I. PAMELA/ATIC AND NEW DARK FORCES

Thermal weakly interacting massive particles (WIMPs) remain one of the most attractive candidates for dark matter. In addition to appearing generically in theories of weak-scale physics beyond the standard model, they naturally give the appropriate relic abundance. Such particles also are very promising in terms of direct and indirect detection, because they must have some connection to standard model particles.

Indirect detection is particularly attractive in this respect. If dark matter annihilates to some set of standard model states, cosmic ray detectors such as PAMELA, ATIC, and Fermi/GLAST have the prospect of detecting it. This is appealing, because it directly ties the observable to the processes that determine the relic abundance.

For a weak-scale thermal particle, the relic abundance in the case of s-wave annihilation is approximately set by

$$\Omega h^2 \approx 0.1 \times \left( \frac{(\sigma v)_{\text{freeze}}}{3 \times 10^{-26} \text{cm}^3\text{s}^{-1}} \right)^{-1}.$$  

For perturbative annihilations, s-wave dominates in the late universe, so this provides an approximate upper limit on the signal that can be observed in the present day. Such a low cross section makes indirect detection, whereby the annihilation products of dark matter are detected in cosmic ray detectors, a daunting task.

However, recent experiments have confirmed the long-standing suspicion that there are more positrons and electrons at 10s–100s of GeV than can be explained by supernova shocks and interactions of cosmic ray protons with the ISM. The experiments are

(i) **PAMELA.—** The Payload for Antimatter Matter Exploration and Light-nuclei Astrophysics has reported results [1] indicating a sharp upturn in the positron fraction \( (e^+/e^+ + e^-) \) from 10–100 GeV, counter to what is expected from high-energy cosmic rays interacting with the interstellar medium (ISM). This result confirms excesses seen in previous experiments, such as HEAT [2,3] and AMS-01 [4]. One possible explanation for this is dark matter annihilation into \( e^+e^- \) [5–7], but this requires a large cross section [8].

(ii) **ATIC.—** The Advanced Thin Ionization Calorimeter is a balloon-borne cosmic ray detector which studies electrons and positrons (as well as other cosmic rays)...
up to \(\sim\)TeV energies, but cannot distinguish positrons and electrons. The primary astrophysical sources of high-energy electrons are expected to be supernovae: electrons are accelerated to relativistic speeds in supernova remnants and then diffuse outward. The ATIC-2 experiment reported a 4–6\(\sigma\) excess (over a simple power law) in its \(e^+ + e^-\) data [9] at energies of \(\sim 300–800\) GeV, with a sharp cutoff in the 600–800 GeV range. Dark matter would seem a natural candidate for this as well, with its mass scale determining the cutoff.

(iii) WMAP.—Studies of the WMAP microwave emission from the galactic center show a hard component not spatially correlated with any known galactic emission mechanism. This “WMAP haze” [10,11] can be explained as synchrotron radiation from electrons and positrons produced from dark matter annihilation in the galactic center [12].

(iv) EGRET.—Gamma-ray measurements in the galactic center (inner 5\(\degree\)) provide hints of an excess at 10–50 GeV [13]. Strong et al. reanalyzed EGRET data and found a harder spectrum at these energies than previously derived, using the improved EGRET sensitivity estimates of [14]. Despite poor spatial resolution, Strong et al. found an excess in this energy range above the expected \(\pi^0\) gamma-ray emission from cosmic ray protons interacting with the interstellar medium (see Fig. 8 of [13]). Such \(\gamma\)’s could naturally arise from inverse-Compton scattering of high-energy electrons and positrons off of starlight and the cosmic microwave background (CMB).

Taken together, these make a compelling case for excessive electronic production in the galaxy. While individual astrophysical explanations may exist for each signal (pulsar wind nebulae for PAMELA and ATIC [15–17], for instance, supernovae for the WMAP haze [18]), the data cry out for a unified explanation. Dark matter annihilations provide an appealing candidate.

In addition to the above, there are two other anomalies that are worth mentioning. The INTEGRAL 511 keV signal indicates \(3 \times 10^{12} e^+ / s\) annihilating in the galactic center, far more than expected from supernovae. The spectrum suggests that these positrons are injected with relatively low energies \((E \lesssim \) few MeV), and so form a distinct population from those above. eXciting dark matter (XDM) [19] can naturally explain such low energy positrons with \(\sim 1\) MeV excited states of the dark matter, while still producing the high-energy positrons via annihilation [20,21]. Lastly, there is the DAMA/LIBRA indication of an annual modulation consistent with that expected from dark matter induced nuclear scattering [22]. Such a signal is difficult to reconcile with null results of other experiments, but can be reconciled with \(\sim 100\) keV excited states in the “inelastic dark matter” (iDM) scenario [23–25]. Although we are motivated by the specific signals above (PAMELA/ATIC as well as the haze and EGRET), the picture we are led to for explaining them naturally incorporates the necessary ingredients to explain the INTEGRAL and DAMA signals as well.

Focusing on only the high-energy positrons and electrons, there are a number of challenges to any model of dark matter. These are

(i) A large cross section.—Studies of PAMELA and ATIC signals seem to require a cross section much larger than what is allowed by thermal relic abundance. Boost factors of \(\mathcal{O}(100)\) or more above what would be expected for a thermal WIMP are required to explain these excesses [26,27].

(ii) A large cross section into leptons.—Typical annihilations via Z bosons produce very few hard leptons. Annihilations into W bosons produce hard leptons, but many more soft leptons through the hadronic shower. Higgs bosons and heavy quarks produce even softer spectra of leptons, all of which seem to give poor fits to the data. At the same time, absent a leptophilic gauge boson, it is a challenge to construct means by which dark matter would annihilate directly to leptons.

(iii) A low cross section into hadrons.—Even if a suitably high annihilation rate into leptons can be achieved, the annihilation rate into hadronic modes must be low. Limits from diffuse galactic gamma rays [28], as well as gamma rays from the center of the galaxy, constrain the production of \(\pi^0\)’s arising from the dark matter annihilation. PAMELA measurements of antiprotons tightly constrain hadronic annihilations as well [27]. Consequently, although quark and gauge boson annihilation channels may occur at some level, the dominant source of leptons must arise through some other channel.

The combination of these issues makes the observed high-energy anomalies—especially ATIC and PAMELA—difficult to explain with thermal dark matter annihilation. However, we shall see that the inclusion of a new force in the dark sector simultaneously addresses all of these concerns.

**New forces in the dark sector**

A new interaction for the dark sector can arise naturally in a variety of theories of physics beyond the standard model, and is thus well motivated from a theoretical point of view. Although there are strong limits on the self-interaction scattering cross section from structure formation [29,30], the presence of some new force-carrying boson should be expected, with only the mass scale in question. A light boson could arise naturally if its mass scale is generated radiatively [31], or if it were a pseudogoldstone boson.

