for generic allowed\footnote{By “generic allowed” here and in the following we mean a D7 described by a generic polynomial of the restricted form (3.4).} surfaces \( S \) by

\[ \int_X \Gamma_{\text{pure}D7} =: \frac{\chi_o(S)}{24}, \]

where \( \Gamma_{\text{pure}D7} \) is the charge of a pure (trivial \( E \)) D7 wrapping \( S \).

Consistency with the F-theory D3-tadpole formula (2.6) requires that

\[ 2 \chi(Z) = \chi_o(D7) + 4 \chi(O7), \]

which in our example gives \( \chi_o(S_{32}) = 45440 \) for generic allowed surfaces \( S_{32} \) of degree 32.

For a D7 \( S \) which globally splits in a smooth D7 \( S_1 \) and its orientifold image \( S'_1 \), the correct identification is simply \( \chi_o(S_1 \cup S'_1) = \chi(S_1) + \chi(S'_1) = 2 \chi(S_1) \), where the Euler characteristics of the components are just the topological ones. This additivity merely represents charge additivity, or put differently, the fact that the induced D3 charge is the integral of a local density (the euler density) over the separate component brane worldvolumes. Note that \( \chi_o(S_1 \cup S_2) \) differs from the topological Euler characteristic of the union: \( \chi_{\text{top}}(S_1 \cup S_2) = \chi_o(S_1 \cup S_2) - \chi(S_1 \cap S_2) \).

Now, as we saw, a generic D7 does not globally split in a brane-image-brane pair, but nevertheless it splits locally; near the curve of double point singularities \( C \), away from the pinch points, \( S \) just looks like a D7 transversally intersecting its image on the O7. This suggest we should parametrize the worldvolume of \( S \) such that the parametrization splits the two branches meeting on the curve \( C \) of double points, similar to the parametrization of the Whitney umbrella \( x^2 = yz^2 \) by \( (x, y, z) = (st, s, t^2) \), which splits the double point curve \( x = y = 0 \) into \( (s, t) = (0, \pm \sqrt{z}) \). Modulo subtleties due to the intrinsically singular
pinch points, we can then expect the proper $\chi_0(S)$ to be the Euler characteristic of the parameter surface.

Mathematically, such a splitting can be realized by blowing up the double point curve $C$. This blowup is of an auxiliary nature though — we are not really physically resolving space, we are just defining a convenient worldvolume parametrization. Concretely, consider the D7 described by (3.4) for arbitrary $m$. We want to blow up the curve $C : \eta = \xi = 0$. This goes as follows. Extend the set of coordinates $(u_1, u_2, u_3, u_4, \xi)$ with two new coordinates $s$ and $t$, and mod out by a new $\mathbb{C}^*$ rescaling $(s,t) \to (\lambda s, \lambda t)$, so $(s,t)$ parametrize a $\mathbb{P}^1$. Furthermore impose the equation

$$t \xi = s \eta(u). \quad (3.30)$$

In order for this to be compatible with the original projective rescalings of $(u_i, \xi)$, we assign weights $(0, m-4)$ to $(s,t)$. In summary we have the following toric $U(1)$ charges (or $\mathbb{C}^*$ weights):

<table>
<thead>
<tr>
<th>$u_1$</th>
<th>$u_2$</th>
<th>$u_3$</th>
<th>$u_4$</th>
<th>$\xi$</th>
<th>$s$</th>
<th>$t$</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>4</td>
<td>0</td>
<td>$m-4$</td>
</tr>
<tr>
<td>$Q^1$</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>0</td>
<td>0</td>
<td>0</td>

</tr>
<tr>
<td>$Q^2$</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Note that away from the curve $C$, (3.30) uniquely determines a point $(s,t)$ in the $\mathbb{P}^1$, so nothing changes. Each point on $C$ on the other hand is replaced by a $\mathbb{P}^1$.

Now let $\Sigma$ be the closure of our D7-divisor $S$ defined by (3.4) but with the curve $C : \eta = \xi = 0$ removed, in this blown up space. Explicitly, after gauge fixing$^{11}$ $s \equiv 1$, this is

$$\Sigma : \quad \xi t = \eta \quad \cap \quad t^2 = \chi \quad \cap \quad \xi^2 = h \quad \quad (3.31)$$

in $W\mathbb{C}^{5}_{1,1,1,1,4,m-4}$. Then the blow-down projection map

$$\pi : \Sigma \to S : (\vec{u}, \vec{\xi}, t) \mapsto (\vec{u}, \xi) \quad \quad (3.32)$$

is one to one except at $\xi = 0$, $t \neq 0$, i.e. the curve of double points $C$ away from the set of pinch points $pp : t = \xi = h = \eta = \chi = 0$, where it is two to one. At the pinch points, it is again one to one. (Note that this parametrization reduces to the $(s,t)$ parametrization

---

$^{11}$We can do this since $s = 0$ implies $\xi = 0$, which is incompatible with the equation for $S$ with $\xi = \eta = 0$ removed.
given above when we apply this prescription to the Whitney umbrella.) This means Σ parametrizes S through the projection π in the way we were after. Hence we expect

\[ \chi_o(S) = \chi(\Sigma) + k n_{pp}, \quad (3.33) \]

where \( k \) is some constant, to be determined, and \( n_{pp} \) the number of pinch points. The second term represents a possible correction due to the isolated pinch point singularities, where the parametrization degenerates.

We now verify this and determine \( k \). Since the coordinate surface \( \Sigma \) is a smooth complete intersection in weighted projective space, it is straightforward (using the adjunction formula, cf. section 5.5 of [5]) to compute its Chern classes and hence its Euler characteristic \( \chi(\Sigma) = \Sigma \cdot c_2(\Sigma) \).

\[
c(\Sigma) = \frac{(1 + [u])^4 (1 + [\xi]) (1 + [t])}{(1 + [h]) (1 + [n]) (1 + [\chi])} \quad (3.34)
\]

\[
= (1 + \tilde{H})^4 (1 + 4\tilde{H}) (1 + (m - 4)\tilde{H})
\]

\[
(1 + 8\tilde{H}) (1 + m\tilde{H}) (1 + (2m - 8)\tilde{H}) \quad (3.35)
\]

\[
= 1 + (4 - 2m)\tilde{H} + (54 - 20m + 4m^2)\tilde{H}^2, \quad (3.36)
\]

where \( \tilde{H} \) is the hyperplane class \([u_1 = 0]\) in \( WP\mathbb{P}^{5}_{1,1,1,1,4,m-4} \), which satisfies \( \tilde{H}^5 = \frac{1}{4(m-4)} \) (cf. [5] section 5.2). Hence, using \( \Sigma = 8m(2m - 8)\tilde{H}^3 \),

\[
\chi(\Sigma) = 16m^3 - 80m^2 + 216m. \quad (3.37)
\]

Furthermore \( n_{pp} = 8m(2m - 8) \). For \( m = 16 \) we thus get \( n_{pp} = 3072 \) and \( \chi(\Sigma) = 45440 + 3072 \). Hence (3.33) exactly reproduces the F-theory result (3.29) provided we take

\[ k = -1. \quad (3.38) \]

For \( S \) of general degree \( 2m \) we get, using (3.33) with \( k = -1 \) and (3.37),

\[
\chi_o(S_{2m}) = 16m^3 - 96m^2 + 280m. \quad (3.39)
\]

As a nontrivial consistency check, one can verify that if we have two generic D7-branes of degrees \( m_1, m_2 \) with \( m_1 + m_2 = 16 \), the total D3-charge of the compactification is integral as it should; in contrast taking e.g. \( k = 0 \) in (3.33) would violate integrality for certain values of \( m_i \).

In conclusion, we propose the following modified formula for the curvature induced D3 charge on a D7 of the kind we are considering:

\[
(\Gamma_{pure\,D7})_{D3} = \frac{\chi_o(S)}{24} \omega, \quad \chi_o(S) = \chi(\Sigma) - n_{pp}, \quad (3.40)
\]

where \( \Sigma \) is the parametrization manifold of the D7 splitting the curve of double points, and \( n_{pp} \) the number of pinch points, where the parametrization degenerates.

In section 4 we will give a direct derivation of this formula from D9-anti-D9 tachyon condensation.
3.4.5 Mathematical characterization of $\chi_o(S)$

The Euler characteristic of a smooth space is defined without any ambiguities. It is always the standard topological Euler characteristic, which satisfies specific additive and multiplicative properties. The topological Euler characteristic can be computed as the integral of the top Chern class. For a singular variety, there are many non-equivalent generalizations of the notion of Euler characteristic that can be viewed as the integral of a suitably generalized top Chern class. Interestingly, $\chi_o(S)$ does not equal any of these common Euler characteristics. However, it is a sensible Euler characteristic that can be described as a top Chern class integral $[96]$.

If $Z$ in an elliptic fibration over a base $B$ of arbitrary dimension, the corresponding Euler characteristic $\chi_o$ satisfies the relation

$$2\chi(Z) = \chi_o(S) + 4\chi(O),$$

where $S$ and $O$ are the two hypersurfaces defined using Sen’s weak coupling limit along the lines that we followed in F-theory to define the hypersurfaces wrapped respectively by the D7 brane and the O7 plane. It is interesting to note that the previous relation can be shown to hold without assuming the Calabi-Yau condition and without any restrictions on the dimensionality of $Z$ $[96]$.

The mathematical definition of $\chi_o(S)$ $[96]$ is closely related to the one of the stringy Euler characteristic, or more generally to motivic integration. This is discussed at length in $[96]$. In a sense, $\chi_o(S)$ is a non-trivial generalization of the stringy Euler characteristic to spaces admitting singularities in codimension one. The usual stringy Euler characteristic is defined only for so-called normal spaces which are always smooth in codimension 1 although they could admit singularities in higher co-dimensions.

3.5 Flux lattice

In general a single D7-brane wrapped on a divisor $S$ can carry internal $U(1)$ fluxes $F$. These take values in the shifted integral lattice $\frac{c_1(S)}{2} + H^2(S, \mathbb{Z})$. If the D7 is a $\mathbb{Z}_2$-invariant brane in the O3/O7 orientifold we are considering, then the only fluxes which survive the orientifold projection are those which satisfy $\sigma^* F = -F$. So in some sense we expect the allowed fluxes on $S$ to be given by $H^2(S, \mathbb{Z})$ (we can drop the half integral shift since $c_1(S)$ is always even in the case at hand). However, again, because $S$ is generically singular, it is not immediately clear how to define $H^2(S, \mathbb{Z})$, and naive attempts ignoring the singularity result in gross discrepancies with F-theory.

Again, the problem is solved by considering the $\Sigma$-parametrization of the D7-worldvolume. The key is to view the fluxes $F$ as living on the smooth surface $\Sigma$ instead of on the singular $S$. Note that the orientifold involution $\sigma$ on $S$ induces on $\Sigma$ the involution

$$\sigma : \xi \to -\xi, \quad t \to -t. \quad (3.41)$$

We define $H^2(\Sigma)$ to be the part of $H^2(\Sigma)$ odd under $\sigma^*$. We propose

$$\text{Lattice of } U(1) \text{ wordlvolume fluxes} = H^2(\Sigma, \mathbb{Z}). \quad (3.42)$$
As a nontrivial check, we will now show that the dimension of this lattice plus the lattice of bulk RR and NSNS fluxes precisely equals the dimension of the F-theory flux lattice in our example.

To compute \( b_2 \equiv \dim H^2(\Sigma) \), we use the Lefshetz fixed point index formula \([97]\), which states

\[
\sum_k \text{Tr}_{H^k(\Sigma)} (-1)^k \sigma^* = \chi(\Sigma^\sigma)
\]

where \( \Sigma^\sigma \) is the fixed point locus of the involution. Noting that the fixed points of \( \sigma \) are nothing but the pinch points \( pp \), we see that in the case at hand this becomes

\[
b_2 = \frac{1}{2} (\chi(\Sigma) - n_{pp}) = \frac{\chi_0(S)}{2} = 8 m^3 - 48 m^2 + 140 m.
\]

For a tadpole-saturating D7 we have \( m = 16 \), so in that case \( b_2 = 22720 \).

To compare to the dimension of the F-theory flux lattice, we should add this to the dimension of the lattice of RR and NSNS fluxes. From \([8.13]\), it follows that this equals (two times) \( b_2^*(X) = \dim H^3_-(X, \mathbb{Z}) \). We always have \( b_3^0(X) = b_3^3(X) = 1 \). Moreover, because none of the complex structure moduli of \( X \) are projected out by the orientifolding, we also have \( h_1^2(X) = h_2^1(X) \). So \( b_2(X) = b_3(X) = 300 \). This can also be verified by the Lefshetz fixed point index formula. Thus we find for the total flux lattice dimension

\[
b = b_2(\Sigma) + 2 b_3(X) = 23320.
\]

This is in precise agreement with the F-theory result \((2.17)\).

