Sex-Linked Hereditary Bilateral Anophthalmos

Pathologic and Radiologic Correlation

Philip J. Brunquell, MD; John H. Papale, MD; Jonathan C. Horton, PhD; Roger S. Williams, MD; Michael J. Zgrabić, MD; Daniel M. Albert, MD; E. Tessa Hedley-Whyte, MD

A 27-year-old man had X-linked true anophthalmos. No evidence of optic globe, nerves, or chiasm was found. Rudimentary structures suggesting optic tracts were present. Lateral geniculate nuclei were present but glotic. Calcineur cortex was thinner but had usual lamination. The normal patches of cytochrome oxidase activity in layers II and III of visual cortex were absent.

A report of a case

The report that follows is a brief summary. For additional details, see the report of Hoefnagel et al.1

The patient was born (weighing 2.7 kg) to a 26-year-old mother (gravid 3, para 2). Parents were nonconsanguineous and of normal intelligence. The pedigree of the family updated from the previous report includes another maternal male cousin with unilateral anophthalmia and contralateral microphthalmia and is shown in Fig 1.

At the age of 7½ years, his head circumference was 49 cm (second percentile). His ears were large and outstanding. The eyeballs were absent, but eyelids, cilia, eyebrows, lacrimal puncta, and tarsal cartilages were present. Epicanthal folds were noted bilaterally, and palpebral fissures were 20 mm in width. Conjunctival membranes of normal appearance lined the orbital cavities, which were 15 mm in their greatest depth. Vigorous lid-closure followed touching the membranes. The lacrimal glands were enlarged, and tearing was normal. There was reactive blinking to touch and loud noise. Cranial nerves other than II, III, IV, and VI were normal. Muscle tone was normal; bulk was diffusely diminished. Sensation to noxious stimuli was intact. Muscle stretch reflexes were 1+ bilaterally with flexor plantar responses. The right testis was descended. Karyotype was normal. An EEG showed absence of a posterior α-rhythm and no driving response to photic stimulation. Skull x-ray films were normal, except for showing shallow orbits and small optic foramina.

At the age of 11½ years, he was admitted to a state institution, at which time height, weight, and head circumference were all less than the second percentile.

When he was 15 years old, a grand mal seizure lasting five minutes was witnessed for the first time. His CSF was normal. An EEG showed, in addition to absent α-rhythm, generalized low-voltage fast activity and intermittent bilateral sharp waves, most prominent posteriorly. Seizures were controlled with phenobarbital and phenytoin (Dilantin). An examination when the patient was 16 years old showed spastic paraparesis, flexion contractures, and a severe scoliosis.

When he was 25 years old, computed tomography (CT) showed densities within the orbits having the appearance of rudimentary extraocular muscles. Ovoid lacunae anteriorly in both orbits were believed to be rudimentary eye tissue (Fig 2). Optic foramina were present bilaterally. The ventricles were slightly enlarged, and cranial asymmetry was noted. Large accessory bony sinuses were present in the frontal regions (Fig 3).

After an episode of hypothermia at the age of 26½ years, he was found to have a low thyroxine level (3.7 µg/dL) and an elevated thyrotropin level (14 mU/mL) and was begun on levothyroxine sodium (Synthroid) therapy. At the age of 26 years, hydrocortisone therapy was started for hypoadrenalism.

He died of aspiration pneumonia at the age of 27 years.

Pathologic findings

Postmortem examination revealed...
bilateral bronchopneumonia, kyphoscoliosis, muscular wasting, bilateral cryptorchidism, and atrophy of the thyroid, adrenal glands, and testes.

The calvarium was asymmetric, with a right parietal protuberance. Head circumference was 54 cm, with thickened cranial sutures. Large accessory bony sinus cavities superior to the orbital contents did not communicate with the frontal sinuses (Fig 3). The pituitary fossa was small, with marked thickening of the anterior and posterior clinoids and the petroclinoid dura.

The orbits were unroofed through the accessory frontal sinuses and contained no identifiable eye tissue. The extraocular muscles were in their normal positions. The anterior portion of the orbital contents in the left eye contained a firm nubbin of connective tissue. Tissue removed from the orbital cavities measured 40 mm in length, 27 mm in width, and 30 mm vertically on the right, and 70 mm in length, 35 mm in width, and 23 mm vertically on the left.

Step sections of both orbital contents revealed similar constituents, including peripheral nerve, autonomic ganglion cells, connective tissue, striated muscle, blood vessels, fat, non-keratinized stratified epithelium, areas of mild chronic nongranulomatous inflammation, and lacrimal glands (Fig 2). There was pigment along some nerve fibers. No trace of cornea, lens, uveal tissue, retina, pigment epithelium, or optic nerve was found.