One of the important modifications that can arise with a new light boson is an enhancement of the annihilation
cross section via a mechanism first described by Sommerfeld [32]. The presence of a new force carrier can distort the wave function of the incoming particles away from the plane-wave approximation, yielding significant enhancements (or suppressions) to annihilation cross sections [33]. Equivalently, ladder diagrams involving multiple exchanges of the force carrier must be resummed (Fig. 1). As we shall describe, the Sommerfeld enhancement can only arise if the gauge boson has a mass \( m_{\phi} \lesssim \alpha M_{DM} \sim \) few GeV. Thus, with the mass scale of \( \sim 800 \text{ GeV} \) selected by ATIC, and the large cross sections needed by both ATIC and PAMELA, the mass scale for a new force carrier is automatically selected. Interactions involving W and Z bosons are insufficient at this mass scale.

Once this new force carrier \( \phi \) is included, the possibility of a new annihilation channel \( \chi\chi \rightarrow \phi\phi \) opens up, which can easily be the dominant annihilation channel. Absent couplings to the standard model, some of these particles could naturally be stable for kinematical reasons; even small interactions with the standard model can then lead them to decay only into standard model states. If they decay dominantly into leptons, then a hard spectrum of positrons arises very naturally. Motivated by the setup of XDM, Cholis, Goodenough, and Weiner [20] first invoked this mechanism of annihilations into light bosons to provide a simple explanation for the excesses of cosmic ray positrons seen by HEAT without excessive antiprotons or photons. Simple kinematics can forbid a decay into heavier hadronic states, and as we shall see, scalars lighter than \( \sim 250 \text{ MeV} \) and vectors lighter than \( \sim \text{GeV} \) both provide a mode by which the dark matter can dominantly annihilate into very hard leptons, with few or no \( \pi^0 \)'s and antiprotons.

In the following sections, we shall make these points more concretely and delineate which ranges of parameters most easily explain the data; but the essential point is very simple: if the dark matter is \( O(800 \text{ GeV}) \) and interacts with itself via a force carrier with mass \( m_{\phi} \sim \text{GeV} \), annihilation cross sections can be considerably enhanced at present times via a Sommerfeld enhancement, far exceeding the thermal freeze-out cross section. If that boson has a small mixing with the standard model, its mass scale can make it kinematically incapable of decaying via a hadronic shower, preferring muons, electrons and, in some cases, charged pions, and avoiding constraints from \( \pi^0 \)'s and antiprotons. If the force-carriers are non-Abelian gauge bosons, we shall see that other anomalies may be incorporated naturally in this framework, explaining the INTEGRAL 511 keV line via the mechanism of “\( \chi\chi \) exciting dark matter”, and the DAMA annual modulation signal via the mechanism of “inelastic dark matter” (iDM). We shall see that the excited states needed for both of these mechanisms \( [O(1 \text{ MeV}) \text{ for XDM and } O(100 \text{ keV}) \text{ for iDM}] \) arise naturally with the relevant mass splitting generated radiatively at the correct scale.

II. SOMMERFELD ENHANCEMENTS FROM NEW FORCES

A new force in the dark sector can give rise to the large annihilation cross sections required to explain recent data, through the “Sommerfeld enhancement” that increases the cross section at low velocities [37]. A simple classical analogy can be used to illustrate the effect. Consider a point particle impinging on a star of radius \( R \). Neglecting gravity, the cross section for the particle to hit and be absorbed by the star is \( \sigma_0 = \pi R^2 \). However, because of gravity, a point coming from a larger impact parameter than \( R \) will be sucked into the star. The cross section is actually \( \sigma = \pi b_{\text{max}}^2 \), where \( b_{\text{max}} \) is the largest the impact parameter can be so that the distance of closest approach of the orbit is \( R \). If the velocity of the particle at infinity is \( v \), we can determine \( b_{\text{max}} \) trivially using conservation of energy and angular momentum, and we find that

\[
\sigma = \sigma_0 \left(1 + \frac{v_{\text{esc}}^2}{v^2}\right)
\]  

where \( v_{\text{esc}}^2 = 2G_NM/R \) is the escape velocity from the surface of the star. For \( v \ll v_{\text{esc}} \), there is a large enhancement of the cross section due to gravity; even though the correction vanishes as gravity shuts off \( (G_N \rightarrow 0) \), the expansion parameter is \( 2G_NM/(Rv^2) \) which can become large at small velocity.

The Sommerfeld enhancement is a quantum counterpart to this classical phenomenon. It arises whenever a particle has an attractive force carrier with a Compton wavelength longer than \( (\alpha M_{DM})^{-1} \), i.e. dark matter bound states are present in the spectrum of the theory. (We generically refer to \( \alpha \sim \text{coupling}^2/4\pi \), assuming such couplings are comparable to those in the standard model, with \( 10^{-3} \leq \alpha \leq 10^{-1} \).

Let us study this enhancement more quantitatively. We begin with the simplest case of interest, namely, a particle interacting via a Yukawa potential. We assume a dark matter particle \( \chi \) coupling to a mediator \( \phi \) with coupling strength \( \lambda \). For \( s \)-wave annihilation in the nonrelativistic limit, the reduced two-body wave function obeys the radial Schrödinger equation.
\[
\frac{1}{m_x} \psi''(r) - V(r)\psi(r) = -m_x v^2 \psi(r),
\]

where the s-wave wave function \(\Psi(r)\) is related to \(\psi(r)\) as \(\Psi(r) = \psi(r)/r\), \(v\) is the velocity of each particle in the center-of-mass frame (here we use units where \(\hbar = c = 1\)), and for scalar \(\phi\) the potential takes the usual Yukawa form,

\[
V(r) = -\frac{\lambda^2}{4\pi r} e^{-m_\phi r}.
\]

The interaction in the absence of the potential is pointlike. As reviewed in the appendix, the Sommerfeld enhancement in the scattering cross section due to the potential is given by

\[
S = \left| \frac{\psi(\infty)/\psi(0)}{\psi'}(0) \right|^2,
\]

where we solve the Schrödinger equation with boundary conditions \(\psi(0) = 0\), \(\psi'(0) = \sin(kr + \delta)\) as \(r \to \infty\). In the recent dark matter literature, a different but completely equivalent expression is used, with

\[
S = |\psi(\infty)/\psi(0)|^2,
\]

where we solve the Schrödinger equation with the outgoing boundary condition \(\psi'(\infty) = \mathrm{im}_\chi \psi(\infty)\) [34].