### 3.6 Moduli

A similar story applies to counting deformation moduli of the D7. In non-orientifolded CY 3-folds, there is a one to one correspondence between infinitesimal holomorphic deformations of the D7 and holomorphic \((2,0)\)-forms on the divisor \( S \) wrapped by the D7. The map is obtained by contracting the holomorphic section of the normal bundle to \( S \) corresponding to the deformation with the holomorphic \((3,0)\)-form \( \Omega \) on the Calabi-Yau \( X \). Equivalently, if \( S \) is described locally by equations \( f(x) = 0 \) (so in particular when \( f(x) \) extends to a global homogeneous polynomial \( P(x) \)), deformations are described by variations \( \delta f \) of \( f \), and we can locally write the associated \((2,0)\)-form \( \rho[\delta f] \) as a Poincaré residue, defined in section 5.6 of \([3]\):

\[
\rho[\delta f] = \frac{1}{2\pi i} \oint_{f=0} \frac{\delta f}{f} \Omega.
\]

Conversely, given a holomorphic \((2,0)\)-form \( \rho \) on \( S \), \( \rho \wedge df \) extends to a holomorphic \((3,0)\)-form in an infinitesimal neighborhood of \( S \), hence we can uniquely define \( \delta f[\rho] \) by writing \( \rho \wedge df = \Omega \delta f + O(f) \) (so \( \rho = \rho[\delta f] \)).

In an orientifolded CY 3-fold, infinitesimal deformations of the D7 respecting the \( \mathbb{Z}_2 \) symmetry \( \sigma \) are given by \( \sigma \)-symmetric holomorphic sections of the normal bundle to the
D7. Contracting this vector field with $\Omega_3$ produces a $(2,0)$-form on the D7 worldvolume which is $\sigma$-antisymmetric, since $\Omega_3$ itself is $\sigma$-antisymmetric. Thus one would naively expect a one to one correspondence between elements of $H^{2,0}(S)$ and deformations of the D7. However this is not quite correct, since, as discussed in section 3.1, not all $\sigma$-symmetric deformations of the D7 are actually allowed. Moreover, at the locus $C$ of double points, the normal bundle to $S$ is not even well-defined.

This leaves us with the question what the proper analog is which does correctly count the number of deformations. A natural guess is

$$\text{Number of D7 deformation moduli} = h_{-2,0}(\Sigma),$$

with $\Sigma$ defined in (3.31). We will justify this in general below, but let us first check that this indeed reproduces the correct counting in our example.

For our example, we can compute the number of allowed D7 deformations directly — for a degree $2m$ surface $S$ it is given by the number of inequivalent deformations of $(\eta_m, \chi_{2m-8})$ in (3.4). For $m > 4$, this is

$$N_{\text{D7 def}} = \left(\frac{m+3}{3}\right) + \left(\frac{2m-8+3}{3}\right) - \left(\frac{m-8+3}{3}\right) - 1 = \frac{4}{3}m^3 - 8m^2 + \frac{59}{3}m,$$

(3.48)

where the first subtraction comes from the equivalence $(\eta, \chi) \simeq (\eta + h\psi, \chi + 2\eta\psi + h\psi^2)$ with $\psi$ of degree $m-8$ and the second one from overall rescaling of the coefficients. When $m < 8$ the first equivalence is absent, but as long as $m > 4$ the subtracted binomial is zero in this case, so the counting is still correctly given by (3.48).

To compute $h_{2,0}(\Sigma)$, we can use the formula for the holomorphic Euler characteristic given in section 5.8 of [5]:

$$1 + h^{2,0}(\Sigma) = \chi_0(\Sigma) = \int_{\Sigma} \text{Td}(\Sigma) = \frac{1}{12} \int_{\Sigma} c_1^2 + c_2,$$

(3.49)

where we also used the Lefschetz hyperplane theorem to conclude $h^{1,0}(\Sigma) = 0$. For our example, plugging (3.34) in (3.49) then gives an explicit formula for $h^{2,0}$.

However, this is not yet what we need: We want $h_{-2,0}(\Sigma)$. This can be computed using the holomorphic Lefschetz fixed point formula. In full generality, this can be stated as follows. Let $V$ be a vector bundle on some manifold $M$ and let $g : V \rightarrow V$ be a holomorphic symmetry descending to a holomorphic symmetry $g : M \rightarrow M$. Then

$$\text{Tr}_{H^p\cdot(M,V)} (-)^p g = \int_{M^g} \text{ch}_{g}(V) \frac{\text{Td}(M^g)}{\text{ch}_{g}(\wedge_{-1} N_{M^g})}.$$  

Here $p$ is the form degree, $\text{ch}_{g}(V) := \text{Tr} g e^F$, $M^g$ is the fixed point locus of $g$, $\wedge_{-1} N := 1 - N \wedge N - N \wedge N \wedge N + \cdots$, and $N_{M^g}$ is the complex conjugate of the normal bundle to $M^g$. Specializing this to $g$ equal to a holomorphic involution $\sigma$ (think of an orientifold involution possibly acting also on the Chan-Paton indices of $V$), let us make this formula a little less obscure. First, in terms of the Chern roots $\lambda^{(V)}_m$ of $V$, we can write

$$\text{ch}_{\sigma}(V) = \sum_m \langle m \mid \sigma \mid m \rangle e^{\lambda^{(V)}_m},$$

(3.51)
where the $|m\rangle$ are the Chan-Paton eigenvectors corresponding to the $\lambda_m$. Moreover, since $\sigma$ acts as $-1$ on the normal bundle to $M^\sigma$, we have in terms of the Chern roots $\lambda_n^{(NM^\sigma)}$ of the normal bundle to $M^\sigma$:

$$
\text{ch}_\sigma(\wedge_{-1} N_{M^\sigma}) = \prod_n \left(1 + e^{-\lambda_n^{(NM^\sigma)}}\right).
$$

(3.52)

In the case at hand, $M = \Sigma$, $V$ is trivial, and the fixed point set $\Sigma^\sigma$ of $\sigma : (\xi,t) \rightarrow (-\xi, -t)$ is a set of isolated points, namely the pinch points $pp$, so $\text{Td}(\Sigma^\sigma) = 1$. Furthermore from (3.52) and the fact that the normal bundle has rank 2 and the Chern roots are zero (because $\dim \Sigma^\sigma = 0$) it follows that $\text{ch}_\sigma(\wedge_{-1} N_{\Sigma^\sigma}) = 2 \times 2 = 4$. Hence (3.50) becomes

$$
1 + h_+^{0.2}(\Sigma) - h_-^{0.2}(\Sigma) = \int_{\Sigma^\sigma} \frac{1}{4} = \frac{n_{pp}}{4}.
$$

(3.53)

Together with (3.49), this implies

$$
h_-^{0.2}(\Sigma) = \frac{1}{24} \int_{\Sigma} c_1^2 + c_2 - \frac{n_{pp}}{8}.
$$

(3.54)

This formula holds in general (if $h^{0.1} = 0$). For our example we have $n_{pp} = 8m(2m - 8)$ and (3.34). Thus we find

$$
h_-^{0.2}(\Sigma) = \frac{4}{3} m^3 - 8 m^2 + \frac{59}{3} m,
$$

(3.55)

in precise agreement with the direct counting (3.48).

We will now show more directly that $h_-^{0.2}$ indeed equals the number of D7 moduli. The D7 is given by the equation $P := \eta^2 - h\chi = 0$. Infinitesimal deformations are of the form $\delta P = 2\eta\delta \eta - h\delta \chi$, parametrized by $(\delta \eta, \delta \chi)$ modulo the equivalence $(\delta \eta, \delta \chi) \simeq (\delta \eta + h\delta \psi, \delta \chi + 2\eta\delta \psi)$.

Now consider the Poincaré residue

$$
\rho = \oint \oint \oint \frac{\omega \cdot V}{(\xi^2 - h)(\xi t - \eta)(\xi^2 - \chi)} \frac{\delta P}{\xi},
$$

(3.56)

where $\omega = du_1 \wedge du_2 \wedge du_3 \wedge du_4 \wedge d\xi \wedge t$, $V = u_i \partial u_i + 4\xi \partial \xi + (m - 4) t \partial t$ and the integration contours are infinitesimal loops around the zeros of the denominator dividing $\omega \cdot V$. Note that this results in a well defined meromorphic $(2,0)$ form on $\Sigma$, since the integrand is gauge invariant (invariant under the projective rescalings). In fact, despite the $1/\xi$ factor, $\rho$ actually has no poles and hence is holomorphic, not just meromorphic. To see this, note that inside the residue integral we can replace

$$
\frac{\delta P}{\xi} = \frac{h\delta \chi - 2\eta \delta \eta}{\xi} \rightarrow \frac{\xi^2 \delta \chi - 2\xi t \delta \eta}{\xi} = \xi \delta \chi - 2t \delta \eta,
$$

(3.57)

where the substitutions $h \rightarrow \xi^2$, $\eta \rightarrow \xi t$ are allowed because inside the residue integral anything with a factor appearing in the denominator dividing $\omega \cdot V$ integrates to zero as

\footnote{see section 5.6 of [1] for notation and the general framework leading to this expression}
the integrand then becomes analytic inside one of the contours. Finally, it is clear that \( \rho \) is antisymmetric under \( \sigma : (\xi, t) \to (-\xi, -t) \), because the integrand is antisymmetric.

Thus any infinitesimal deformation of the D7 maps to an element \( \rho \) of \( H^{2,0}(\Sigma) \) by this map. Conversely, every element \( \rho \) of \( H^{2,0}(\Sigma) \) can be written as a residue

\[
\rho = \oint \oint \oint \frac{\omega \cdot V}{(\xi^2 - h)(\xi t - \eta)(t^2 - \chi)} Q(u, \xi, t) \tag{3.58}
\]

where \( Q(u, \xi, t) \) is a degree 2\( m - 4 \) polynomial antisymmetric under \( \sigma \). Using the fact that we can substitute \( \xi^2 \to h(u) \), \( t^2 \to \chi(u) \) and \( \xi t \to \eta(u) \), the most general such \( Q \) is of the form \( Q(u, \xi, t) = \xi Q_1(u) + t Q_2(u) \). Comparing to (3.57), we see that \( \delta P/\xi \) parametrizes the most general \( Q \) of this kind, and therefore every \( \rho \in H^{2,0}(\Sigma) \) maps to a D7 deformation.

This completes the proof that there is a one to one map between \( H^{2,0}(\Sigma) \) and the infinitesimal deformations of the D7. Although we set up the proof in the context of our example, it is clear that the argument generalizes.

### 3.7 Open string flux vacua

Now we know how to correctly compute tadpoles, flux lattice dimensions and moduli space dimensions, we can move on to constructing open string flux vacua. These are configurations of D-branes carrying worldvolume magnetic gauge fluxes, with all D-brane moduli frozen, in a given closed string background. We will restrict here to the case without closed string background fluxes.

For our purposes, a supersymmetric open string flux vacuum, in the large volume limit, is hence given by a (possibly reducible, i.e. multi-component) holomorphic 4-cycle \( \Sigma \) as described above, together with a \( U(1) \) flux\(^{13} \) \( F \in H^2(\Sigma) \), such that \( F \) is anti-self dual:

\[
F = -\ast F,
\]

or equivalently:

\[
F^{0,2} = F^{2,0} = 0, \quad F \wedge J = 0, \tag{3.59}
\]

where \( J \) is the Kähler form on \( X \) pulled back to \( \Sigma \). The flux is integrally quantized up to a shift\(^{14} \) \( \Delta F = \frac{c_1(\Sigma)}{2} [\mathbb{P}^1, \mathbb{P}^3] \).

Since cohomology classes have unique harmonic representatives, and \( F \wedge J \) is harmonic if \( F \) is harmonic, it is sufficient to consider the equations (3.59) in cohomology. Note also that if \( \Sigma \) is irreducible, the second equation \( F \wedge J = 0 \) follows automatically from the fact that \( F \) is odd under \( \sigma \) while \( J \) is even. For a D7-image-D7 pair on the other hand, we can a priori turn on an arbitrary flux \( F \) on one D7 and the image flux \( -\sigma^* F \) on the image D7. In this case the condition \( F \wedge J = 0 \) must be enforced on the two components separately and becomes nontrivial (see section 4.4).

While the second equation can be thought of as a D-term constraint, which involves the background Kähler moduli, the first equation can be though of as an F-term constraint. Indeed it is the critical point equation \( \partial_\psi W(\psi, z) = 0 \) of the following superpotential

\[^{13}\text{Nonabelian fluxes are possible too, of course. For simplicity we restrict to abelian fluxes in most of this section.}\]

\[^{14}\text{There might be more subtle constraints on } F \text{ as well, along the lines of } [\mathbb{P}^3].\]
\[ W_F(\psi, z) = \int_{\Gamma_F(z)} \Omega(\psi) \] (3.60)

where \( \Omega \) is the holomorphic 3-form on \( X \) and \( \Gamma_F \) is the 3-chain swept out by a 2-cycle Poincaré dual to \( F \) on the D7-worldvolume \( \Sigma \) by varying \( \Sigma \) from some reference \( \Sigma_0 \) to \( \Sigma_z \).

