(Dated: February 1, 2008)

The WMAP experiment has revealed an excess of microwave emission from the region around the center of our Galaxy. It has been suggested that this signal, known as the “WMAP Haze”, could be synchrotron emission from relativistic electrons and positrons generated in dark matter annihilations. In this letter, we revisit this possibility. We find that the angular distribution of the WMAP Haze matches the prediction for dark matter annihilations with a cusped density profile, \( \rho(r) \propto r^{-1.2} \) in the inner kiloparsecs. Comparing the intensity in different WMAP frequency bands, we find that a wide range of possible WIMP annihilation modes are consistent with the spectrum of the haze for a WIMP with a mass in the 100 GeV to multi-TeV range. Most interestingly, we find that to generate the observed intensity of the haze, the dark matter annihilation cross section is required to be approximately equal to the value needed for a thermal relic, \( \sigma v \sim 3 \times 10^{-26} \text{ cm}^3/\text{s} \). No boost factors are required. If dark matter annihilations are in fact responsible for the WMAP Haze, and the slope of the halo profile continues into the inner Galaxy, GLAST is expected to detect gamma rays from the dark matter annihilations in the Galactic Center if the WIMP mass is less than several hundred GeV.

The Wilkinson Microwave Anisotropy Probe (WMAP) has made precise measurements of the cosmic microwave background (CMB) anisotropies, providing valuable constraints on the cosmological parameters \[1\]. In addition, WMAP data has been used to provide the best measurements to date of the standard ISM emission mechanisms, including thermal dust, spinning dust, ionized gas, and synchrotron. Surprisingly, these observations have revealed an excess of microwave emission in the inner 20\( \text{O} \) of the Galactic Center, where a positive residual (WMAP Haze) is present, and the slope of the halo profile continues into the inner Galaxy, as shown in Figure 1. This excess, which is uncorrelated to the known foregrounds, is known as the “WMAP Haze” \[2\].

Thus far, the origin of the WMAP haze is unknown. It was initially thought to be thermal bremsstrahlung (free-free emission) from hot gas \((10^4 \text{ K} \gg T \gg 10^6 \text{ K})\), although this is now ruled out by the absence of an \( \text{H} \alpha \) recombination line and X-ray emission. Other possible origins, such as thermal dust, spinning dust, and Galactic synchrotron as traced by low-frequency surveys, also seem unlikely \[2\].

More recently, it has been suggested that the haze could be synchrotron emission from a distinct population of \( e^+ e^- \) produced by dark matter particles annihilating in the inner Galaxy \[3\]. In this letter, we argue that this hypothesis is plausible for a number of reasons. Firstly, the distribution of relativistic electrons/positrons needed to match the angular distribution of the haze is consistent with that found for dark matter annihilations in a cusped halo. Secondly, the total power observed in the haze is approximately that predicted to be injected through dark matter annihilations for the case of a cusped halo profile and an annihilation cross section needed to generate thermally the measured cosmological abundance of dark matter. Thirdly, the observed spectrum of the WMAP Haze is consistent with that expected for the synchrotron emission from the annihilation products of a typical electroweak scale dark matter candidate.

As each of the standard components of the WMAP Haze (thermal dust, spinning dust, ionized gas, and synchrotron) are optically thin to microwaves, the observed sky maps are simply linear combinations of the various components, each of which can be modeled by a spatial template based on other data. The thermal dust template is derived from a far-IR map \[4\], and that same map modulated by dust temperature appears to be a reasonable template for spinning dust \[2\]. The thermal bremsstrahlung of the ionized gas is traced by the \( \text{H} \alpha \) recombination line in neutral H at 656.3 nm, as both forms of emission are proportional to the ionized gas density squared, integrated along the line of sight. Data from three surveys were combined and corrected for dust absorption, resulting in a full-sky template of thermal bremsstrahlung \[5\]. Synchrotron emission dominates at low frequencies, and is spatially correlated with the 408 MHz survey of Haslam et al. \[4\]. The four components have characteristic spectra which vary slightly spatially but, in the limit of constant spectra, may be derived by a multilinear regression of the 5 WMAP frequency bands. Such a regression fits the data reasonably well over the whole sky, with the striking exception of the region within \( \sim 20^\circ \) of the Galactic Center, where a positive residual remains — i.e. the haze \[2\].