Defining the dimensionless parameters

\[
\alpha = \frac{\lambda^2}{4\pi}, \quad \epsilon_v = \frac{v}{\alpha}, \quad \epsilon_\phi = \frac{m_\phi}{\alpha m_x},
\]

and rescaling the radial coordinate with \(r' = \alpha m_x r\), we can rewrite Eq. (3) as

\[
\psi''(r') + \left(\epsilon_v^2 + \frac{1}{r'} e^{-\epsilon_\phi r'}\right)\psi(r') = 0.
\]

In the limit where the \(\phi\) mass goes to zero (\(\epsilon_\phi \to 0\)), the effective potential is just the Coulomb potential and Eq. (8) can be solved analytically, yielding an enhancement factor of

\[
S = \left| \frac{\psi(\infty)/\psi(0)}{\psi'}(0) \right|^2 = \frac{\pi/\epsilon_v}{1 - e^{-\pi/\epsilon_v}}.
\]

For nonzero \(m_\phi\) and hence nonzero \(\epsilon_\phi\), there are two important qualitative differences. The first is that the Sommerfeld enhancement saturates at low velocity—the attractive force has a finite range, and this limits how big the enhancement can get. At low velocities, once the deBroglie wavelength of the particle \((Mv)^{-1}\) gets larger than the range of the interaction \(m_\phi^{-1}\), or equivalently once \(\epsilon_v\) drops beneath \(\epsilon_\phi\), the Sommerfeld enhancement saturates at \(S \sim \frac{1}{\epsilon_\phi}\). The second effect is that for specific values of \(\epsilon_\phi\), the Yukawa potential develops threshold bound states, and these give rise to resonant enhancements of the Sommerfeld enhancement. We describe some of the parametrics for these effects in the appendix, but for reliable numbers Eq. (8) must be solved numerically, and plots for the enhancement as a function of \(\epsilon_\phi\) and \(\epsilon_v\) are given there. As we will see in the following, we will be interested in a range of \(m_\phi \sim 100\) MeV–GeV; with reasonable values of \(\alpha\), this corresponds to \(\epsilon_\phi\) in the range \(\sim 10^{-2} – 10^{-1}\), yielding Sommerfeld enhancements ranging up to a factor \(\sim 10^3 – 10^4\). At low velocities, the finite range of the Yukawa interaction causes the Sommerfeld enhancement to saturate, so the enhancement factor cannot greatly exceed this value even at arbitrarily low velocities. The nonzero mass of the \(\phi\) thus prevents the catastrophic overproduction of gammas in the early universe pointed out by [39].

Having obtained the enhancement \(S\) as a function of \(\epsilon_\phi\) and \(\epsilon_v\), we must integrate over the velocity distribution of the dark matter in Earth’s neighborhood, to obtain the total enhancement to the annihilation cross section for a particular choice of \(\phi\) mass and coupling \(\lambda\). We assume a Maxwell-Boltzmann distribution for the one-particle velocity, truncated at the escape velocity:

\[
f(v) = \begin{cases} \frac{Nv^2 e^{-v^2/2\sigma^2}}{\sqrt{2\pi}\sigma} & v \leq v_{esc} \\ 0 & v > v_{esc}. \end{cases}
\]

The truncation does not significantly affect the results, as the enhancement factor drops rapidly with increasing velocity. The one-particle rms velocity is taken to be \(150\) km/s in the baseline case, following simulations by Governato et al. [40]. Figure 2 shows the total enhancement as a function of \(m_\phi/m_\chi\) and the coupling \(\lambda\) for this case.

**FIG. 2.** Contours for the Sommerfeld enhancement factor \(S\) as a function of the mass ratio \(m_\phi/m_\chi\) and the coupling constant \(\lambda\), \(\sigma = 150\) km/s.
One can inquire as to whether dark matter annihilations in the early universe experience the same Sommerfeld enhancement as dark matter annihilations in the galactic halo at the present time. This is important, because we are relying on this effect precisely to provide us with an annihilation cross section in the present day much larger than that in the early universe. However, it turns out that particles leave thermal equilibrium long before the Sommerfeld enhancement turns on. This is because the Sommerfeld enhancement occurs when the expansion parameter $\alpha/v = 1/\epsilon_v$ is large. In the early universe, the dark matter typically decouples at $T_{\text{CMB}} \sim m_\chi/20$, or $v \sim 0.3c$. Since we are taking $\alpha \leq 0.1$ generally, the Sommerfeld enhancement has not turned on yet. More precisely, in the early-universe regime $\epsilon_v \gg \epsilon_\phi$, so we can use Eq. (9) for the massless limit. Where $\epsilon_v \gg 1$, Eq. (9) yields $S = 1 + \pi/2 \epsilon_v$: thus the enhancement should be small and independent of $m_\phi$. Figure 3 shows this explicitly. We are left with the perturbative annihilation cross section $\sigma \sim \alpha^2/m_\chi^2$, which gives us the usual successful thermal relic abundance.

At some later time, as the dark matter velocities redshift to lower values, the Sommerfeld enhancement turns on and the annihilations begin to scale as $a^{-5/2}$ (before kinetic decoupling) or $a^{-2}$ (after decoupling). From decoupling until matter-radiation equality, where the Hubble scale begins to evolve differently, or until the Sommerfeld effect is saturated, dark matter annihilation will produce a uniform amount of energy per comoving volume per Hubble time. This uniform spread of energy injected could have potentially interesting signals for observations of the early universe. An obvious example would be a possible effect on the polarization of the CMB, as described in [41–43]. Because at the time of matter-radiation equality, the dark matter may have slowed to velocities of $v \sim 10^{-6}c$ or slower, the large cross sections could yield a promising signal for upcoming CMB polarization observations, including Planck. However, we emphasize that saturation of the cross section at low $v$ avoids the runaway annihilations discussed by [39].

III. MODELS OF THE SOMMERFELD FORCE AND NEW ANNIHILATION CHANNELS

What sorts of forces could give rise to a large Sommerfeld enhancement of the dark matter annihilation? As we have already discussed, we must have a light force carrier. On the other hand, a massless particle is disfavored by the agreement between big bang nucleosynthesis calculations and primordial light element measurements [44], as well as constraints from WMAP on new relativistic degrees of freedom [45]. Thus, we must have massive degrees of freedom, which are naturally light, while still coupling significantly to the dark matter. There are three basic candidates.

(i) The simplest possibility is coupling to a light scalar field, which does give rise to an attractive interaction. However, given that we need an $O(1)$ coupling to the DM fields, this will typically make it unnatural for the scalar to stay as light as is needed to maximize the Sommerfeld enhancement, unless the dark matter sector is very supersymmetric. This can be a challenge given that we are expecting the dark matter to have a mass $O(\text{TeV})$. Consequently, the natural scale for a scalar which couples to it would also be $O(\text{TeV})$, although this conclusion can be evaded with some simple model-building.

(ii) The scalar could be naturally light if it is a pseudo-scalar $\pi$ with a goldstone-like derivative coupling to matter $1/FJ_\mu \partial^\mu \pi$. This does lead to a long-range spin-dependent potential of the form $V(\vec{r}) = \frac{1}{r} (\vec{S}_1 \cdot \vec{S}_2 - 3 \vec{S}_1 \cdot \hat{r} \vec{S}_2 \cdot \hat{r})$, but the numerator vanishes when averaged over angles, so there is no long-range interaction in the $s$-wave and hence no Sommerfeld enhancement.

(iii) Finally, we can have a coupling to spin-1 gauge fields arising from some dark gauge symmetry $G_{\text{dark}}$. Since the gauge fields must have a mass $O(\text{GeV})$ or less, one might worry that this simply begs the question, as the usual explanation of such a light gauge boson requires the existence of a scalar with a mass of $O(\text{GeV})$ or less. However, because that scalar need not couple directly to the dark matter, it is sufficiently sequestered that its small...
mass is technically natural. Indeed, the most straightforward embedding of this scenario within SUSY [31] naturally predicts the breaking scale for $G_{\text{dark}}$ near $\sim$ GeV. Alternatively, no fundamental scalar is needed, with the vector boson possibly generated by the condensate of a strongly coupled theory.