The physical interpretation of this superpotential is that its norm represents the tension of a domain wall interpolating between different open string flux vacua — in the weak string coupling limit such a domain wall is a D5-brane wrapping \( \Gamma_F \). See [5] for a detailed account of the relation of this superpotential to the Gukov-Vafa-Witten superpotential of F-theory.

Although elegant, (3.60) is of little practical use for explicit construction of flux vacua. For our example, we would need to identify a basis of the 23320-dimensional flux lattice of \( \Sigma \), compute its intersection form, compute the 23320 corresponding 3-chain periods of \( \Omega \) as a function of the 3728 D7 moduli, and find critical points of the resulting superpotential for given flux quanta. Needless to say, this is not quite feasible.

There is however a much simpler, geometrical way to construct open string flux vacua, to which we now turn.

### 3.8 Flux vacua and holomorphic curves

The F-term constraint \( F^{0,2} = F^{2,0} = 0 \) is equivalent to \( F \) being Poincaré dual to a rational linear combination of holomorphic curves on \( S \). Thus, flux vacua can be constructed by picking a (possibly multi-component) curve \( \gamma \) in \( X \), taking \( S \) to contain \( \gamma \), and putting

\[ F := \text{PD}_\Sigma(\tilde{\gamma}) - \text{PD}_\Sigma(\tilde{\gamma}') \] (3.61)

where \( \Sigma \) is the parameter surface (3.31), \( \tilde{\gamma} \) is the lift of \( \gamma \) to \( \Sigma \), and \( \tilde{\gamma}' = \sigma \tilde{\gamma} \) its orientifold image. This form guarantees the orientifold projection \( F = -\sigma^* F \) is satisfied.

This construction (for D4-branes in non-orientifolded CY manifolds) was used extensively in [83, 82] for the purpose of enumeration of supersymmetric D-brane configurations. For the purpose of explicitly constructing D7 flux vacua in IIB orientifolds, one could proceed as follows.

For concreteness we consider our basic example with a D7 equation of full degree 32 (so \( m = 16 \)), and restrict to the case where \( \gamma \) is a rational curve of degree \( d \), that is, in the coordinates used in (3.31):

\[ (\xi, \bar{u}) = (\Xi(x, y), \bar{U}(x, y)) \), \quad [x : y] \in \mathbb{CP}^1 \] (3.62)

where \( (\Xi, U_i) \) are homogeneous polynomials of degree \( (4d, d) \) in \( (x, y) \). Requiring the curve \( \gamma \) to lie in \( S \) is equivalent to imposing that for all \( (x, y) \):

\[ \Xi^2(x, y) = h(\bar{U}(x, y)) \] (3.63)

\[ \eta^2(\bar{U}(x, y)) = \Xi^2(x, y) \chi(\bar{U}(x, y)) \] (3.64)

The first equation is the condition for the curve to lie in the Calabi-Yau \( X \). It is of degree \( 8d \) in \( (x, y) \), so it amounts to \( 8d + 1 \) independent equations on the coefficients of \( \Xi \) and the
There are \((4d+1) + 4(d+1) = 8d+5\) such coefficients, of which 4 can be set to zero by a \(GL_2\) reparametrization of the \(\mathbb{CP}^1\), resulting in \(8d+1\) independent curve deformations in the space parametrized by \((\xi, \vec{u})\). Hence for a given \(h\) we generically expect a discrete set of curves solving the first equation. The number of solutions is roughly speaking given by the genus zero Gopakumar-Vafa invariants. For our example this is 29,504 for \(d = 1\) and 128,834,912 for \(d = 2\) \([102]\).

The second equation, \((3.64)\), is of degree \(32d\), and since we know \(\Xi\) and \(\vec{U}\) already from the previous step, this can be thought of as a set of

\[
N_{\text{constr}}(\gamma) = 32d + 1
\]

(3.65)
equations for the coefficients of \(\chi\) and \(\eta\) determining the D7 embedding. Thus we see explicitly that turning on flux freezes some of the moduli. Note that since the number of independent deformations of the D7 is 3728, we need at least \(d \geq 117\) if we want to freeze all D7 deformation moduli in this way.

However, we must take into account D3 tadpole cancelation. Supersymmetric fluxes will induce positive D3-charge. The D3 charge induced by the flux \((3.61)\) equals \(Q_{\text{D3}}(\gamma) = -\int_{\Sigma} F_2^2 = -\bar{\gamma}^2 |_{\Sigma}\). Here we dropped a term \(+\bar{\gamma} \cdot \bar{\gamma}'|_{\Sigma}\) which we can typically expect to be zero, because for rational curves we generically only expect intersection points of \(\gamma\) and \(\gamma'\) at \(\xi = 0\), but these are split by the lifting to \(\bar{\gamma}\) and \(\bar{\gamma}'\), except in the nongeneric case in which they happen to coincide with pinch points. (If the intersection happens to be nonzero after all, it will only make \(Q_{\text{D3}}\) larger.) The self-intersection product can be computed using the adjunction formula: \(\bar{\gamma}^2|_{\Sigma} = -\chi(\bar{\gamma}) + \bar{\gamma} \cdot c_1(\Sigma) = -2 - 28d\), where we used \((3.34)\) and \(\chi(\mathbb{CP}^1) = 2\). We conclude

\[
Q_{\text{D3}}(\gamma) = 28d + 2.
\]

(3.66)

So, if we take \(d \geq 117\), as we saw necessary to freeze all moduli in this way, we get \(Q_{\text{D3}} > 3276\), which, interestingly, is quite a bit higher than the maximal value allowed by tadpole cancelation, 1944 (minus the curvature induced D3 charge). We conclude that we cannot supersymmetrically freeze all D7 deformation moduli by turning on fluxes of the form \((3.61)\) with \(\gamma\) a rational curve. This behavior generally persists when \(\gamma\) is taken to be a collection of curves of total euler characteristic positive or not too negative. For large negative Euler characteristics, the situation is not clear, also because there may now be curve moduli. These observations suggest the possible existence of a no-go theorem forbidding moduli stabilization at weak coupling by worldvolume fluxes alone. It would be interesting to investigate this further.

4. Weak coupling D9-anti-D9 picture

Through tachyon condensation, D7-branes can be obtained as bound states of (multiple) D9 branes carrying a certain vector bundle \(E\) with their orientifold image anti-D9 branes, offering an alternative description of D7-branes in orientifolds. We will see in this section that this allows us to derive all of the formulae inferred in the previous section from comparison with F-theory, as well as obtain further results on the systematics of D7-branes.
in orientifolds, including determining enhanced gauge symmetries and charged particle spectra, all using nothing more than simple polynomial manipulations.

4.1 D9-anti-D9 bound states: non-orientifold case

4.1.1 Tachyon quotient construction

Bound states of D-branes on Calabi-Yau manifolds have been discussed extensively in the context of non-orientifolded $\mathcal{N} = 2$ theories, beginning with the work [58] and fitting at the most general level in the categorical framework of [59], as reviewed in [60]. For the state of the art of this program, see [61].

In orientifolds, such bound states are less well understood, and the proper mathematical framework has not been developed in full generality. Let us therefore first briefly review some of what is known in the non-orientifold case, while trying to make the discussion as concrete and practical as possible. In the next subsection we will make the necessary generalizations to the orientifold case.

We will first give the general abstract construction and then turn to concrete examples.

When D9-branes and anti-D9-branes, each carrying gauge fields strengths (bundles) giving rise to lower dimensional charges, are placed on top of each other, the combined system will not be supersymmetric at large volume. Under favorable conditions however (where “favorable” is determined by D-term/stability constraints), tachyonic open string modes $T$ exist between the brane and the anti-brane systems, which can condense to form a new supersymmetric bound state [103] (reviewed in [104]). This leads to the string theoretic incarnation of K-theory (see e.g. [105]) as the proper classifications scheme for D-brane charges [106]. A sampling of papers on this topic is [92, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 119, 120, 121].

Classical supersymmetric bound states of a stack of D9-branes carrying a bundle $F$ of rank $r$ and a stack of anti-D9 branes carrying a bundle $E$ of rank $r' \leq r$ can be represented as follows (concrete examples will be given below).\footnote{We will use $F$ both to denote bundles and gauge field curvatures. We regret the confusion this may cause.} The tachyon can be thought of as a section of $F \otimes E^*$, or equivalently as a linear map

$$T : E \to F,$$

which locally can be represented by an $r \times r'$ matrix function on the CY manifold $X$. To get a supersymmetric configuration, $T$ must be holomorphic, which we will assume from now on.

If the tachyon is everywhere a one to one map between the vector space fibers of $E$ and $F$, then $E$ and $F$ are isomorphic — in other words the second brane is the exact anti-brane of the first — and tachyon condensation annihilates them completely, leaving the vacuum behind. If $T$ is not everywhere one to one, then annihilation will only be partial, resulting in a D-brane described by the quotient $G = F/TE$. What we mean by this quotient\footnote{which we can also write as the short exact sequence $0 \to E \overset{T}{\to} F \to G \to 0$.} is...
essentially the fiberwise equivalence

\[ f \simeq f + T \cdot e \]  

(4.2)

for vectors \( f \) and \( e \) in the fibers of \( F \) and \( E \) respectively. Indeed when \( T \) is everywhere one to one, this quotient leaves the zero element everywhere, i.e. the vacuum. When this is not the case, the quotient amounts, loosely speaking, to annihilating the “part” of \( E \) isomorphic to \( F \). When \( r' < r \), the quotient will generically leave a fiber of dimension \( r - r' \) behind, as expected when \( r' \) anti-D9-branes annihilate \( r' \) out of \( r \) D9-branes. When \( r = r' \), which is the case we will be interested in, \( T \) will generically be invertible everywhere except at points where \( \det T = 0 \), so the quotient will be trivial except at this complex codimension 1 locus.

A physical derivation of this prescription leading to K-theory, based on RG flow between boundary CFTs, can be found in [121].

Since the dimension of the fiber is not constant, the quotient is not a vector bundle. The proper mathematical description of this is a sheaf. Physically thinking of sections as wave functions of a hypothetical charged particle, a sheaf can essentially be thought of as a description of a system by the set of all possible wave functions with respect to all possible local observers. A bundle on the other hand describes a system by specifying the gauge transformations of wave functions between a number of local observers which together cover the space.

Thus, in the quotient (4.2), we can think of \( f \) as the possible wave functions of (particles living on) the D9 and \( e \) as the wave functions of the anti-D9, and the result are the wave functions of the bound state. The fact that the quotient is zero outside of

\[ S : \det T = 0 \]  

(4.3)

just means that the wave functions are localized on this complex codimension one locus, i.e. we get a D7-brane localized at \( S \).

The D7 will in general again carry a holomorphic vector bundle determined by (4.2). There is a slight subtlety, in that the actual bundle carried by the worldvolume gauge fields on the corresponding D7-brane is not exactly the bundle obtained by taking the quotient (4.2) restricted to \( S \), but rather this bundle tensored by the “line bundle” \( K_S^{-1/2} \), where \( K_S \) is the canonical line bundle if \( S \) (whose first Chern class is \(-c_1(S)\)). In practice this can be thought of as the gauge flux \( F \) being shifted by a diagonal \( U(1) \) flux \( \Delta F = +\frac{c_1(S)}{2} \). The need for this shift can easily be checked from charge conservation, as we will illustrate in an example below.