The brain weighed 1,050 g. Optic nerves and chiasm were absent (Fig 4). The third and sixth cranial nerves were present but smaller than normal. The frontal lobes were particularly small. All primary gyri and sulci were identified, although the calcarine fissures were shorter than normal (Fig 5).

Although medial geniculate nuclei were well defined in coronal section, lateral geniculate nuclei and optic tracts were not grossly visible. The subcortical white matter of the cerebral hemispheres was diffusely firm, and the ventricles were slightly dilated. The brain stem, cerebellum, spinal cord, and blood vessels were normal.

The sites of the optic tracts were visible microscopically, more apparent on the left than the right, as small gliotic structures without myelinated fibers. The lateral geniculate bodies occupied their normal position (Fig 6) but were small, measuring 0.3 × 0.2 mm, with an anteroposterior extent of only 2.5 mm. The nucleus was severely gliotic, with a few, both small and large, neurons, but normal lamination was completely lacking (Fig 6). The optic radiations were much thinner than normal.

In serial sections through the left calcarine cortex, primary visual cortex (area 17) could be clearly identified by the boundary between areas 17 and 18 (Fig 7). The basic layering pattern of area 17 was preserved, although several anomalies were noted. Area 17 seemed less richly laminated than usual. Layer IVb was not visible as the usually cell-poor gap between IVc and the supragranular layers. Myelin stains confirmed the absence of a well-myelinated line of Gennari. Finally, with the use of Nissl’s staining method, the density and size of cells seemed generally reduced throughout striate cortex. Superior colliculi appeared normal in cell stains, but the myelinated fiber bundles of the stratum opticum, the retinocollicular afferents in the normal brain, were absent.

In specimens of normal human striate cortex, regular patches of enhanced cytochrome oxidase activity are visible, particularly in layers II and III’ (Fig 8). In this case of anophthalmia, no cytochrome oxidase
patches were present, as shown in Fig 8, a tangential section through layers II and III. In addition, the thick band of dark enzyme staining usually present in layer IVc was very weak.

The small neurons of neocortical layer IV appeared diminished in number in inferior frontal and temporal areas. The inferior olives were gliotic, with marked decrease in cell numbers, increased numbers of astrocytes, and diminution of myelinated fibers in the hilum. The cerebellum showed diffuse decrease of granule cells and Purkinje's cells. There were numerous spheroids in the cuneate nuclei bilaterally without demyelination in the posterior cord.

**COMMENT**

Although Lycosthenes referred to anophthalmos in 1557, it was not until a century later that Bartholin provided the first medical description. In the early 19th century, called attention to the possible familial occurrence of the disease. The first large clinical series, albeit without histologic verification, was by Treacher-Collins in 1887. Numerous reports followed, with little attempt to delineate the precise nature of any intraorbital tissue until Mann subdivided this heterogeneous group into three distinct entities: primary anophthalmos resulting from failure of development of the optic vesicles; secondary anophthalmos, where failure of eye formation occurs as a component of more generalized abnormal forebrain development; and degenerative or consecutive anophthalmos due to complete regression or involution of a previously formed optic vesicle. In all cases there is virtual absence of any neuroectodermal derivatives within the orbit. When such derivatives are present in a patient with no grossly evident eye structures, extreme microphthalmos is a more appropriate designation. Despite the apparent ease of this classification, it offers little insight into pathogenesis, since cases with no residual eye tissue
Fig 6.—Left, Lateral geniculate body is small but well defined (arrowheads) and in normal proximity to medial geniculate nucleus (M). It shows lack of lamination and neuronal depopulation (Nissl’s method, X22). Right, Close-up view of lateral geniculate nucleus shows nonlaminated neuronal population (30-μm-thick section; Nissl’s method, X64).

Fig 7.—Calcarine fissure (C) with striate cortex above and junction between areas 17 and 18 below (arrowhead). Note well-laminated striate cortex with thinner than usual layer IVb (20-μm-thick section; Nissl’s method, X26).

Fig 8.—Left, Tangential section through superficial layers I, II, and III of normal visual cortex stained for cytochrome oxidase activity showing regular patches of cytochrome oxidase activity (X10). Right, Comparable section of patient’s visual cortex showing uniform distribution of cytochrome oxidase activity with no patches (X10).

may not always be ascribable to agenesis or degeneration. Furthermore, extrapolation to experimental models is limited as these are not characterized by complete failure of optic cup evagination.