At this juncture it is worth discussing an important point. As we have emphasized, to produce a Sommerfeld enhancement, we need an attractive interaction. Scalars (like gravitons) universally mediate attractive forces, but gauge fields can give attraction or repulsion, so do we generically get a Sommerfeld enhancement? For the case of the Majorana fermion (or real scalar), in particular, the dark matter does not carry any charge, and there does not appear to be any long-range force to speak of, so the question of the enhancement is more interesting. As we discuss in a little more detail in the appendix, the point is that the gauge symmetry is broken. The breaking dominates the properties of the asymptotic states. For instance, the dark matter must be part of a multiplet with at least two states, since a spin-1 particle cannot have a coupling to a single neutral state. The gauge symmetry breaking leads to a mass splitting between the states, which dominates the long-distance behavior of the theory, determining which state is the lightest, and therefore able to survive to the present time and serve as initial states for collisions leading to annihilation. However, if the mass splitting between the states is small enough compared to the kinetic energy of the collision, the gauge-partner DM states will necessarily be active in the collision, and eventually at distances smaller than the gauge boson masses, the gauge breaking is a negligible effect. Since the asymptotic states are in general roughly equal linear combinations of “positive” and “negative” charge gauge eigenstates, the result of asymptotic gauge breaking at short distances is that the incoming scattering states are linear combinations of gauge eigenstates, so the two-body wave function will be a linear combination of attractive and repulsive channels. While two-body wave function in the repulsive channel is indeed suppressed at the origin, the attractive part is enhanced. Therefore there is still a Sommerfeld enhancement, suppressed at most by an $\mathcal{O}(1)$ factor reflecting the attractive component of the two-body state. (This is of course completely consistent with the Sommerfeld enhancements seen for ordinary WIMP annihilations, mediated by $W/Z/\gamma$ exchange.)

Because of the presence of a new light state, the annihilation $\chi \chi \rightarrow \phi \phi$ can, and naturally will, be significant. In order not to spoil the success of nucleosynthesis, we cannot have very light new states in this sector, with a mass $\lesssim 10$ MeV, in thermal equilibrium with the standard model; the simplest picture is therefore that all the light states in the dark sector have a mass $\sim$ GeV. Without any special symmetries, there is no reason for any of these particles to be exactly stable, and the lightest ones can therefore only decay back to standard model states, indeed many SM states are also likely kinematically inaccessible, thus favoring ones that produce high-energy positrons and electrons. This mechanism was first utilized in [20] to generate a large positron signal with smaller $\pi^0$ and $\bar{\rho}$ signals. Consequently, an important question is the tendency of $\phi$ to decay to leptons. This is a simple matter of how $\phi$ couples to the standard model. (A more detailed discussion of this can be found in [31].)

A scalar $\phi$ can couple with a dilatonlike coupling $\phi F_{\mu\nu} F_{\mu\nu}$, which will produce photons and hadrons (via gluons). Such a possibility will generally fail to produce a hard $e^+ e^-$ spectrum. A more promising approach would be to mix $\phi$ with the standard model Higgs with a term $\kappa \phi^2 h^4$. Should $\phi$ acquire a vev $\langle \phi \rangle \sim m_\phi$, then we yield a small mixing with the standard model Higgs, and the $\phi$ will decay into the heaviest fermion pair available. For $m_\phi \lesssim 200$ MeV it will decay directly to $e^+ e^-$, while for $200$ MeV $\leq m_\phi \leq 250$ MeV, $\phi$ will decay dominantly to muons. Above that hadronic states appear, and pion modes will dominate. Both $e^+ e^-$ and $\mu^+ \mu^-$ give good fits to the PAMELA data, while $e^+ e^-$ gives a better fit to PAMELA + ATIC.

A pseudoscalar, while not yielding a Sommerfeld enhancement, could naturally be present in this new sector. Such a particle would typically couple to the heaviest particle available, or through the axion analog of the dilaton coupling above. Consequently, the decays of a pseudoscalar would be similar to those of the scalar.

A vector boson will naturally mix with electromagnetism via the operator $F^{\mu\nu}_V F_{\mu\nu}$. This possibility was considered some time ago in [46]. Such an operator will cause a vector $\phi^\mu_\mu$ to couple directly to charge. Thus, for $m_\phi \approx 2 m_\mu$, it will decay to $e^+ e^-$, while for $2 m_\mu \leq m_\phi \lesssim 2 m_\pi$ it will decay equally to $e^+ e^-$ and $\mu^+ \mu^-$. Above $2 m_\pi$, it will decay $40\% e^+ e^-$, $40\% \mu^+ \mu^-$, and $20\% \pi^+ \pi^-$. At these masses, no direct decays into $\pi^0$’s will occur because they are neutral and the hadrons are the appropriate degrees of freedom. At higher masses, where quarks and QCD are the appropriate degrees of freedom, the $\phi$ will decay to quarks, producing a wider range of hadronic states, including $\pi^0$’s, and, at suitably high masses $m_\phi \approx 2$ GeV, antiprotons as well [47]. In addition to XDM [19], some other important examples of theories under which dark matter interacts with new forces include WIMPless models [49], mirror dark matter [50], and secluded dark matter [51].

Note that, while these interactions between the sectors can be small, they are all large enough to keep the dark and standard model sectors in thermal equilibrium down to temperatures far beneath the dark matter mass, and (as mentioned in the previous section), we can naturally get the correct thermal relic abundance with a weak-scale dark matter mass and perturbative annihilation cross sections. Kinetic equilibrium in these models is naturally maintained down to the temperature $T_{\text{CMB}} \sim m_\phi$ [52].
IV. A NONABELIAN $G_{\text{dark}}$: INTEGRAL, DIRECT DETECTION, AND DAMA

Up to this point we have focused on a situation where there is a single force-carrying boson $\phi$, whether vector or scalar. Already, this can have significant phenomenological consequences. In mixing with the standard model Higgs boson, there is a nuclear recoil cross section mediated by $\phi$. With technically natural parameters as described in [19], the rate is unobservable, although in a two-Higgs doublet model the cross section is within reach of future experiments [53].