For generic \( T \), the fiber dimension of the resulting bundle will be one, so we have a line bundle. Physically, this corresponds to a single smooth D7 carrying a type (1,1) \( U(1) \) flux, equal to first chern class of the line bundle. A convenient and useful way to describe this flux \( F \) is by its Poincaré dual 2-cycle on the divisor \( S \) wrapped by the D7. This was used extensively in [78, 79], whose construction we put in a more general framework here. Because \( F \) is a (1, 1)-form, the 2-cycle will be a linear combination of holomorphic curves, i.e. a divisor on \( S \). Concretely the divisor is given by the zeros and poles of a section of the line bundle corresponding to \( F \).
To make this precise, assume for simplicity that $F$ restricted to $S$ has a holomorphic section $f(x)$ and let $[f(x)]$ be its equivalence class under \([4.2]\). By construction, $[f(x)]$ is a section of a line bundle on $S$. As such it is associated to a divisor $\gamma : [f(x)] = 0$, i.e.

$$\gamma = \{ x \in S | \exists e(x) : f(x) = T(x) \cdot e(x) \},$$

where $e(x)$ denotes a local section of $E$ restricted to $S$. We can rewrite the equation in \([4.4]\) in the following useful way. Let $\tilde{T}(x)$ be the matrix of cofactors ($(r - 1) \times (r - 1)$ minors) obtained from $T(x)$. Then $\tilde{T}^t \cdot T = (\det T) \cdot 1 = 0$ on $S$, so each $x \in \gamma$ satisfies the system of holomorphic equations $\tilde{T}^t(x) \cdot f(x) = 0$. Conversely, if $x \in S$ is such that $\tilde{T}^t(x) \cdot f(x) = 0$, then $f(x)$ is in the image of $T(x)$. This can be checked most easily by going to a basis where $T(x)$ is upper triangular with only the lowest diagonal element equal to zero (which we can do since by assumption $\det T$ has a simple zero on $S$). Thus

$$\gamma = \{ x \in S | \tilde{T}^t(x) \cdot f(x) = 0 \}.$$  \hspace{5cm} (4.5)

Taking the above mentioned flux shift into account, we thus find that the flux carried by the D7-brane is

$$F = \text{PD}_S(\gamma) + \frac{c_1(S)}{2} = \text{PD}_S(\gamma) - \frac{\iota^* [S]}{2},$$

Here $\text{PD}$ stands for Poincaré dual and $\iota^*[S]$ denotes the pullback of the 2-cohomology class $[S]$ to $S$. In the last step we used that in a CY, $c_1(TS) = -c_1(NS) = -\iota^*[S]$. This expression for $F$ can be checked for example by matching the charge of the bound state to the sum of the charges of the constituents, as we will illustrate below.

Finally, the moduli space of these supersymmetric bound states is parametrized by different choices of $T$ (sections of $F \otimes E^*$ invertible at generic points of $X$) modulo internal holomorphic complexified gauge transformations:

$$T \rightarrow g_F T g_E^{-1}. \hspace{5cm} (4.7)$$

Here $g_F : F \rightarrow F$ and $g_E : E \rightarrow E$ are (not necessarily constant) automorphisms.\(^{18}\)

The residual gauge symmetry is the set of gauge transformations \([4.7]\), with $g_F$ and $g_E$ automorphisms independent of the internal coordinates, that leave $T$ invariant. We usually express the residual gauge groups in their real rather than complexified forms (e.g. $U(N)$ instead of $GL(N)$). For generic $T$, the gauge group is completely broken to a diagonal $U(1)$, as expected for a single D-brane. For special choices of bundles and $T$, there can be a larger residual gauge group. There can also be subspaces of $X$ where locally the residual symmetry gets enhanced; if these loci intersect $S$, this typically signals the presence of massless matter arising e.g. at D-brane intersections.

\(^{17}\)Different choices of $f(x)$ will lead to homologous divisors.

\(^{18}\)An automorphism of the bundle $E$ is a change of basis respecting the bundle structure, i.e. an invertible linear map sending sections to sections. It is a holomorphic section of $E \otimes E^*$. 

– 30 –
4.1.2 Bound states of fluxed D9-anti-D9 branes and brane recombination

Let us now turn to some examples. The simplest possibility is to take $E$ and $F$ to be two line bundles. For example on the quintic Calabi-Yau, let us choose $E = O(-a)$, $F = O(b)$, where we take $a, b > 0$, so we have holomorphic sections for $E^* = O(a)$ and $F$. The holomorphic sections are just the homogeneous polynomials of degree $a$ resp. $b$. Then $T$ is a section of $F \otimes E^* = O(a + b)$, a polynomial of degree $a + b$, hence the class of the D7 divisor $S$ is $[S] = (a + b)H$ with $H$ the hyperplane class. Furthermore $\tilde{T} = 1$, so we can take $\gamma$ to be the zero locus of simply some degree $b$ polynomial $f(x)$, and from (4.6)

$$F = \iota^*_S (bH - \frac{[S]}{2}) = (b - \frac{a + b}{2}) \iota^*_S H = \frac{b - a}{2} \iota^*_S H. \quad (4.8)$$

Charge conservation requires that the total charge of the constituents as given by (3.10):

$$(\text{ch} F - \text{ch} E)(1 + c_2(X)/24) = (e^{bH} - e^{-aH})(1 + c_2(X)/24) \quad (4.9)$$

equals that of a D7 wrapping $S$ with flux $F$, as given by (3.11) and (3.12):

$$(a + b)H + \frac{(b + a)(b - a)}{2} H^2 + \frac{(a + b)^3 H^3 + (a + b)c_2(X) \cdot H + (a + b)(b - a)^2 H^3}{24} \quad (4.10)$$

This is indeed the case, as can be checked by a short computation. (For the quintic, $c_2(X) \cdot H = 50$, but this is not needed to show the equality.)

The moduli space of such supersymmetric bound states is the projectivization of the space of nonzero holomorphic sections of $O(a + b)$ on the quintic, i.e. the space of nonzero degree $a + b$ homogeneous polynomials modulo $\mathbb{C}^*$ rescalings and modulo the defining equation of the quintic. This is indeed the moduli space of the corresponding D7-brane wrapping $S$.

A less trivial and important class of examples is obtained by taking $E$ and $F$ to be the direct sum of line bundles

$$E = \bigoplus_{i=1}^r O(-U_i), \quad F = \bigoplus_{i=1}^r O(V_i), \quad (4.11)$$

where we take the $U_i$ and $V_i$ to be divisors such that there are holomorphic sections of $E^*$ and $F$ (for example this is guaranteed when they are very ample). In more basic terms, $F$ describes a superposition of $r$ D9 branes, each carrying a U(1) flux $F_i = c_1(O(V_i))$, which is the Poincaré dual to the divisor $V_i$. Similarly, $E$ describes a collection of anti-D9 branes.

Then $T$ is a $r \times r$ matrix with $T_{ij}$ a holomorphic section of $O(V_i + U_j)$. The D7 divisor class is

$$[S] = \sum_{i=1}^r V_i + U_i, \quad (4.12)$$

and the curve $\gamma$ is given by the system of equations

$$v_i(x) \tilde{T}_{ij}(x) = 0, \quad x \in S, \quad (4.13)$$

$v_i(x)$ being an arbitrary section of $O(V_i)$ and $\tilde{T}$ again the matrix of cofactors of $T$. This reproduces and clarifies the results of [79].
For a more explicit example (which will also be relevant further on), take \( r = 2, \) \( X \) the quintic, \( E = \mathcal{O}(-a) \oplus \mathcal{O}(-b), \) \( F = \mathcal{O}(a) \oplus \mathcal{O}(b), \) with \( a, b > 0. \) Then the most general tachyon is of the form \( T = \left( \begin{array}{cc} P & Q \\ R & W \end{array} \right) \) with \((P, Q, R, W)\) polynomials of degree \((2a, a + b, a + b, 2b)\). The divisor \( S \) wrapped by the D7 is given by the degree \( 2(a + b) \) equation \( P(x)W(x) - Q(x)R(x) = 0 \) \((x \in X)\), and \( T = \left( \begin{array}{cc} W & -R \\ -Q & P \end{array} \right). \) Taking for instance \( v(x) = (v_1(x), 0) \), where \( v_1 \) is of degree \( a \), we get for the curve \( \gamma : v_1(x)W(x) = 0, v_1(x)R(x) = 0 \) \((x \in S)\). This splits in two components, because we have chosen \( v_2 \equiv 0 \). The first is just the intersection of the divisor \( v_1(x) = 0 \) with \( S \). The second is the curve \( R(x) = W(x) = 0, \) which indeed always lies on \( S \), but not on an arbitrary divisor in the class \([S]\). This is a manifestation of the fact that the dual flux \( F \) puts a restriction on the divisor deformation moduli, as discussed at length in \([78, 79]\).

In the special case in which \( T = \left( \begin{array}{cc} P & 0 \\ 0 & W \end{array} \right) \), with \( P \neq W \), the residual gauge symmetry \((4.7)\) is enhanced to \( U(1) \times U(1) \). This case corresponds to two intersecting D7 branes wrapping \( S_1 : P(x) = 0 \) and \( S_2 : W(x) = 0 \). The curve construction prescription given above becomes somewhat degenerate in this non-generic case, so in order to determine the flux carried by these D7-branes it is best to go back to the original quotient prescription \((4.2)\). On the branch \( P(x) = 0 \), \( W(x) \neq 0 \), we see that the equivalence relation is fixed by putting \( f_2 \equiv 0 \). Hence on \( S_1 \) we get a line bundle \( \mathcal{O}(a)|_{S_1} \otimes K_{S_1}^{-1/2} = \mathcal{O}(a) \otimes \mathcal{O}(-a) = \mathcal{O}(0), \) which corresponds to zero flux, and similarly on \( S_2 \) we get zero flux. Thus, as in \([78, 79]\), we see that two branes without any flux can smoothly and physically continuously recombine into a single brane with flux. This happens through condensation of bifundamental matter with charge \((1, -1)\) and \((-1, 1)\) under the \(U(1) \times U(1)\) gauge group, which corresponds to the off-diagonal degree \( a + b \) polynomials \( Q \) and \( R \).

When \( a = b \) we can consider \( T = \left( \begin{array}{cc} P & 0 \\ 0 & P \end{array} \right). \) In this case we get two coincident D7-branes on \( P(x) = 0 \) and the residual gauge symmetry is enhanced to \( U(2). \) The bundle carried this system is easily seen from the quotient construction to be \((\mathcal{O}(a) \oplus \mathcal{O}(a)) \otimes K_{S'}^{-1/2} = (\mathcal{O}(a) \oplus \mathcal{O}(a)) \otimes \mathcal{O}(-a) = \mathcal{O}(0) \oplus \mathcal{O}(0), \) i.e. no flux.

### 4.1.3 Other D9-anti-D9 bound states, ideal sheaves and Donaldson-Thomas invariants

We could also start from more complicated D9-D7-D5-D3 bound states. In particular, even in the rank 1 case, for suitable values of the moduli, supersymmetric stringy bound states may exist of a single D9 with a “gas” of D5 and D3 branes. Unlike the higher rank case, these branes cannot dissolve as flux into the D9, so these bound states do not have a smooth bundle description. However they can still be described by sheaves, more precisely they are rank 1 ideal sheaves \([123, 127]\). These D9-branes and their charge conjugates in turn can be used to build large classes of D7-brane bound states through tachyon condensation. Since ideal sheaves are basically just collections of polynomials vanishing on the given loci, this can again be done very explicitly using only polynomial manipulations. Compared to the line bundle case, the tachyon matrix entries \( T_{ij} \) must satisfy the additional constraint that they have to vanish on the D5 and D3 brane loci inside the \( \mathbb{D}^9_i \) and the D9j stacks. This implies in particular that on solutions the D7 locus \( S : \det T = 0 \) must contain the D5.
and D3 branes. This reproduces the picture of flux vacua of section 3.8. It is conceivable that in fact all D7-brane vacua can be constructed in this way.

Ideal sheaves of a given charges are counted by (rank 1) Donaldson-Thomas invariants, which are related to Gromov-Witten invariants and hence to the topological string [123, 124, 125, 126]. Bound states of ideal sheaves and their charge conjugates played a key role in [83] in enumerating D4 BPS states and proving a version of the OSV conjecture, suggesting a similar role for enumeration of D7 flux vacua. We leave this for future work.

4.2 D7-branes as D9-D9′ bound states: the orientifold case

We will now generalize the results reviewed in the previous subsection to orientifolds. A proper mathematical framework for the description of D-branes in terms of D9-D9′ in orientifolds has been studied in [127, 128]. See also [135].

4.2.1 Tachyon quotient construction

From section 3.4.2, it follows that the orientifold image of a D9 carrying a bundle $F$ is the charge conjugate of a brane with bundle $F' = \sigma^* F^*$, where $F^*$ denotes the dual bundle, obtained by from $F$ by inverting the gauge field. We can thus consider bound states of such a D9 with its image anti-D9, resulting in a D7. This gives us an alternative way to compute various topological quantities such as RR charges.

Before tachyon condensation, the D9-D9′ system has a $G \times G$ gauge symmetry, where $G$ is the subgroup of $U(r)$ leaving the bundle $F$ invariant. The orientifold projection reduces this to $G$, since [3,21] relates the gauge field $A'$ on the D9′ to the gauge field $A$ on the D9 as $A' = -\sigma^* A$, and correspondingly the gauge transformations as $g' = \sigma^* g^{-1}$ (the superscript $t$ denotes the transpose). The tachyon $T$ therefore transforms as

$$T \rightarrow g \cdot T \cdot (g')^{-1} = g \cdot T \cdot \sigma^* g^t$$

under $G$. $T$ is now a holomorphic linear map from $F' = \sigma^* F^*$ to $F$, or in other words a section of $F \otimes F'^* = F \otimes \sigma^* F$. We impose orientifold projection condition

$$T = -\sigma^* T^t.$$  (4.15)

As will see, this choice of sign corresponds to the O7− projection we want, while a plus sign corresponds to the O7+ projection. Note that the projection is compatible with (4.14).