Initial indications were that the haze spectrum \( \langle I_{\nu} \rangle \propto \nu^{-0.25} \) was much harder than synchrotron \( \langle I_{\nu} \rangle \propto \nu^{-0.7} \) and was therefore more likely to be thermal bremsstrahlung \[2\]. However, the haze is uncorrelated with the \( \text{H} \alpha \) map (by construction) and inspection of this map shows no notable emission in the inner Galaxy south of the Galactic Plane, where the haze is the most robust. Because \( I_{ff}/I_{H\alpha} \sim T^{1/2} \) and the \( \text{H} \alpha \) traces primarily \( 10^4 \text{ K} \) gas, the low \( \text{H} \alpha \) intensity could be explained...
by very hot \((T > 3 \times 10^5 \text{ K})\) gas, but parameters derived from the ROSAT X-ray data \[8\] constrain the emission measure of hotter gas to be small. Furthermore, the cooling efficiency of gas is such that it tends to be \(10^4\) or \(10^5\) K, but spends little time at intermediate temperatures \[5\]. The presence of a large amount of gas at a thermally unstable temperature with very little gas at hotter or colder stable temperatures seems implausible. For this reason, we interpret the haze signal as a hard synchrotron emission, distinct from the softer 408 MHz-correlated component.

Synchrotron emission from relativistic electrons with energy distribution \(dN/dE \propto E^{-\gamma}\) produces a synchrotron specific intensity \(I_\nu \propto \nu^{\alpha}\) with spectral index \(\alpha = -(\gamma - 1)/2\). For reference, a constant injection of electrons into a box at high energy has a steady state solution of \(\gamma = 2\) and \(\alpha = -0.5\). Sudden loss of electrons in a sink (e.g. a dense gas cloud) or escape from the box by diffusion can harden the steady-state spectrum, but a spectrum much harder than -0.5 is difficult to achieve. Recent work \[6\] has shown that the haze spectrum may be a bit softer than first expected, but still a hardening of about 0.3 in spectral index is observed, relative to the spectral index required to agree with the 408 MHz data. This hardening is not generally observed elsewhere in the Milky Way, leading to the conclusion that the high energy excess of electrons is produced by a separate physical mechanism.

We emphasize that, although young SN remnants have a harder spectrum, a superposition of SNe in the inner Galaxy cannot reproduce this result. The presence of more supernovae (of many different ages) is not sufficient to harden the spectrum; they just produce more emission. An increase in diffusion near the center could lead to diffusion hardening but, if anything, the magnetic field is expected to increase near the Galactic Center, suppressing diffusion. The timescale of energy loss for 100 GeV electrons is of order 10^6 years, so the numerous SNe expected in the inner kpc on this timescale makes the steady-state assumption valid. While it is possible that a single very energetic explosion within the last million years could produce the haze, standard assumptions about diffusion and energy loss in the Milky Way would have to be modified \[10\]. On balance, we find it most plausible that the haze is produced by electrons from an entirely different source, which can produce high energy (\(\sim 100\) GeV) electrons with a harder spectrum than SNe.

The WMAP haze exhibits approximate radial symmetry around the center of the Milky Way, and extends out to at least 20° with consistent spatial morphology in each of the 5 WMAP frequency channels. In Fig. 1 we show the intensity of the WMAP haze, as a function of the angle observed away from the Galactic Center (in the direction perpendicular to and below the Galactic Plane). In each of the five frequency channels, there is a very strong increase of the signal within the inner 10°-20°. In the figure, we have plotted only the statistical error bars, reflecting the formal error in the fit. In addition, there are systematic errors (not shown), resulting from the subtraction of the cosmological anisotropy signal, which are highly correlated in both space and frequency.