In contrast, an 800 GeV WIMP which interacts via a particle that couples to charge is strongly constrained. Because the $\phi$ boson is light and couples to the electromagnetic vector current, there are strong limits. The cross section per nucleon for such a particle is [51]

$$\sigma_0 = \frac{16\pi Z^2 \alpha_{\text{SM}} \alpha_{\text{Dark}} \epsilon^2 \mu_{ne}}{A^2 m_\phi} = \left( \frac{Z^2}{32} \frac{A}{10^{-3}} \frac{\epsilon}{137^{-1}} \frac{\mu_{ne}}{938 \text{ MeV}} \right) \left( \frac{1 \text{ GeV}}{m_\phi} \right)^4 \times 1.8 \times 10^{-37} \text{ cm}^2,$$  \hspace{1cm} (11)

where $\alpha_{\text{Dark}}$ is the coupling of the $\phi$ to the dark matter, $\epsilon$ describes the kinetic mixing, $\mu_{ne}$ is the reduced mass of the DM-nucleon system, and $\alpha_{\text{SM}}$ is the standard model electromagnetic coupling constant. With the parameters above, such a scattering cross section is excluded by the present CDMS [54] and XENON [55] bounds by 6 orders of magnitude. However, this limit can be evaded by splitting the two Majorana components of the Dirac fermion [23] or by splitting the scalar and pseudoscalar components of a complex scalar [56,57]. Since the vector coupling is off-diagonal between these states, the nuclear recoil can only occur if there is sufficient kinetic energy to do so. If the splitting $\delta > v^2 \mu/2$ (where $\mu$ is the reduced mass of the WIMP-nucleus system) no scattering will occur. Such a splitting can easily arise for a $U(1)$ symmetry by a $U(1)$ breaking operator such as $\frac{1}{M} \psi^c \psi h^* h^*$ which generates a small Majorana mass and splits the two components (see [24] for a discussion).

Remarkably, for $\delta \sim 100$ keV one can reconcile the DAMA annual modulation signature with the null results of other experiments [23–25], in the “inelastic dark matter” scenario. We find that the ingredients for such a scenario occur here quite naturally. However, the splitting here must be $O(100 \text{ keV})$ and the origin of this scale is unknown, a point we shall address shortly.

Exciting dark matter from a non-Abelian symmetry

One of the strongest motivations for a $\sim$GeV mass $\phi$ particle prior to the present ATIC and PAMELA data was in the context of eXciting dark matter [19]. In this scenario, dark matter excitations could occur in the center of the galaxy via inelastic scattering $\chi \chi \rightarrow \chi' \chi'$. If $\delta = m_{\chi'} - m_\chi - m_\chi \geq 2m_\xi$, the decay $\chi' \rightarrow e^+ e^-$ can generate the excess of 511 keV x-rays seen from the galactic center by the INTEGRAL [58,59] satellite. However, a large (nearly geometric) cross section is needed to produce the large numbers of positrons observed in the galactic center, necessitating a boson with mass of the order of the momentum transfer, i.e., $m_\phi \lesssim M_\nu \sim \text{GeV}$, precisely the same scale as we require for the Sommerfeld enhancement. But where does the scale $\delta \sim \text{MeV}$ come from? Remarkably, it arises radiatively at precisely the appropriate scale. [60]

We need the dark matter to have an excited state, and we will further assume the dark matter transforms under a non-Abelian gauge symmetry. Although an excited state can be present with simply a $U(1)$, this only mediates the process $\chi \chi \rightarrow \chi' \chi'$. If this requires energy greater than $4m_\xi$, it is very hard to generate enough positrons to explain the INTEGRAL signal. If we assume the dark matter is a Majorana fermion, then it must transform as a real representation of the gauge symmetry. For a non-Abelian symmetry, the smallest such representation will be three-dimensional [such as a triplet of $SU(2)$]. This will allow a scattering $\chi_1 \chi_1 \rightarrow \chi_2 \chi_3$. If $m_3$ is split from $m_3 \sim m_1$ by an amount $\delta \sim \text{MeV}$, we have arrived at the setup for the XDM explanation of the INTEGRAL signal.

Because the gauge symmetry is Higgsed, we should expect a splitting between different states in the dark matter multiplet. This could arise already at tree level, if the dark matter has direct couplings to the Higgs fields breaking the gauge symmetry; these could naturally be as large as the dark gauge breaking scale $\sim \text{GeV}$ itself, which would be highly undesirable, since we need these splittings to be not much larger than the DM kinetic energies in order to get a Sommerfeld enhancement to begin with. However, such direct couplings to the Higgs bosons could be absent or very small (indeed most of the Yukawa couplings in the standard model are very small). We will assume that such a direct coupling is absent or negligible. The gauge breaking in the gauge boson masses then leads, at one loop, to splittings between different dark matter states, analogous to the familiar splitting between charged and neutral components of a Higgsino or Dirac neutrino. These splittings arise from infrared effects and so are completely calculable, with sizes generically $O(\alpha m_\phi)$ in the standard model or $O(\alpha m_{\phi}) \sim \text{MeV}$ in the case at hand. Thus we find that the MeV splittings needed for XDM arise automatically once the mass scale of the $\phi$ has been set to $O(\text{GeV})$.

We would like $\chi_2$ and $\chi_1$ to stay similar in mass, which can occur if the breaking pattern approximately preserves a custodial symmetry. However, if they are too degenerate, we are forced to take $\epsilon < 10^{-5}$ in order to escape direct-detection constraints. On the other hand, we do not want too large of a splitting between $\chi_2$ and $\chi_1$, as this would
suppress the rate of positron production for INTEGRAL. Thus, we are compelled to consider \( \delta_{21} \sim 100-200 \text{ keV} \), which puts us precisely in the range relevant for the inelastic dark matter explanation of DAMA. (See Fig. 4.)

All of these issues require detailed model-building, which we defer to future work; however, existence proofs are easy to construct. The Lagrangian is of the form

\[
\mathcal{L} = \mathcal{L}_{\text{SM}} + \mathcal{L}_{\text{Dark}} + \mathcal{L}_{\text{mix}}.
\]

As a familiar example, imagine that \( G_{\text{Dark}} = SU(2) \times U(1) \), with gauge bosons \( w_{\mu \lambda} \) and \( b_{\mu} \), which we collectively refer to as \( a_{\mu i} \), and the dark matter multiplet \( \chi \) transforming as a triplet under \( SU(2) \) and neutral under the \( U(1) \); it could be either a scalar or fermion. We also assume that some set of Higgs bosons completely break the symmetry. Working in unitary gauge, the tree-level dark sector Lagrangian is

\[
\mathcal{L}_{\text{Dark}} = \mathcal{L}_{\text{Gauge Kin}} + \frac{1}{4} m_i^2 a_{\mu i} a_{\mu j} + \cdots,
\]

where the \( m_i^2 \) makes all the dark spin-1 fields massive, and \( \cdots \) refers to other fields such as the physical Higgses that could be present. At one loop, this broken gauge symmetry will induce splittings between the three real DM states all of \( \mathcal{O}(\alpha_{\text{Dark}} m_{\text{Dark}}) \) as just discussed above. The leading interaction between the two sectors is via kinetic mixing between the new \( U(1) \) and the photon (which is inherited from such a mixing with hypercharge):

\[
\mathcal{L}_{\text{mix}} = \frac{1}{2} e b_{\mu \nu} F_{\mu \nu}.
\]

We put an \( e \) in front of this coupling because it is natural for this coupling to be small; it can be induced at one loop by integrating out some heavy states (of any mass between the GeV and Planck scales) charged under both this new \( U(1) \) and hypercharge. This can easily make \( e \sim 10^{-4} \sim 10^{-3} \). Even without a \( U(1) \), a similar mixing could be achieved with an “S-parameter” type operator \( \text{Tr}[(\Phi/M)^2 G_{\mu \nu} F_{\mu \nu}] \), where \( \Phi \) is a dark Higgs field with quantum numbers such that \( (\Phi/M)^2 \) transforms as an adjoint under \( G_{\text{Dark}} \); it is reasonable to imagine that the scale \( M \) suppressing this operator is near the weak scale.