It is possible to deduce such orientifold projection conditions from first principle using a more elaborate mathematical formalism [135].

The resulting D7-brane will again be wrapped around the divisor $S : \det T = 0$, and carries a bundle given by the quotient $F/TF'$ shifted by $K^{-1/2}_S$.

For concreteness we specialize to the orientifold example described in section 3.1 and to the case in which $F$ is the direct sum of $r$ line bundles of degree $a_i \geq 0$,

$$F = O(a_1) \oplus \cdots \oplus O(a_r),$$  (4.16)

i.e. the superposition of $r$ D9 branes wrapping the Calabi-Yau 3-fold, each carrying a U(1) flux $F_i = a_i H$, $i = 1, \ldots, r$, where $H$ is as before the hyperplane class $[u_1 = 0]$. Its
orientifold image is the anti-brane of the D9 system with inverted fluxes $F'_i = -a_i H$ (the action of $\sigma^*$ is trivial in the example, as $H^2(X) = 0$). By charge conservation, the total charge of the D9-D9' bound state (assuming it exists) is the sum of the charges of the constituents, which is, using (3.10):\[ \Gamma_{\text{D9-D9'}} = 2 \sum_i a_i H \oplus \left( \frac{1}{3} \sum_i a_i^3 + \frac{11}{6} \sum_i a_i \right) H^3. \] (4.17)

The tachyon $T$ is an $r \times r$ matrix with $T_{ij}$ a section of $\mathcal{O}(a_i) \otimes \mathcal{O}(a_j) = \mathcal{O}(a_i + a_j)$, i.e. a homogeneous polynomial in $(u_1, u_2, u_3, u_4, \xi)$ of degree $a_i + a_j$. The orientifold projection (4.15) constrains $T$ to be of the form\[ T(u, \xi) = A(u) + \xi S(u), \] (4.18)
where $A_{ij}$ and $S_{ij}$ are sections of $\mathcal{O}(a_i + a_j)$ resp. $\mathcal{O}(a_i + a_j - 4)$ satisfying\[ A^t = -A, \quad S^t = S. \] (4.19)

Terms of higher order in $\xi$ can be eliminated using the CY equation $\xi^2 = h(u)$. A modified projection condition (4.15) with the plus sign instead would give $T = S + \xi A$. Both give a D7 equation $\det T = 0$ invariant under $\sigma : \xi \rightarrow -\xi$.

A crucial subtlety is that to avoid an uncanceled $\mathbb{Z}_2$ tadpole, we must restrict to even $r$. One (slick\textsuperscript{19}) way to see this is through a probe argument\textsuperscript{[119]}: The worldvolume theory of a D3-probe placed on the $O7^-$ in the presence of $r$ D9-branes is an $SU(2) \mathcal{N} = 1$ gauge theory coupled to $r$ chiral multiplets in the fundamental of $SU(2)$ coming from open string stretching from the D3 (and its image) to the D9;\textsuperscript{20} thus, if $r$ is odd, we have an odd number of Weyl fermions in the fundamental of $SU(2)$, and this results in a $\mathbb{Z}_2$ anomaly\textsuperscript{[129]}. Thus we conclude $r$ must be even. As will become clear below, odd $r$ would moreover give results in contradiction with what we obtained in the previous sections.

### 4.2.2 Bound states of fluxed D9-D9' branes and brane recombination

Since $r$ must be even, the simplest possibilities are bundles of the form $F = \mathcal{O}(a) \oplus \mathcal{O}(b)$. These give rise to a D7 of charge $2(a + b)H$. The tachyon is of the form\[ T = \begin{pmatrix} 0 & \eta(u) \\ -\eta(u) & 0 \end{pmatrix} + \xi \begin{pmatrix} \rho(u) & \psi(u) \\ \psi(u) & \tau(u) \end{pmatrix}, \] (4.20)
with $(\eta, \rho, \tau, \psi)$ are homogeneous polynomials of degree $(a + b, 2(a - 2), 2(b - 2), a + b - 4)$. The D7 is localized at $S : \det T = 0$, i.e.\[ S : \eta^2 = \xi^2 (\psi^2 - \rho \tau). \] (4.21)

\textsuperscript{19}As stated before, probe arguments are not entirely satisfactory since it might be the probe that is inconsistent. They can in certain cases be shown to be equivalent to more direct K-theory arguments\textsuperscript{[118]}. It should be possible to provide such more direct arguments for our setup as well, perhaps using the framework of\textsuperscript{[134]}.

\textsuperscript{20}Strings stretching to the D9' are identified with string stretching to the D9 and should therefore not be counted separately.
Satisfyingly, this is precisely of the general allowed form \( (3.3) \). Note that if we had chosen the other sign in \( (4.15) \) or if we had started from an \( r = 1 \) pair, this would not have been the case.\(^{21}\)

If \( a < 2 \), \( \rho \) must be zero, and the D7 splits in two components \( \eta = \pm \xi \psi \). We will see in section 4.4 that such configurations cannot be supersymmetric at large CY volume because they violate the D-term constraints.\(^{22}\) Therefore we take \( a \geq 2 \) and similarly \( b \geq 2 \).

The largest number of tachyon degrees of freedom is obtained for the minimal case \( a = 2 \). In this case \( (4.21) \) gives the most general equation of the form \( (3.3) \). Moreover, the D3-charge for this case is, using \( (4.17) \) and putting \( m := a + b = 2 + b \): \( \Gamma|_{D3} = \left(\frac{2}{3}m^3 - 4m^2 + \frac{35}{3}m\right)\omega \). Happily, this is in exact agreement with our earlier proposed modified charge formula \( (3.28) \) using \( (3.39) \) for \( \chi_o \), assuming there is no flux on the D7. In the following we will see that for \( a = 2 \) the latter is indeed true.

Let us compute the flux carried by the D7 for general \( a, b \). For generic polynomials, \( (4.21) \) describes a single D7, smooth everywhere except on the curve \( C : \eta = \xi = 0 \), where we have double point singularities. To deduce the line bundle carried by this D7, it is convenient to use the \( \Sigma \) parametrization of section 3.4.4 again. In this parametrization we can write the tachyon \( T \) and its matrix \( \tilde{T} \) of cofactors as:

\[
T = \xi \begin{pmatrix} \rho & \psi + t \\ \psi - t & \tau \end{pmatrix}, \quad \tilde{T} = \xi \begin{pmatrix} \tau & -\psi + t \\ -\psi - t & \rho \end{pmatrix},
\]

and \( \Sigma \) is given by

\[
\Sigma : t^2 = \psi^2 - \rho \tau.
\]

Now we consider the quotient \( (F/TF')|_{\Sigma} \) defined by \( (1.2) \) on \( \Sigma \). More precisely we first remove the locus \( \xi = \eta = 0 \), compute the quotient bundle and then extend it to the closure \( \Sigma \); this amounts to throwing out the degenerate \( \xi = 0 \) branch. According to the general prescription, the line bundle carried by the D7 is

\[
\mathcal{L} = (F/TF')|_{\Sigma} \otimes K^{-1/2}_{\Sigma},
\]

which corresponds to a \( U(1) \) flux \( F = c_1(\mathcal{L}) \)

\[
F = PD\Sigma(\gamma) + \frac{1}{2}c_1(\Sigma)
\]

where \( \gamma \) is a curve \( (P_a, P_b) \cdot \tilde{T} = 0 \) on \( \Sigma \) with \( P_a, P_b \) arbitrary polynomials of degree \( a, b \). Taking \( P_a \equiv 0 \), we get \( \gamma = \gamma_1 \cup \gamma_2 \) with

\[
\gamma_1 : P_b(u) = 0, \quad \gamma_2 : \rho(u) = 0, \quad t + \psi(u) = 0,
\]

\(^{21}\)In particular taking the opposite sign in \( (4.15) \) would result in a D7 equation of the form \( S : \xi^2 \eta^2 = (\psi^2 - \rho \tau) \), which generically does not have double D7-O7 intersections. This is compatible with the claim that this choice of sign corresponds to the O7\(^+\) projection, which as discussed in section 3.2 is not expected to have the double intersection property.

\(^{22}\)Except when \( a = b = 1 \), in which case only \( \eta \) is nonzero and of degree 2.
which are two smooth curves on \( \Sigma \). Furthermore from (3.34) we get \( c_1(\Sigma) = (4-2(a+b))H_\Sigma \), with \( H_\Sigma \) a shorthand for \( t_\Sigma \hat{H} \), the pullback of the hyperplane class \( \hat{H} = [u_1 = 0] \) to \( \Sigma \). Therefore, using \( \text{PD}_\Sigma(\gamma_1) = bH_\Sigma \):

\[
F = \text{PD}_\Sigma(\gamma_2) - (a-2)H_\Sigma. \tag{4.27}
\]

This does not look like it respects the orientifold projection \( \sigma^*F = -F \). But it actually does, as we will now show. Let \( \gamma'_2 = \sigma(\gamma_2) \) be the orientifold image of \( \gamma_2 \), obtained by inverting \( t \to -t \) in (4.26). Now note that \( \gamma_2 \cup \gamma'_2 \) equals the complete intersection of \( \Sigma \) with the degree 2\((a-2)\) divisor \( \rho = 0 \). Hence

\[
\text{PD}_\Sigma(\gamma_2) + \text{PD}_\Sigma(\gamma'_2) = 2(a-2)H_\Sigma, \tag{4.28}
\]

and, substituting this in (4.27),

\[
F = \frac{1}{2}(\text{PD}_\Sigma(\gamma_2) - \text{PD}_\Sigma(\gamma'_2)). \tag{4.29}
\]

This is manifestly antisymmetric under exchange of \( \gamma_2 \) and \( \gamma'_2 \), so we see that, after all, \( \sigma^*F = -F \).

We also see that in the minimal case \( a = 2 \), we have \( \gamma_2 = 0 \) since \( \rho \) is a constant in that case, and therefore \( F = 0 \), confirming our claim made above that the corresponding D7 has no flux.

We can also study brane recombination in this framework. If we take a nongeneric \( T \) with \( \rho = \tau = 0 \), the D7 splits into a D7-image-D7 pair \( \Sigma_{\pm} : t \pm \psi = 0 \). In fact since now the individual branes are smooth, it is no longer necessary to introduce the \( \Sigma \) parametrization, and we can just consider the surfaces \( S_{\pm} : \eta \pm \xi \psi = 0 \) in \( X \). To compute the line bundles \( (F/T'F')|_{S_{\pm}} \), we go back to the basic definition of the quotient itself. On say \( S_+ \) the tachyon becomes

\[
T|_{S_+} = \begin{pmatrix} 0 & 0 \\ 2\xi \psi & 0 \end{pmatrix}. \tag{4.30}
\]

Hence the equivalence relation is simply

\[
(f_1, f_2) \simeq (f_1, f_2 + 2\xi \psi f'_1), \tag{4.31}
\]

so for generic \( \psi \) we get a line bundle whose sections have unique representatives \( (f_1, 0) \), i.e. it is identified with \( O(a)|_{S_+} \) inside \( (O(a) \oplus O(b))|_{S_+} \). Furthermore \( c_1(S_+) = -(a+b)H_{S_+} \), so the flux on \( S_+ \) is

\[
F_{S_+} = aH_{S_+} - \frac{a+b}{2}H_{S_+} = \frac{a-b}{2}H_{S_+}. \tag{4.32}
\]

Similarly

\[
F_{S_-} = \frac{b-a}{2}H_{S_-}. \tag{4.33}
\]

So we get a D7 brane-image-brane pair with opposite fluxes turned on, as expected. When the two branes coincide (i.e. \( \psi \equiv 0 \)), one similarly computes that the rank two bundle on brane at \( \eta = 0 \) is \( O(\frac{a-b}{2}) \oplus O(\frac{b-a}{2}) \).
The charges of the two smooth D7-branes on $S_\pm$ are readily computed using (3.11) and (3.12):

$$\Gamma_{D7^\pm} = mH \oplus \pm \frac{a-b}{2}mH^2 \oplus \left( \frac{(m^2 + 22)m}{24} + \frac{1}{2} \left( \frac{a-b}{2} \right)^2 \right)mH^3,$$

(4.34)

with $m = a + b$. As a check, summing these up agrees with the charges obtained from (4.17).

Note that when $a = b$, there is no flux on the separate branes. Yet on the recombined branes, the flux (4.29) is nonzero. Thus we see again that fluxes can (and must, to respect charge conservation) be turned on by physically smooth recombination processes.