To calculate the angular and spectral distribution of synchrotron emission from relativistic electrons/positrons produced in dark matter annihilations, we first calculate the distribution of electrons and positrons in the inner Galaxy by solving the diffusion-loss equation \[11\]. The distribution of radiation and magnetic fields in the inner Galaxy are not well known, however, making precise estimates of the relevant diffusion parameters difficult. We have adopted diffusion parameters which reflect a reasonable estimate of the relevant astrophysical properties. For the diffusion constant, we use \(K(E_e) \approx 1 \times 10^{28} (E_e/1\text{ GeV})^{0.33} \text{ cm}^2\text{s}^{-1}\). This somewhat larger than is typically used for Galactic diffusion, reflecting the expected presence of larger magnetic fields in the inner region of our Galaxy. For the electron/positron inverse energy loss time, we adopt \(b(E_e) = 5 \times 10^{-16} (E_e/1\text{ GeV})^{-2} \text{ s}^{-1}\). This is the result of inverse Compton scattering on starlight, emission from dust and the CMB, and corresponds to an average energy density of the interstellar radiation fields of approximately 5 eV/cm^3. This density is expected to be larger at small Galactocentric distances, where starlight is dom-
particular, we treat our diffusion zone as a cylindrical
region. We have adopted a thickness of $L = 3 \text{ kpc}$ for
our default choice.

The source term in the diffusion-loss equation reflects
the distribution of dark matter in the Galaxy, as well
as the mass, annihilation cross section, and dominant
annihilation modes of the WIMP. The dark matter halo
profile is the most important factor in calculating the
angular distribution of the resulting synchrotron emission.
The WIMP’s mass and leading annihilation modes are
important in determining the spectrum of that emission.

To constrain the halo profile needed to produce the
WMAP Haze, we focus on the 22 GHz band, which con-
tains the least noise of the five bands. In the upper frame
of Fig. 2 we show the angular distribution of 22 GHz syn-
chrotron for the simple case of a 100 GeV WIMP, anni-
hilating to $e^+ e^-$, using our default diffusion parameters.
We have used a 10 $\mu$G magnetic field for calculating the
synchrotron spectrum and intensity. We first consider
the Navarro-Frenk-White (NFW) halo profile [13], which
is shown as a solid line. Here, the dark matter annihil-
ation cross section was normalized to the data. It is clear
that the NFW profile results in too little synchrotron power
near the Galactic Center. This problem can be alleviated,
however, if we consider a somewhat steeper profile model.
Examples of such halo profiles include the Moore et al. profile [14], as well as distributions which have been steepened by adiabatic contraction [15]. The dashed line in the upper frame of Fig. 2 shows the result for a profile which scales as $\rho(r) \propto r^{-1.2}$ within the scale radius (rather than the $\rho(r) \propto r^{-1.0}$ behavior of NFW). This profile fits the WMAP data very well within the inner 15° for our choice of default diffusion parameters.

In the lower frame of Fig. 2 we consider an NFW pro-
file, but with diffusion parameters different from our
default choices. As a dashed line, we show the case of a
diffusion zone width of $L = 2 \text{ kpc}$, smaller than our
default choice. As a dotted line we show the case of an
energy loss rate half as large as our default value (or
equivalently, a diffusion constant twice as large). From
this, we conclude that variations in the diffusion coeffi-
cient or energy loss rate are unlikely to provide the large
synchrotron power in the inner Galaxy without a halo
profile somewhat steeper than NFW. Narrowing the dif-
fusion zone could increase the intensity of the haze in the
inner 10°, but produces less at larger angles. Variations
in the WIMP’s mass and annihilation modes have only a
mild effect on the synchrotron’s angular distribution.

By comparing the intensity of the haze in the various
WMAP frequency bands, we can estimate the spectrum
of injected electrons and positrons needed to generate the
haze. This, in turn, can be used to constrain the prop-
erties of the WIMP which are required. The synchrotron
spectrum depends on the energy of the emitting elec-
trons/positions, with higher energy particles contributing
more at high frequencies.

We consider the ratio of intensities observed in
WMAP’s 22 and 33 GHz frequency channels, taking ad-
vantage of the fact that the relative intensity between the
channels does not significantly vary with direction. This
allows us to consider an average of spectral information
over a range of angles. We focus on the 22 and 33 GHz
bands, as they are considerably less noisy and are more
robust to the foreground subtraction method than the
higher frequency channels.