In 1963, Duke-Elder acknowledged the difficulty in distinguishing the nature of orbital contents on clinical grounds alone and pointed out that the true form of anophthalmos was rare and that most cases showed some intraorbital representation of neuroectodermal structures. This observation is strengthened by the fact that only 13 cases of primary anophthalmos had been tabulated as of 1980.12 Newer noninvasive techniques, such as orbital ultrasound and CT scan, may suggest a premortem diagnosis but must be interpreted with caution. In this case, for instance, the central collection of orbital fat (low absorption) surrounded by muscle, peripheral nerves, and connective tissue (medium absorption) suggested the presence of globes.

The heredity of familial anophthalmos is heterogeneous. Most cases are distributed in an autosomal recessive pattern, but a dominant pattern has also been reported. However, when anophthalmia is associated with mental retardation and/or multiple congenital malformations, case distribution is more consistent with a sex-linked recessive pattern of inheritance. Anophthalmos has also been associated with drugs, congenital infection, vitamin A deficiency, mechanical trauma to the fetus, chromosomal aberrations and idiopathic multiple malformation syndromes. Animal models exist for many of these and also suggest a few others, such as radiation and altered immunity. The association of anophthalmos with parietal mass lesions suggests that local pressure may destroy the developing visual system.
the eyelids, cilia, lacrimal apparatus, conjunctival lining, and extraocular muscles. The absence of the lens seems to be due to the failure of the optic cup to make proper contact with the lens placode, suggesting that the critical period is the development of the optic vesicle and cup. This has been demonstrated in the mutant anophthalmic mouse ZRDCT/An, which serves as a suitable animal model for the human disorder. The mutant also be conformation of the oxidase stain. The conclusion was nevertheless, judging survivors, develop, apparently the visual cortex in striate cortex geniculate nucleus diagnosis for the human disorder. The mouse anophthalmic demonstrated the survival of lateral neurons, as a model for the human disorder. The lens cup to make proper contact with the survival of lateral neurons, in contrast to their degeneration following postnatal eye enucleation.

In adult human beings, monocular enucleation causes anterograde trans-neuronal degeneration in the lateral geniculate nucleus and superior colliculus, with increased connections to posterior thalamus, are also established. These connections may ensure the survival of lateral geniculate neurons, in contrast to their degeneration following postnatal eye enucleation.

In the anophthalmic mouse, geniculate neurons establish contact normally with area 17 of the neocortex. Striate cortical afferents to lateral geniculate nucleus and superior colliculus, with increased connections to posterior thalamus, are also established. These connections may ensure the survival of lateral geniculate neurons, in contrast to their degeneration following postnatal eye enucleation.

In normal monkeys and human beings were lacking. The macaque monkey, these patches receive a direct projection in layers II and III from the lateral geniculate body. Following eye removal in the macaque monkey, the patches innervated by geniculate laminae, corresponding to the missing eye, turn pale and shrink. In view of the appearance of the geniculate body (Fig 6), it was not surprising that the patches were absent altogether in this case. Finally, connections within striate cortex were also probably abnormal, since the dense tangential fiber plexus in layer IVb was extremely faint.

Our findings can be compared with those in three reports in the English literature that included gross and microscopic descriptions of all parts of the visual system. All three cases were characterized by complete absence of eye tissue, optic nerves, chiasm, and tracts. The lateral geniculate nuclei were not found in one case and were small and nonlaminated in the other two. In one case, the calcarine cortex was normal grossly with normal cellular laminaation, save for absence of the myelinated line of Gennari. The other two had small striate areas, one with and one without a line of Gennari, the latter case showing grossly malformed calcarine fissures.

It is possible that this patient's growth retardation is due to a single gene defect that affects the development of multiple areas, including the hypothalamus and the eye. A multivariate analysis of the pleiotropic effects caused by WhWh (anophthalmic white) in the Syrian hamster showed a high correlation with six hypothalamically mediated indicators. They included growth retardation, thyroid dysfunction, adrenal atrophy, and sterility, all findings that were present in this patient. Studies of some anophthalmic mice revealed pathologic changes in the hypothalamus, including alterations of the suprachiasmatic nuclei that were deprived of normal retinal afferents. Rats that are blinded or deprived of visual stimulation show growth retardation, delayed puberty, and reduced pituitary stores of growth hormone. Although this suggests an interdependence of hypothalamic and visual function, no histologic hypthalamic alterations were recognized in this case. Serial sections of the hypothalamus were not done, and in the absence of an optic chiasm, the suprachiasmatic nucleus could not be reliably identified.

Russell Kerschmann, MD, performed the non-neuroophthalmologic portion of the autopsy.