4.2.3 Moduli

The moduli space of these supersymmetric bound states is parametrized by different choices of $T$ modulo internal holomorphic complexified gauge transformations:

$$T \rightarrow g \cdot T \cdot \sigma^* g^t,$$

(4.35)

where $g : F \rightarrow F$ is an automorphism of $F$.

Specializing again to the case $F = \mathcal{O}(a) \oplus \mathcal{O}(b)$, we get that $g$ is a $2 \times 2$ matrix of polynomials of degrees

$$\begin{pmatrix} 0 & a-b \\ a-b & 0 \end{pmatrix}.$$

(4.36)

Note that if $b > a$, then $g_{12} = 0$. Let the number of degree $k$ homogeneous polynomials on $\mathbb{CP}^3$ be $N_k$, i.e. $N_k = \binom{k+3}{3}$ (and $N_k \equiv 0$ if $k < 0$). The number of degrees of freedom of $T$ is $N_{a+b} + N_{2(a-2)} + N_{2(b-2)} + N_{a+b-4}$, the number of degrees of freedom of $g$ is $2N_0 + N_{a-b} + N_{a-b-4} + N_{b-a} + N_{b-a-4}$, and we expect the dimension of the moduli space to be the difference of these. (Here $N_{a-b-4}$ and $N_{b-a-4}$ are the numbers of polynomials of degree $a-b$ and $b-a$ with one factor of $\xi$.) To compare to the results of section 3.6, we consider the fluxless D7 case $a = 2, b = m - 2$:

$$\#\text{moduli} = N_m + N_0 + N_{2(m-4)} + N_{m-4} - 2N_0 - N_{m-4} - N_{m-8}$$

(4.37)

$$= N_m + N_{2m-8} - N_{m-8} - N_0,$$

(4.38)

which reproduces (3.48).

4.2.4 Enhanced gauge symmetries

After tachyon condensation, the residual gauge group in the four dimensional low energy effective field theory is given by the gauge transformations (1.14) for automorphisms $g : F \rightarrow F$ independent of the internal coordinates (so $\sigma^* g = g$) which leave $T$ invariant, i.e.

$$G = \{ g \mid g T g^t = T \}.$$

(4.39)

At generic values of $T$, this leaves only a discrete $O(1) = \mathbb{Z}_2$. In particular, unlike the non-orientifolded case, there will generically be no residual $U(1)$s. From the geometric D7
point of view this is also clear: the generic D7 will be a single component brane invariant under the orientifold involution, so the photon polarized in the noncompact spacetime gets projected out.

At particular values of $T$, the gauge group may be enhanced. Supersymmetric deformations away from these special loci correspond to massless matter in the low energy effective field theory. Some examples in the $r = 2$, $F = O(a) + O(b)$ case, with $T$ as in (4.20) are:

<table>

</tbody>
</table>

These are consistent with expectations from the D7 worldvolume theory in the O7$^-$ projection; in particular we expect orthogonal groups for flux-free branes coincident with the O7$^-$, symplectic groups for flux-free, transversal, non-Higgsed brane stacks, and subgroups of those for branes obtained by turning on additional fluxes or by various Higgsings (i.e. deformations); in particular brane-image-brane stacks will carry unitary groups.

Let us go through the above (non-exhaustive) list and check compatibility with the rules summarized in footnote [3]:

- The first case is the most generic D7. It has a single component and maps to itself under the orientifold involution, so the photon is projected out in the four dimensional effective field theory and only a $O(1) = \mathbb{Z}_2$ gauge symmetry remains.

- The second case describes a brane-image-brane pair, each carrying some flux. The orientifold action maps one component to the other, so we get a single $U(1)$.

- The third and fourth case are similar. The fourth configuration corresponds to a stack of two flux free, coincident, transversal, involution invariant branes ($\eta^2 = 0$), hence the $SU(2) = USp(2)$ group. The third case corresponds to the same rank two stack, however, with a non-trivial flux that breaks the $SU(2)$ down to $U(1)$.

- The fifth case describes a stack of two flux-free branes coincident with the O-plane. Hence the $O(2)$ gauge group.

- The sixth case describes a brane-image-brane pair, so the $SO(2)$ can be thought of as a $U(1)$ group, just as in the second case.
Note that the first case can be thought of as a Higgsing of the second case, whereby a brane-image-brane pair have recombined (i.e. whereby $\rho$ and $\tau$ acquire vev’s), and the $U(1)$ group is broken to $\mathbb{Z}_2$. It can also be thought of as a Higgsing of any of the other cases with matching values of $(a, b)$. Fluxes can be induced by the recombination process, as required by charge conservation, and ensuring geometric and gauge theory degrees of freedom match each other.

If we had chosen the other sign in the orientifold projection condition (3.2), we would have found flipped roles for orthogonal and symplectic gauge groups, consistent with the $O7^+$ projection; for example two D7-branes coincident with the O7 would have been described by a tachyon $T = \begin{pmatrix} 0 & \xi \\ -\xi & 0 \end{pmatrix}$, with residual gauge group $SU(2) = USp(2)$.

We can also consider higher (even) rank $r$. For example we could consider the bundle $F = O(2) \oplus O(2) \oplus \cdots \oplus O(2)$ (4.40) with $r$ terms in the sum. This gives a tachyon of the form

$$ T = A(u) + \xi S, $$

with $A$ a $r \times r$ antisymmetric matrix with polynomial entries of degree 4, and $S$ a constant symmetric matrix, which generically after a suitable complexified gauge transformation we can take to be the unit matrix. When $A \equiv 0$, this describes $r$ coincident D7 branes on the O7 locus $\xi = 0$, with zero flux, and $O(r)$ enhanced gauge symmetry ($U(r)$ transformations $g$ satisfying $gg^t = 1$). When $A \neq 0$, the D7 is described by

$$ S : \det(A(u) + \xi 1) = 0 $$

so for each $u$, the solution set for $\xi(u)$ is the set of eigenvalues of $A(u)$, which is invariant under $\xi \rightarrow -\xi$. Again there will be a particular flux on the worldvolume of this D7, computed according to the general quotient prescription, which restricts its moduli and balances the charges.

Note in particular that a configuration with $r = 8$ will saturate the D7 tadpole, leading to an $O(8)$ enhanced gauge symmetry at $A = 0$, and a D3 charge $\frac{304}{3}\omega$, so the total D7+O7 charge is, using (3.2), $\Gamma_{D7} + \Gamma_{O7} = 152\omega$. This can also be seen to agree with F-theory: in the $O(8)$ limit under consideration the fibration of the fourfold degenerates to a $D_4$ singularity over $\xi = 0$, so the Euler characteristic of the fourfold is $\chi([\xi = 0]) \cdot \chi(D_4) = 304 \cdot 6 = 1824$ and the D3-charge (in CY$_3$ units) equals $152\omega$.

The number of moduli in this $O(8)$ sector equals the number of tachyon degrees of freedom minus the number of holomorphic complexified gauge transformations, i.e.

$$ \# \text{ moduli} = 28 \times 35 + 36 \times 1 - 64 = 952. \tag{4.43} $$

Notice that this is quite a bit less than the number of moduli in the generic D7 sector, 3728.

Similarly, we can describe $n$ coincident copies of a single generic D7-brane described by a $2 \times 2$ tachyon matrix $T_0$ by the $2n \times 2n$ tachyon matrix

$$ T = T_0 \oplus \cdots \oplus T_0. \tag{4.44} $$

This will have gauge group $O(n)$. 

– 39 –
4.2.5 Charged matter fields

The massless matter representations at enhanced symmetry points can be read off easily as well. For example at the $SU(2)$ locus, $\eta$ corresponds to matter in the antisymmetric (1) representation, and $\rho, \tau, \psi$ to matter in the symmetric (3) representation. At the $U(1)$ locus $T = \left( \begin{array}{cc} 0 & \xi \psi + \eta \\ \xi \psi - \eta & 0 \end{array} \right)$, $\eta$ and $\psi$ are neutral, while $\rho$ has charge $+2$ and $\tau$ charge $-2$. At the $O(8)$ locus, $A$ is matter in the antisymmetric (28) and $S$ in the symmetric (36) representation.

The physical number of degrees of freedom of a given charge equals the number of linearized degrees of freedom of $T$ of that charge minus the number of those that can be absorbed in a linearized holomorphic complexified gauge transformation. Taking the example of the $U(1)$ locus $T_0 = \left( \begin{array}{cc} 0 & \xi \psi + \eta \\ \xi \psi - \eta & 0 \end{array} \right)$, the linearized degrees of freedom of $T$ are $\delta\rho, \delta\tau, \delta\psi$ and $\delta\eta$. The linearized gauge holomorphic complexified internal gauge transformations of $T_0$ for $b > a$ correspond to fluctuations

$$
\delta\rho = 0, \quad \delta\tau = \alpha\psi + \beta\eta, \quad \delta\eta = \gamma\eta, \quad \delta\psi = \gamma\psi, \quad \text{(4.45)}
$$

where $(\alpha, \beta, \gamma)$ are infinitesimal polynomials of degree $(b-a, b-a-4, 0)$. Thus the number of physical degrees of freedom in each charge sector is

$$
N_{2(a-2)} - N_{2(b-2)} - N_{b-a} - N_{b-a-4} - N_{a+b-4} + N_{a+b} - N_0
$$

where as before $N_k := \left( \begin{array}{c} k+3 \\ 3 \end{array} \right)$. Notice that this is $N_0 = 1$ more than the number of moduli computed in 4.2.4. The extra massless field gets eaten up by the Brout-Englert-Higgs mechanism when moving off the $U(1)$ locus.

From the D7 point of view, the charged massless fields arise from open strings stretching between the flux-carrying D7 and its orientifold image, given in the table in section 4.2.4.

The net chirality of the spectrum is

$$
\#(+2) - \#(-2) = N_{2(a-2)} - N_{2(b-2)} - N_{b-a} + N_{b-a-4}. \quad \text{(4.46)}
$$

This vanishes when $a = b$, i.e. when there is no flux on the D7 and its image. The index can be computed more directly from an index theorem as well, to which we now turn.

4.3 Open string indices

Index theorems give a powerful way to compute the number of massless degrees of freedom in various settings in string theory, or at least to compute such numbers counted with alternating signs according to some grading (referred to as “net” number). A thorough discussion of open string indices in the absence and presence of orientifold projections can be found e.g. in [21], part of whose results (adapted to our setup) we review here. As in the rest of the paper, we will assume here that the $B$-field vanishes.

4.3.1 General formulae

In the non-orientifolded case, the Witten index counting the net number of open string modes stretching between two D-branes, say between an anti-D9 carrying a bundle $E_1$ and
a D9 carrying a bundle $E_2$, is

$$I(1, 2) = \sum_n (-)^n h^{0,n}(E_1 \otimes E_2^*) . \quad (4.47)$$

By the Hirzebruch-Riemann-Roch formula ([3] section 5.8), this equals

$$I(1, 2) = \int_X \text{ch}(E_1 \otimes E_2^*) \text{Td}(X) = \int_X \text{ch}(E_1) \text{ch}(E_2)^* \text{Td}(X) \quad (4.48)$$

$$= \int_X \left( \text{ch}(E_1) \sqrt{\text{Td}(X)} \right) \left( \text{ch}(E_2) \sqrt{\text{Td}(X)} \right)^* \quad (4.49)$$

$$= \int_X \Gamma_1 \wedge \Gamma_2^* . \quad (4.50)$$

Here $\Gamma^*$ is defined as the form obtained by flipping the sign of the 2- and 6-form components of $\Gamma$, i.e. $\Gamma^* := \sum_k (-1)^k \Gamma^{(2k)}$ where $\Gamma^{(2k)}$ is the $(2k)$-form component of $\Gamma$. This generalizes to arbitrary pairs of branes of charge $\Gamma_1$ and $\Gamma_2$:

$$I(1, 2) = \int_X \Gamma_1 \wedge \Gamma_2^* =: \langle \Gamma_1, \Gamma_2 \rangle . \quad (4.51)$$

The symplectic product thus defined is called intersection product of the charges $\Gamma_1$ and $\Gamma_2$ of the two branes. In the mirror IIA picture it is the geometric intersection product, counting the number of 3-cycle intersection points with signs.