Going back to PAMELA/ATIC, the non-Abelian self-couplings of the vector bosons can have an interesting effect on the annihilation process. For large enough \( \alpha_{\text{Dark}} \), the gauge bosons radiate other soft and collinear gauge bosons leading to a “shower”; this can happen when \( \alpha_{\text{Dark}} \log^2(M_p/m_p) \gtrsim 1 \). While for quite perturbative values of \( \alpha_{\text{Dark}} \) this is not an important effect, it could be interesting for larger values, and would lead to a greater multiplicity of softer \( e^+e^- \) pairs in the final state.

Before closing this section, it is important to point out that it is not merely a numerical accident that the excited states relevant for INTEGRAL and DAMA can actually be excited in the DM-DM collisions and DM collisions with direct-detection nuclei, but is rather a parametric consequence of maximizing the Sommerfeld enhancement for the annihilation cross section needed to explain ATIC/PAMELA. As we already emphasized in our discussion of Sommerfeld enhancement with vector states, vector boson couplings necessarily connect different dark matter mass eigenstates, and therefore there is no enhancement for the annihilation cross section needed to explain ATIC/PAMELA if the mass splittings are much larger than the kinetic energy available in the collision. But this parametrically implies that dark matter collisions should also have the kinetic energy needed to create the excited states, as necessary for the INTEGRAL signal. It is also interesting to note that the condition needed for the large geometric capture cross section, \( m_p \lesssim M_\nu \), also tells us that the Sommerfeld enhancement is as large as can be at these velocities, and has not yet been saturated by the finite range of the force carrier. Furthermore, since the mass of the heavy nuclei in direct-detection experiments is comparable to the dark matter masses, the WIMP-nucleus kinetic energy is also naturally comparable to the excited state splittings. In this sense, even absent the direct experimental hints, signals like those of INTEGRAL and inelastic scattering for direct detection of dark matter are parametric predictions of our picture.

V. SUBSTRUCTURE AND THE SOMMERFELD ENHANCEMENT

As we have seen, the Sommerfeld enhancement leads to a cross section that scales at low energies as \( \sigma v \sim 1/v \). This results in a relatively higher contribution to the dark matter annihilation from low-velocity particles. While the largest part of our halo is composed of dark matter particles with an approximately thermal distribution, there are subhalos with comparable or higher densities. Because these structures generally have lower velocity dispersions than the approximately thermal bulk of the halo, the Sommerfeld-enhanced cross sections can make these components especially important.

Subhalos of the Milky Way halo are of particular interest, and N-body simulations predict that many should be present. There is still some debate as to what effect substructures can have on indirect detection prospects. However, some of these subhalos will have velocity dis-
the low velocity dispersion (of order 10 km/s) of a density comparable to the local density \[65\]. Because of the substructure, with dynamics which mirror those stars, and the Milky Way disk should have an associated dark matter component, with dynamics which mirror those stars, and a density comparable to the local density \[65\]. Because of the low velocity dispersion (of order 10 km/s), our estimates of what is a reasonable Sommerfeld boost may be off by an order of magnitude.

As a consequence of this and other substructure, the Sommerfeld boost of Fig. 2 should be taken as a lower bound, with contributions from substructure likely increasing the cross section significantly further. We will not attempt to quantify these effects here beyond noting the possible increases of an order of magnitude or more suggested by Fig. 5. However, understanding them may be essential for understanding the size and spectrum if this enhancement of the cross section is responsible for the signals we observe.

**VI. OUTLOOK: IMPLICATIONS FOR PAMELA, PLANCK, FERMI/GLAST, AND THE LHC**

If the excesses in positrons and electrons seen by PAMELA and ATIC are arising from dark matter, there are important implications for a wide variety of experiments. It appears at this point that a simple modification of a standard candidate such as a minimal supersymmetric standard model (MSSM) neutralino is insufficient. The need for dominantly leptonic annihilation modes with large cross sections significantly changes our intuition for what we might see, where, and at what level. There are a few clear consequences looking forward.

(i) The positron fraction seen by PAMELA should continue to rise up to the highest energies available to them (\(\sim 270\) GeV), and the electron + positron signal should deviate from a simple power law, as seen by ATIC.

(ii) If the PAMELA/ATIC signal came from a local source, we would not expect additional anomalous electronic activity elsewhere in the galaxy. Dark matter, on the other hand, should produce a significant signal in the center of the galaxy as well, yielding significant signals in the microwave range through synchrotron radiation and in gamma rays through inverse-Compton scattering. The former may already have been seen at WMAP \[10,12\] and the latter at EGRET \[13,14\]. Additional data from Planck and Fermi/GLAST will make these signals robust \[66\].

(iii) We have argued that the most natural way to generate such a large signal is through the presence of a new, light state, which decays dominantly to leptons. It is likely these states could naturally be produced at the LHC in some cascade, leading to highly boosted pairs of leptons as a generic signature of this scenario \[31\].

(iv) Although the cross section is not Sommerfeld enhanced during freeze-out, it can keep pace with the expansion rate over large periods of the cosmic history, between kinetic decoupling and matter-radiation equality. This can have significant implications for a variety of early-universe phenomena as well as the cosmic gamma-ray background \[66\].
(v) The Sommerfeld enhancement is increasingly important at low velocity. Because substructure in the halo typically has velocity dispersions an order of magnitude smaller than the bulk of the halo, annihilations can be an order of magnitude higher, or more. With the already high local cross sections, this makes the prospects for detecting substructure even higher. With the mass range in question, continuum photons would be possibly visible at GLAST, while monochromatic photons [which could be generated in some models [31] would be accessible to air Cerenkov telescopes, such as HESS (see [67] for a discussion, and [68] for HESS limits on DM annihilation in the Canis Major overdensity)].

We have argued that dark matter physics is far richer than usually thought, involving a multiplet of states and a new sector of dark forces. We have been led to propose this picture not by a flight of fancy but rather directly from experimental data. Even so, one can justifiably ask whether such extravagances are warranted. After all, experimental anomalies come and go, and it is entirely possible that the suite of hints that motivate our proposal are incorrect, or that they have more conventional explanations. However, we are very encouraged by the fact that the theory we have presented fits into a very reasonable picture of particle physics, is supported by overlapping pieces of experimental evidence, and that features of the theory motivated by one set of experimental anomalies automatically provide the ingredients to explain the others. Our focus in this paper has been on outlining this unified picture for dark matter; new experimental results coming soon should be able to tell us whether these ideas are even qualitatively on the right track. Needless to say it will then be important to find a specific and simple version of this theory, with a small number of parameters, to more quantitatively confront future data.