When averaged over angles out to 15°, we find
$F_{22 \text{ GHz}} / F_{33 \text{ GHz}} \approx 1.18 \pm 0.10$ (corresponding to a spec-
tral index of $I_\nu \propto \nu^{-0.4}$), where the range reflects the
statistical errors. This result depends on how we per-
form the foreground subtraction, however, and could be
somewhat altered if the foregrounds are subtracted dif-
ferently. For this reason, the information we can derive
regarding the synchrotron spectrum is limited.

In the upper frame of Fig. 3 we compare this ratio
to the prediction from synchrotron emission from dark
matter annihilation products, using our default diffusion
parameters and a halo profile with an inner slope of 1.2.
The horizontal dashed lines represent the $2\sigma$ (statisti-
cal) measured range. The results for several specific dark

![Figure 2: The specific intensity of microwave emission in the 22 GHz WMAP channel as a function of the angle from the Galactic Center, compared to the synchrotron emission from the annihilation products of a 100 GeV WIMP annihilating to $e^+ e^-$. In the upper frame, our default diffusion parameters have been used. The solid line denotes the choice of an NFW halo profile, while the dashed line is the result from a profile with a somewhat steeper inner slope, $\rho(r) \propto r^{-1.2}$. In the lower frame, we have used an NFW profile with our default propagation parameters (solid), and with a smaller diffusion zone of $L = 2 \text{ kpc}$ (dashed), and a longer energy loss time of $\tau(1 \text{ GeV}) = 4 \times 10^8 \text{ s}$ (dotted).]
matter annihilation modes are plotted, each as a function of the WIMP mass. We conclude that the data are consistent with any of these annihilation modes, especially if systematic uncertainties associated with foreground subtraction and diffusion parameters are considered. Very light WIMPs are unlikely to be capable of generating the observed spectrum of the haze.

In the lower frame of Fig. 3 we plot the annihilation cross section required to generate the observed intensity of the WMAP haze in the 22 GHz channel. Remarkably, we find that for a wide range of WIMP masses and annihilation modes, the cross section required is very close to the value expected from a thermal relic with an s-wave annihilation cross section, $\sigma v \sim 3 \times 10^{-26} \text{cm}^3/\text{s}$. Note that boost factors, which could result from a clumped dark matter distributions, are not required to generate the observed intensity of the haze.

To summarize, we have shown that the observed features of the WMAP haze match the expected signal produced through the synchrotron emission of dark matter annihilation products for a model with a cusped halo profile scaling as $\rho(r) \propto r^{-1.2}$ in the inner kiloparsecs, and an annihilation cross section of $\sim 3 \times 10^{-26} \text{cm}^3/\text{s}$. A wide range of annihilation modes are consistent with the synchrotron spectrum, and no boost factors are required.

We emphasize that the properties required of a WIMP to generate the haze are precisely those anticipated for the most theoretically attractive particle dark matter candidates. In particular, neutralinos in supersymmetric models typically annihilate to heavy quarks or gauge or Higgs bosons, and naturally have masses and annihilation cross sections in the range inferred by the haze. Kaluza-Klein dark matter particles in models with universal extra dimensions annihilate mostly to charged leptons, which favors somewhat larger WIMP masses to generate the haze. Non-thermal dark matter candidates with annihilation cross sections much larger than $3 \times 10^{-26} \text{cm}^3/\text{s}$ appear to be ruled out, as they would have generated a brighter haze intensity than is observed.

If, in fact, the haze is generated through dark matter annihilations, this will have very interesting implications for the upcoming GLAST experiment. If the $\rho(r) \propto r^{-1.2}$ slope of the halo profile continues to the inner Galaxy, the gamma ray flux from the Galactic Center will be observable by GLAST, so long as the WIMP is lighter than several hundred GeV, in spite of the presence of the observed HESS source in the region.\[18\]

We would like to thank Joanna Dunkley for discussions. This work has been supported by the US Department of Energy and by NASA grant NAG5-10842.