Let us now compute the analogous index of open strings between a D9 stack with bundle $F$ and its orientifold image (more accurately from the latter to the former), i.e. the strings giving rise to our tachyon field $T$. This is

$$I_o(F) := \sum_n \text{Tr}_{H^{0,n}(X,F \otimes \sigma^* F)} (-)^n \frac{1}{2}(1 - \sigma) . \quad (4.52)$$

Here $\sigma$ denotes the full orientifold $\mathbb{Z}_2$ action including worldsheet orientation reversal. The insertion of $\frac{1}{2}(1 - \sigma)$ is equivalent to imposing the $O7^-$ tachyon projection (4.15), since

$$\sigma(T) = \sigma^* T^t . \quad (4.53)$$

The charge of the D9, $\Gamma_{D9}$, and that of its image, $\Gamma_{D9'}$, are

$$\Gamma_{D9} = \text{ch}(F) \sqrt{\text{Td}(X)} , \quad \Gamma_{D9'} = -\Gamma_{D9}^* = -\text{ch}(F^*) \sqrt{\text{Td}(X)} . \quad (4.54)$$

The charge of a O7 plane wrapping $X^\sigma$ is

$$\Gamma_{O7} = -8 \sqrt{\frac{L(T_{X^\sigma})}{L(N_{X^\sigma})}} [X^\sigma] . \quad (4.55)$$

Using (4.54), we rewrite the index $I_o(F)$ as

$$I_o(F) = \frac{1}{2} (\langle \Gamma_{D9'}, \Gamma_{D9} \rangle - \sum_n \text{Tr}_{H^{0,n}(X,F \otimes \sigma^* F)} (-)^n \sigma) . \quad (4.56)$$
Following section 3.3 of [21], the second term can be written as
\[
\text{Tr}_{H^0,\star(X,F \otimes \sigma^*F)} (-)^p \sigma = 2^{\dim_{\mathbb{R}} X^\sigma - \frac{1}{2} \dim_{\mathbb{R}} X} \int_{X^\sigma} \text{ch}(F^*) \sqrt{\text{Td}(X)} \sqrt{\frac{L(\frac{1}{2} T X^\sigma)}{L(\frac{1}{2} N X^\sigma)}}.
\] (4.57)

For an O7-plane wrapping a complex surface of a Calabi-Yau three-fold, we have \(\dim_{\mathbb{R}} X^\sigma = 4\) and \(\dim_{\mathbb{R}} X = 6\). It follows that
\[
\text{Tr}_{H^0,\star(X,F \otimes \sigma^*F)} (-)^p \sigma = 2 \int_{X^\sigma} \text{ch}(F^*) \sqrt{\text{Td}(X)} \sqrt{\frac{L(\frac{1}{2} T X^\sigma)}{L(\frac{1}{2} N X^\sigma)}} \left(-8 \sqrt{\frac{L(\frac{1}{4} T X^\sigma)}{L(\frac{1}{4} N X^\sigma)}} [X^\sigma]\right)
\] (4.58)
\[
= -\frac{1}{4} \int_X \left(\text{ch}(F) \sqrt{\text{Td}(X)}\right)^* \left(-8 \sqrt{\frac{L(\frac{1}{4} T X^\sigma)}{L(\frac{1}{4} N X^\sigma)}} [X^\sigma]\right)
\]
\[
= -\frac{1}{4} \int X \Gamma_{D9}^* \wedge \Gamma_{O7}
\]
\[
= -\frac{1}{4} \langle \Gamma_{O7}, \Gamma_{D9} \rangle.
\] (4.59)

We finally get the simple result
\[
I_o(F) = \frac{1}{2} \left(\langle \Gamma_{D9}', \Gamma_{D9} \rangle + \frac{1}{4} \langle \Gamma_{O7}, \Gamma_{D9} \rangle\right).
\] (4.60)

This immediately generalizes to arbitrary \((\Gamma, \Gamma')\) brane-image-brane systems and to the case where \(X^\sigma\) has several different components corresponding to Op-planes:
\[
I_o(\Gamma) = \frac{1}{2} \left(\langle \Gamma', \Gamma \rangle + \frac{1}{4} \langle \Gamma_{O}, \Gamma \rangle\right), \quad \Gamma_{O} = \sum \Gamma_{Op},
\] (4.61)

where \(\Gamma_{O}\) denotes the sum of all Op-planes\(^{23}\). Along the same lines, more refined indices can be derived counting the net number of bifundamental, symmetric and antisymmetric matter representations with respect to the various brane gauge groups [62] (see [3] or [56] section 5.1.3. for a summary). The indices derived here trace over these representations.

**4.3.2 Application to the example**

It is instructive to make contact with the direct polynomial counting we did in the previous subsections.

For our example, taking \(\Gamma\) to be a D9 stack with \(F = \mathcal{O}(a) \oplus \mathcal{O}(b)\), we have \(\Gamma_{D9} = (e^{aH} + e^{bH})(1 + \frac{c_2}{24})\), and \(c_2 = 22 H^2, H^3 = 2\) and the O7-charge is given by (3.24), so (4.61) gives
\[
I_o(D9) = \frac{5a^2}{3} + \frac{5b^2}{3} + ba^2 + b^2a - 4a^2 - 4b^2 + \frac{22a}{3} + \frac{22b}{3} - 2,
\]
which can be checked to be the total number of coefficients of the polynomials appearing in the tachyon matrix \(T\) given in (4.20). The latter equals the number of holomorphic sections of \(F \otimes \sigma^*F\) satisfying (4.15). The reason why this total number matches the index is the Kodaira vanishing theorem, implying \(h^{0,q}(F \otimes F) = 0\) for \(q > 0\) in the case at hand.

\(^{23}\)This formula also holds for any choice of sign in the projection (4.15). The other sign would change \(\sigma\) to \(-\sigma\) in (4.52), but this gets compensated by the fact that we also have \(\Gamma_{Op^+} = -\Gamma_{Op^-}\). The universality of this formula can be understood physically from the “orientifold” picture, which will be discussed elsewhere.
The D7-D7′ degeneration $\eta = \pm \xi \psi$ discussed above has $D7-D7'$ charges given in (4.34), leading to a D7-D7′ index $I_0(D7) = a^3 - b^3 + a^2b - b^2a - 4a^2 + 4b^2$, in agreement with the net chirality index (4.40). However, as is clear from the table in section 4.2.5, the total number of charged matter fields generally exceeds the index. The advantage of the direct tachyon matrix analysis is that it allows straightforward enumeration of all charged matter fields using elementary methods.

### 4.4 Stability / D-term constraints

Four dimensional $\mathcal{N} = 1$ supersymmetric vacua have vanishing $F$- and $D$-term potentials. So far we have only studied the $F$-flatness constraints for our D-brane configurations, which are encoded in holomorphic equations and depend on the complex structure moduli. The $D$-flatness constraints are nonholomorphic and depend on the Kähler moduli. Mathematically, these correspond to stability conditions, most generally to II-stability [130, 59, 131]. They are also related to stability conditions of BPS black hole bound states [132, 83].

This subject is rather involved. We will restrict ourselves here to a few simple observations.

In an O3/O7 type orientifold, part of the $D$-flatness condition is that all D-brane components must have zero central charge phase. The central charge of a D-brane of charge $\Gamma$ is, in the large radius regime and for zero $B$-field

$$Z(\Gamma) = \langle \Gamma, -e^{iJ} \rangle = \int \Gamma \wedge ( -1 + iJ + \frac{J^2}{2} - i\frac{J^3}{6} ).$$

(4.62)

Zero phase at large $J$ therefore means $\Gamma|_{D7} \cdot J^2 > 0$ and

$$\Gamma|_{D5} \cdot J - \Gamma|_{D9} J^3 = 0,$$

(4.63)

where we can replace $\Gamma|_{D5}$ by the $\sigma$-even part $\Gamma|_{D5,\ +} \in H^2_+$ because $\Gamma|_{D5,\ -} \cdot J = 0$. Thus, in the large radius limit $J \to \infty$, no brane configuration which includes a component of nonzero D9-charge can be supersymmetric. When there is more than one Kähler modulus, there can be special real codimension 1 loci in the Kähler moduli space where D-brane components with $\Gamma|_{D5,\ +} \neq 0$ are supersymmetric. These are typically walls of marginal stability, with supersymmetric brane recombination occurring on one side of the wall.

In our example, there is only one modulus, so any brane configuration with a component of nonzero D5-charge will be nonsupersymmetric. In particular, $D7-D7$ configurations such as (4.34) will in fact be nonsupersymmetric when $a \neq b$: they are F-flat, but not D-flat. This implies also that when $a < 2$ or $b < 2$ and $a \neq b$, there are no supersymmetric D9-D9′ bound states of the type considered in section 4.2.2, because in this case $\rho \tau = 0$ so the D7 condensate necessarily splits with charges as in (4.34). Furthermore, when $a = b \leq 0$, the condition $\Gamma|_{D7} \cdot J^2 > 0$ is violated, leaving $a = b = 1$ as a special acceptable case. This justifies the claim made in the beginning of section 4.2.2.

### 5. Some generalizations

Throughout this paper, we have often focused on our basic example to illustrate the various computational geometrical methods that can be used to analyze D-branes in compact
orientifolds. It is clear however that many of the results we derived for this example can be generalized and systematized.

Let us for example give general formulae for the curvature induced D3 charge, the number of moduli and the flux lattice dimension for arbitrary D7-branes in O7− orientifolds. As we have argued, the D7 will in general obey an equation of the form \( S : \eta^2 = \xi^2 \chi \). Let \( D \) be the divisor \( \xi = 0 \) wrapped by the O7−. To construct the parameter surface \( \Sigma \), we blow up the double intersection curve \( \xi = \eta = 0 \), by introducing an additional coordinate \( t \) and imposing the equation \( \eta = \xi t \). Consistency requires \( t \) to be a holomorphic section of \( O(S^2 - D) \). The existence of such a section in turn requires

\[
S - 2D \geq 0 ,
\]

in the sense of positivity of line bundles. If this is not the case, the D7 doubly wraps the smooth divisor \( S' : \eta = 0 \). We will discuss this case separately below, and assume for now that (5.1) is satisfied.

The surface \( \Sigma \) is the proper transform of \( S \) in the blown up space, which is given by the equation \( \Sigma : t^2 = \chi \). Denoting the divisor class \([\eta = 0]\) by \([\eta]\) and similarly for the other polynomials and coordinates, we thus have

\[
[\eta] = \frac{S}{2}, \quad [\xi] = D, \quad [\chi] = S - 2D, \quad [t] = \frac{S}{2} - D .
\]

The number of pinch points is

\[
n_{pp} = \int_X [\eta][\xi][\chi] = \frac{1}{2} \int_X \frac{1}{2} SD(S - 2D) .
\]

The Chern class of \( \Sigma \) can be computed using the adjunction formula:

\[
c(\Sigma) = \frac{c(X) (1 + [t])}{(1 + [\eta])(1 + [\chi])} = 1 + (D - S) + (S^2 + c_2 + 2D^2 - \frac{S}{2} DS) .
\]

This allows us to compute the orientifold Euler characteristic of \( S \):

\[
\chi_o(S) = \int_{\Sigma} c_2(\Sigma) - n_{pp} = \int_X S^3 + c_2 \cdot S + 3DS(D - S) .
\]

The curvature induced D3 charge \(-Q_c(S)\) and dimension \( b(S)\) of the flux lattice are derived from this using (3.40) and (3.44):

\[
Q_c(S) = \frac{\chi_o(S)}{24} , \quad b(S) = b^2_-(\Sigma) = \frac{\chi_o(S)}{2} .
\]

Similarly, assuming \( h^{0,1}(\Sigma) = 0 \) (as will be automatic if \( \Sigma \) is ample, by the Lefshetz hyperplane theorem), the number of D7 deformation moduli \( N_{def}(S) \) is given by (3.54):

\[
N_{def}(S) = h^{2,0}_-(\Sigma) = \frac{1}{24} \int_{\Sigma} c_1(\Sigma)^2 + c_2(\Sigma) - \frac{n_{pp}}{8} = \int_X \frac{S^3}{12} + \frac{c_2 S}{24} + \frac{1}{4} DS(D - S) .
\]
If we take the D7 to cancel the O7 tadpole, we have

\[ S = 8D. \]  \hfill (5.10)

Plugging this in the above formulae and recalling (3.17) gives for the total curvature induced D3 charge \(-Q\) on D7, O7 and O3 planes\(^{24}\) (for generic D7):

\[ Q = \frac{N_{O3}}{2} + \frac{29D^3}{2} + \frac{c_2D}{2} \quad \text{(generic)}. \]  \hfill (5.11)

Similar formulae are obtained for the total number of D7-worldvolume fluxes and moduli for the most generic D7, by substituting (5.10) in (5.7) and (5.9). These formulae allow for efficient computation of these physical topological quantities.