ACKNOWLEDGMENTS

We would like to thank Ilias Cholis, Lisa Goodenough, Peter Graham, Juan Maldacena, Patrick Meade, Michele Papucci, Nati Seiberg, Leonardo Senatore, David Shih, Tomer Volansky, and Yosi Gelfand for many stimulating discussions. We thank Matias Zaldarriaga for an enjoyable discussion about classical and quantum Sommerfeld effects, and David Shih for pointing out an error in our discussion of the parametrics for how the enhancement works for various kinds of interactions.

Consider a nonrelativistic particle moving around some origin. There is an interaction Hamiltonian $H_{ann} = U_{ann} \delta^3(\vec{r})$ localized to the origin, which e.g. annihilates our particle or converts to another state in some way. Imagine that the particle is moving in the $z$ direction so that its wave function is

$$\psi_k^{(0)}(\vec{x}) = e^{ikz}$$

(A1)

then the rate for this process is proportional to $|\psi_k^{(0)}(0)|^2$. But now suppose we also have a central potential $V(r)$ attracting or repelling the particle to the origin. We could of course treat $V$ perturbatively, but again at small velocities the potential may not be a small perturbation and can significantly distort the wave function, which can be determined by solving the Schrödinger equation

$$-\frac{1}{2M} \nabla^2 \psi_k + V(r) \psi_k = \frac{k^2}{2M} \psi_k$$

(A2)

with the boundary condition enforcing that the perturbation can only produce outgoing spherical waves as $r \to \infty$:

$$\psi \to e^{ikz} + f(\theta) \frac{e^{ikr}}{r} \quad \text{as} \quad r \to \infty.$$  

(A3)

Now, since the annihilation is taking place locally near $r = 0$, the only effect of the perturbation $V$ is to change the value of the modulus of the wave function at the origin relative to its unperturbed value. Then, we can write

$$\sigma = \sigma_0 S_k,$$

(A4)

where the Sommerfeld enhancement factor $S$ is simply

$$S_k = \frac{|\psi_k^{(0)}(0)|^2}{|\psi_k^{(0)}(0)|^2} = |\psi_k(0)|^2,$$

(A5)

where we are using the normalization of the wave function $\psi$ as given by the asymptotic form of Eq. (A3).

Finding a solution of the Schrödinger equation with these asymptotics is a completely elementary and standard part of scattering theory in nonrelativistic QM, which we quickly review for the sake of completeness. Any solution of the Schrödinger equation with rotational invariance around the $z$ axis can be expanded as

$$\psi_k = \sum_l A_l P_l(\cos \theta) R_{kl}(r),$$

(A6)

where $R_{kl}(r)$ are the continuum radial functions associated with angular momentum $l$ satisfying
\[ -\frac{1}{2M} \frac{d}{dr} \left( r^2 \frac{d}{dr} R_{kl} \right) + \frac{(l+1)}{r^2} + V(r) R_{kl} = \frac{k^2}{2M} R_{kl}. \] 

(A7)

The \( R_{kl}(r) \) are real, and at infinity look like a spherical plane wave which we can choose to normalize as 
\[ R_{kl}(r) \sim \frac{1}{r} \sin(\delta_k r) \] 
where \( \delta_k \ll kr \) as \( r \to \infty \). The phase shift \( \delta_k \) is determined by the requirement that \( R_{kl}(r) \) is regular as \( r \to 0 \). Indeed, if the potential \( V(r) \) does not blow up faster than \( 1/r \) near \( r \to 0 \), then we can ignore it relative to the kinetic terms, and we have that \( R_{kl}(r) \sim r^l \) as \( r \to 0 \); all but the \( l = 0 \) terms vanish at the origin. We now have to choose the coefficients \( A_l \) in order to ensure that the asymptotics of Eq. (A3) are satisfied. Using the asymptotic expansion of \( e^{ikr} \)
\[ e^{ikr} \to \frac{1}{2i\epsilon} \sum_j (2l+1)P_j(\cos \theta) \left[ e^{ikr} - (-1)^l e^{-ikr} \right] \] 
\( (A9) \)
determines the expansion to be 
\[ \psi_k = \frac{1}{k} \sum_j i^j(2l+1)e^{i\delta_j} P_j(\cos \theta) R_{kl}(r). \] 
\( (A10) \)

It is now very simple to determine \( \psi_k(0) \), since as we just commented, \( R_{kl}(r = 0) \) vanishes for every term other than \( l = 0 \). Thus, we have 
\[ S_k = \left| \frac{R_{kl=0}(0)}{k} \right|^2. \] 
\( (A11) \)

We can furthermore make the standard substitution \( R_{kl=0} = \chi_k/r \), then the Schrödinger equation for \( \chi \) turns into a one-dimensional problem 
\[ -\frac{1}{2M} \frac{d^2}{dr^2} \chi_k + V(r) \chi_k = \frac{k^2}{2M} \chi_k, \] 
\( (A12) \)
which we normalize at infinity with the condition 
\[ \chi_k(r) \to \sin(kr + \delta), \] 
\( (A13) \)
and since \( R_{kl=0} \) goes to a constant as \( r \to 0 \), we have to have that \( \chi \to 0 \) as \( r \to 0 \), or
\[ \chi_k(r) \to r \frac{d\chi_k}{dr}(0) \quad \text{as} \quad r \to 0. \] 
\( (A14) \)
Effectively, we can imagine launching \( \chi \) from \( \chi = 0 \) at \( r = 0 \) with different velocities \( \frac{d\chi_k}{dr}(0) \), and these will evolve to some waveform as \( r \to \infty \), but the correct \( \chi_k(0) \) is determined by the requirement that the waveform at infinity have unit amplitude.

Summarizing, then, the Sommerfeld enhancement is 
\[ S_k = \left| \frac{\chi_k(\infty)}{\chi_k(0)} \right|^2. \] 
\( (A15) \)

where \( \chi_k \) satisfies the 1D Schrödinger equation \( (A12) \) with boundary conditions Eqs. (A13) and (A14). As a sanity check, let us see how this works with vanishing potential. The solution that vanishes as \( r \to 0 \) is \( \chi_k(r) = A \sin(kr) \), and matching the asymptotics forces \( A = 1 \). Then \( \chi_k'(0) = k \) and \( S_k = 1 \).