As promised we now briefly return to the case when (5.1) is not satisfied and the D7 hence doubly wraps the surface \(S'\): \(\eta = 0\) (so there is an enhanced gauge symmetry \(SU(2)\)). Since this is generically smooth, we can simply use the standard formulae. For example, \(Q_c(S) = 2 \times \frac{(S')^3+c_2S'}{24} = \frac{s_3}{96} + \frac{c_2S}{24}\), and instead of (5.11) we now get

\[ Q = \frac{N_{O3}}{2} + \frac{11D^3}{2} + \frac{c_2D}{2} \quad \text{(SU(2) sector)}. \]  \hfill (5.12)

Similarly, in the \(O(8)\) sector, with all D7 branes coincident with the O7\(^-\), we get

\[ Q = \frac{N_{O3}}{2} + \frac{D^3}{2} + \frac{c_2D}{2} \quad \text{(O(8) sector)}. \]  \hfill (5.13)

Finally, by making use of index theory, some further interesting relations can be derived. From the Lefshetz fixed point index theorem (3.43), we get

\[ 2h + 4 = \chi(X^\sigma), \]  \hfill (5.14)

where \(h\) can be expressed in terms of the \(\sigma^*\) even and odd Hodge numbers of \(X\), or in terms of the corresponding numbers of massless closed string modes of the orientifold compactification:

\[ h := h_{1,1}^+ - h_{1,1}^- + h_{2,1}^+ - h_{2,1}^- \]  \hfill (5.15)

\[ = \text{Kähler moduli} - (B,C)\text{-axions} + \text{compl. struct. moduli} - U(1) \text{ vectors}. \hfill (5.16)\]

This is also equal to the number of geometric moduli of the original \(\mathcal{N} = 2\) theory minus twice the number of these moduli which get projected out by the orientifold projection. In (5.14), \(X^\sigma\) is the fixed point set of \(\sigma\), i.e. the collection of all O3-planes and O7-planes. Thence:

\[ D^3 + c_2D + N_{O3} = 2h + 4. \]  \hfill (5.17)

From the holomorphic Lefshetz fixed point theorem (3.50) with trivial bundle, we get similarly

\[ -D^3 + c_2D + 3N_{O3} = 48. \]  \hfill (5.18)

\(^{24}\)Here and in what follows we assume the “standard” O-plane projection, i.e. giving rise to O7\(^-\) and O3\(^+\), which have signs of D7 resp. D3 charge opposite to that of the D7 and D3 in our charge sign conventions.
These two equations can be solved to eliminate $D_3$ and $c_2D$ in the above equations. For example with this and (5.11) we find for the total $D_3$ tadpole from $O_3$, $O_7$ and $D_7$:

$$Q = -306 + 15 h + 14 N_{O_3} \quad \text{(generic).} \quad (5.19)$$

For our basic example, this curious formula indeed gives $Q = -306 + 15 \times (1 - 0 + 149 - 0) + 0 = 1944$. Similarly

$$Q = -108 + 6 h + 5 N_{O_3} \quad \text{(SU(2) sector),} \quad Q = h + 2 \quad \text{(O(8) sector).} \quad (5.20)$$

The last case can be compared to the resolved $T^6/Z_2 \times Z_2$ model of [67], which indeed has $h = 51 - 0 + 3 - 0 = 54$ and $Q = 56$.

For the generic $D_7$ case, we furthermore obtain by combining the above formulae the following relations between total $D_3$-tadpole, $D_7$ flux lattice dimension, number of $D_7$ moduli and $h$:

$$N_{\text{def}} + h + 10 = 2Q, \quad 7b = 2h + 82Q - 668, \quad 2 N_{\text{def}} = 86Q - 7b - 688. \quad (5.21)$$

These generalizations can also be studied in the tachyon condensation picture, where the generic, $D_7$-tadpole canceling, flux free $D_7$-configuration is given by the $D_9$-$D_9'$ condensate for a $D_9$ carrying the rank two bundle

$$F = \mathcal{O}(D_7/2) \oplus \mathcal{O}(\overline{D}_7/2). \quad (5.22)$$

In particular this reproduces the curvature induced $D_3$ charges given above. Note however that $D$ might not be even, in which case the above “minimal” bundle $F$ does not exist. In fact, this is as it should: On the $D_7$-side, this corresponds to the Minasian-Moore-Freed-Witten effect, i.e. the fact that if the first Chern class of the wrapped 4-cycle is odd, the brane must carry some compensating half-integral flux [92, 93].

Further generalizations will be explored in [133].

6. Summary and conclusions

With model building applications in mind, we have laid out and clarified several different approaches to the analysis of type IIB $O_3/O_7$ orientifold compactifications, with emphasis on global aspects of the $D_7$-brane sector. In particular:

1. We pointed out that generic $D_7$-branes have singular double intersections with $O_7^-$ planes. This means that on an CY orientifold $X$ given by $X : \xi^2 = h(\vec{u})$ and involution $\sigma : \xi \rightarrow -\xi$, $D_7$-branes are given by equations of the form

$$S : \eta^2(\vec{u}) = \xi^2 \chi(\vec{u}), \quad (6.1)$$

where $h$, $\eta$ and $\chi$ homogeneous polynomials. One obtains this form from Sen’s weak coupling limit of F-theory [84] (this was also observed in [88]), and we argued that it is implied for $O_7^-$ but not for $O_7^+$ by the Dirac quantization condition. We
also showed that it is reproduced by D9-anti-D9 tachyon condensation in the O7−
projection, taking into account a subtlety requiring the number of D9-D9′ pairs to be
even. The surface $S$ has double points along $\xi = \eta = 0$, and pinch point singularities
at $\xi = \chi = \eta = 0$. A local model for it is the Whitney umbrella in $\mathbb{C}^3$.

2. The singular nature of $S$ invalidates the standard formulae for physical topological
properties such as curvature induced D3 charge $-Q_{c,D7}$, number of moduli $N_{D7 \text{def}}$ and
flux lattice dimension $b$. Naive application of the standard formulae or naive modifications thereof results in large discrepancies with F-theory. We gave a prescription
for computing these numbers directly in perturbative IIB theory by introducing an
auxiliary parameter surface $\Sigma$ splitting up the double intersection locus, namely the
proper transform of the D7 worldvolume in the CY blown up in the double intersection curve. In particular we found

$$Q^{(\text{IIB})}_{c,D7} = \frac{\chi(\Sigma) - n_{pp}}{24}, \quad N_{D7 \text{def}} = h^{2,0}_-(\Sigma), \quad b = b^2_-(\Sigma) = 12 Q_{c,D7}, \quad (6.2)$$

where $n_{pp}$ is the number of pinch points and the minus subscript on the Hodge
numbers refers to the $\sigma^*$ parity. These results were derived independently from
F-theory, from D7 geometry and from tachyon condensation, and we found exact
agreement between these different approaches.

Using index theorems, we gave general explicit formulae for the above numbers. In
particular this led to curious formulae relating for example the total D3-tadpole
induced by O3 and O7 and D7 curvature to the closed string massless spectrum, as
well as to various nontrivial relations between D3-tadpole, D7 flux lattice dimension
and the open and closed string massless spectrum in four dimensions; see eqs. (5.15),
(5.19), (5.20) and (5.21).

3. We explained how to explicitly construct D7 flux vacua from holomorphic curve
embeddings, by picking a curve $\gamma \in X$ together with its orientifold image $\gamma'$, requiring
$S$ to contain these, and setting

$$F = \text{PD}_\Sigma(\bar{\gamma}) - \text{PD}_\Sigma(\bar{\gamma}') \quad (6.3)$$

where $\bar{\gamma}$ is the lift of $\gamma$ to $\Sigma$. We pointed out that at least for rational curves $\gamma$, this
procedure consumes the available D3 charge tadpole (i.e. $-Q_{c,D7} - Q_{c,O7} - \frac{1}{2} \int_\Sigma F^2 > 0$)
before it freezes all D7 moduli, suggesting a potential problem for supersymmetric
stabilization of D7 moduli in the weak coupling limit using only worldvolume fluxes
and taking tadpole cancelation into account.

4. We emphasized in particular the practical power of the tachyon condensation pic-
ture, which allows one in principle to compute charges, moduli, enhanced gauge
groups and matter spectra using elementary methods — essentially just polynomial
manipulations.

---

25Here and in what follows we use IIB conventions for the D3-charge; see footnote 2.
The tachyon arises from open strings to a stack of D9 branes with bundle $E$ from their image anti-D9 branes with bundle $E' = \sigma^* E^*$ and is formalized as a linear map
\[ T : E' \rightarrow E, \] (6.4)
i.e. a section of $E \otimes \sigma^* E$. The O7$^-$ projection imposes $\sigma^* T = -T^t$ and an anomaly argument implies that the rank $r$ of $E$ must be even in this case. The D7 locus is given by $S : \det T = 0$, reproducing embedding equations of the form (6.1) in this case.

When $E$ is the direct sum of line bundles $O(D_i)$, the tachyon entries $T_{ij}$ are holomorphic sections of $O(D_i + D_j)$, which when $X$ is given as a submanifold of a toric variety are simply polynomials of degrees determined by $D_i + D_j$. More generally we could have a gas of D5- and D3-branes wrapped on curves and points in each of the D9-branes (i.e. consider ideal sheaves), and then $T_{ij}$ must vanish on the curves and points wrapped by the brane gas in $D9_i$ and $D9_j$, implying in particular that $S$ must contain all of these curves and points. This makes contact with (6.3), and, since ideal sheaves are counted by Donaldson-Thomas invariants, suggests a role for the latter in counting D7 flux vacua similar to their role in counting D4-D0 black hole microstates in [83, 82].

5. Even when $E$ is just the sum of line bundles $O(D_i)$, the resulting D7 bound state will in general carry flux. We illustrated how to explicitly compute this flux (on $\Sigma$ as defined above). In general the D7 will carry a bundle
\[ L = E/TE'|_\Sigma \otimes K^{-1/2}_\Sigma, \] (6.5)
where the quotient is simply the fiberwise equivalence $e \simeq e + Te'$. For generic $S$ this will be a line bundle, corresponding to $U(1)$ flux $F = c_1(L)$. More concretely, we found
\[ F = \frac{1}{2} (\text{PD}_\Sigma(\bar{\gamma}) - \text{PD}_\Sigma(\bar{\gamma}')), \] (6.6)
with $\bar{\gamma}$ the lift (proper transform) of the curve obtained as the zero locus of for example the first row of cofactors (maximal minors) of the matrix $T_{ij}$:
\[ \gamma = \{ x \in S \mid \bar{T}_{1j}(x) = 0 \ \forall j \}. \] (6.7)

We observed in this framework that D7 brane recombination can induce fluxes on branes even if these were originally absent on the constituent branes. This is needed for charge conservation, and explains from the geometric point of view the reduction in number of D7 moduli in sectors with enhanced gauge symmetry points. This generalizes the observations of [78, 79], for space-localized D4 branes on non-orientifolded Calabi-Yau manifolds, to D7-branes in orientifolds. Note that this implies that similarly in F-theory, 4-form fluxes will in general be induced when deforming away from a singular fourfold with enhanced gauge symmetry.
6. We illustrated how to obtain residual gauge symmetries, moduli and charged matter multiplets from the tachyon picture. The (F-term) D7 moduli space is parametrized by tachyon configurations \( T \) modulo
\[
T \rightarrow g \cdot T \cdot g^*,
\]
for automorphisms \( g : E \rightarrow E \). The physical moduli space also must take into account D-term constraints, which we briefly discussed.

The residual gauge symmetries \( G \) for a given \( T \) are the automorphisms \( g : F \rightarrow F \) independent of the internal coordinates, for which \( T = g \cdot T \cdot g^\dagger \). Generically this is \( G = \mathbb{Z}_2 \), but at special values of \( T \) this can be enhanced. Charged matter then corresponds to linearized fluctuations of particular entries in the tachyon matrix, modulo linearized equivalences (6.8).

7. Finally, we compared these results to general open string index computations, in particular to the index counting the net number of open string modes between a brane of charge \( \Gamma \) and its image brane of charge \( \Gamma' \):
\[
I_o(\Gamma) = \frac{1}{2} \left( \langle \Gamma', \Gamma \rangle + \frac{1}{4} \langle \Gamma_O, \Gamma \rangle \right),
\]
where \( \Gamma_O \) is the total charge of the orientifold planes. This agrees with the net number found in the tachyon picture, but the latter also gives the absolute number, which typically exceeds the net number.

These results remove some of the obstacles to developing a systematic understanding of the landscape of IIB orientifold vacua. In particular our analysis clarifies the relation between gauge theory and geometry. The framework we presented is in principle sufficient for detailed enumeration of supersymmetric D7 flux vacua in IIB orientifolds in a way similar to how D4 flux vacua are enumerated in the context of type IIA D4-D2-D0 black hole microstate counting. We plan to return to this in a future publication.

One important element which we did not address however is the effect of bulk flux on the D-brane sector, and the interplay between bulk and brane sectors as far as moduli stabilization is concerned. It seems to us that this is best addressed in the full F-theory framework. On the other hand, the D9-D9' tachyon condensation picture is the most efficient and concrete framework to derive gauge theory content and connect gauge theory to geometry, but it is a perturbative string construction. It would therefore be desirable to find the analog of this tachyon condensation mechanism in F-theory.