In the recent literature on the subject, a different expression for the Sommerfeld enhancement is used, arising from the use of the optical theorem. We are instructed to solve the same 1D Schrödinger equation \( (A12) \), this time with no special boundary conditions at \( \chi = 0 \), but with boundary conditions so that \( \chi \propto e^{i\epsilon kr} \) as \( r \to \infty \). Then, the Sommerfeld enhancement is said to be
\[ S_k = \frac{|\chi_k(\infty)|^2}{|\chi_k(0)|^2}. \] 
\( (A16) \)

It is very easy to show that these two forms for \( S_k \) agree exactly. To see this, let us begin by denoting \( \chi_1(r) \) to be the solution to the Schrödinger equation \( (A12) \) with the boundary condition \( \chi_1(r) \to \sin(kr + \delta) \) as \( r \to \infty \) \( (A13) \). As shown above, \( \chi_1(0) = 0 \). Let \( \chi_2(r) \) be the linearly independent solution with the boundary condition \( \chi_2(r) \to \cos(kr + \delta) \) as \( r \to \infty \), and define \( A \equiv \chi_2(0) \). Now Eq. (A12) has a conserved Wronskian
\[ W = \chi_1(r)\chi_2'(r) - \chi_2(r)\chi_1'(r). \] 
\( (A17) \)
It is easy to verify directly from the differential equation that \( W'(r) = 0 \); this is true (Abel’s theorem) because there are no \( \chi \) terms in the differential equation. But comparing the values of the conserved Wronskian at zero and \( \infty \),
\[ W(\infty) = -k(\sin^2(kr + \delta) + \cos^2(kr + \delta)) = -k \]
\( = W(0) = -A \chi_1'(0). \] 
\( (A18) \)
So then \( |\chi_1'(0)| = k/|A| \), and our new expression for the Sommerfeld enhancement, \( (A15) \), is just \( S_k = 1/|A|^2 \). Now, our second form \( S_k = |\chi(\infty)|^2 \), where \( \chi(r) \) satisfies the boundary conditions \( \chi(r) \to ikr \chi(r) \) as \( r \to \infty \), and \( \chi(0) = 1 \). By the asymptotic behavior at large \( r \), we can identify \( \chi(r) \) as the linear combination \( \chi(r) = C(\chi_2(r) + i\chi_1(r)) \), where \( C \) is some complex constant. But then \( \chi(0) = CA = 1 \), and \( S_k = |C|^2 \), so as previously we obtain \( S_k = 1/|A|^2 \). Thus the two formulas for the Sommerfeld enhancement are equivalent.

1. Attractive Coulomb potential
Let us see how this works in some simple examples. We are solving the Schrödinger equation for a particle of mass \( M \) and asymptotic velocity \( v \), with potential
\[ V(r) = -\frac{\alpha}{2r}, \quad (A19) \]

which we solve with the boundary conditions of Eqs. (A13) and (A14).

We simplify the analysis by working with the natural dimensionless variables, with the unit of length normalized to the Bohr radius, i.e. we take

\[ r = \alpha^{-1} M^{-1} x. \quad (A20) \]

Then the Schrödinger equation becomes

\[ -\chi'' - \frac{1}{x} \chi = \epsilon^2 \chi. \quad (A21) \]

where we have defined the parameter

\[ \epsilon_v \equiv \frac{v}{\alpha}. \quad (A22) \]

Of course we can solve this exactly in terms of hypergeometric functions to find the result obtained by Sommerfeld

\[ S_k = \left| \frac{x}{1 - e^{-\pi (\epsilon_v)}} \right|. \quad (A23) \]

Note that as \( \epsilon_v \to \infty, S_k \to 1 \) as expected; there is no enhancement at large velocity. For the attractive Yukawa at small velocities we have the enhancement

\[ S_k \to \frac{\pi \alpha}{v}. \quad (A24) \]

while for the repulsive case, there is instead the expected exponential suppression from the need to tunnel through the Coulomb barrier

\[ S_k \sim e^{-\pi(\epsilon_v)/v}. \quad (A25) \]

To get some simple insight into what is going on, let us rederive these results approximately. For \( x \) much smaller than \( 1/\epsilon_v^2 \), we can ignore the kinetic term. In the WKB approximation, the waves are of the form \( x^{1/4} e^{\sqrt{x}} \), so the amplitudes grow like \( x^{1/4} \). In order to match to a unit norm wave near \( x \sim 1/\epsilon_v \), we have to scale the wave function at small \( x \) by a factor \( \sim \epsilon_v^{1/2} \), so that near the origin

\[ \chi \sim x \epsilon_v^{1/2} \sim \alpha M r \epsilon_v^{1/2} \quad (A26) \]

from which we can read off the derivative at the origin

\[ \frac{d\chi}{dr}(0) = \epsilon_v^{1/2} \alpha M, \quad \text{and with } k = M v \text{ we can determine} \]

\[ S_k \sim \left| \frac{\epsilon_v^{1/2} \alpha M}{M v} \right|^2 = \frac{\alpha}{v}. \quad (A27) \]

which is correct parametrically. We can also arrive at this result from the second form for \( S_k \). The computation is even more direct here. We have waveforms growing as \( x^{1/4} \) towards \( x \sim 1/\epsilon_v^{1/2} \). In the region near \( x \sim 1/\epsilon_v \), we must transition to a purely outgoing wave. This is a transmission/reflection problem, and ingoing and outgoing waves from the left will have comparable amplitude. When we continue these back to the origin, we will then have an amplitude reduced by a factor \( \sim \epsilon_v^{1/2} \). Then,

\[ S_k \sim \left( \frac{1}{\epsilon_v^{1/2}} \right)^2 \sim \frac{\alpha}{v}. \quad (A28) \]

2. Attractive well and resonance scattering

Let us do another example, where

\[ V = -V_0 \theta(L - r), \quad V_0 = \frac{\kappa^2}{2M} \quad (A29) \]

The solution inside is \( \chi(r) = A \sin k_m r \), where \( k_m^2 = \kappa^2 + k^2 \), while outside we write it as \( \sin(k(r - L) + \delta) \). Then, matching across the boundary at \( r = L \) gives

\[ A \sin k_m L = \sin \delta, \quad k_m A \cos k_m L = k \cos \delta. \quad (A30) \]

Squaring these equations and adding them we can determine

\[ A^2 = \frac{1}{\sin^2 k_m L + \frac{k_m^2}{\kappa^2} \cos^2 k_m L} \quad (A31) \]

and so

\[ S_k = \frac{A^2 k_m^2}{k^2} = \frac{1}{\frac{k_m^2}{\kappa^2} \sin^2 k_m L + \cos^2 k_m L}. \quad (A32) \]

Now for \( k^2/2M \ll V_0 \), we have \( k_m = \kappa + k^2/(2\kappa) + \cdots \). Clearly, if \( \cos kL \) is not close to zero, there is no enhancement. However, if \( \cos kL = 0 \), then we have a large enhancement

\[ S_k \sim \frac{\kappa^2}{k^2}. \quad (A33) \]

This has a very simple physical interpretation in terms of resonance with a zero-energy bound state. Our well has a number of bound states, and typically the binding energies are of order \( V_0 \). We see that if \( \cos kL \) is not close to zero, we have to have \( A \sim k/k_m \) be small. However, if accidentally \( \cos kL = 0 \), then there is a zero-energy bound state: the wave function can match on to \( \psi = 1 \) for \( r > L \) smoothly, giving a zero-energy bound state. The enhancement is of the form

\[ S \sim \frac{V_0}{E - E_{\text{bound}}} \sim \frac{\kappa^2}{k^2}. \quad (A34) \]

Note this formally diverges as \( v \to 0 \), but is actually cut off by the finite width of the state as familiar from Breit-Wigner.
3. Attractive Yukawa potential

Now let us examine

$$V(r) = -\frac{\alpha}{2r} e^{-m\phi r}. \quad (A35)$$

Working again in Bohr units, we have

$$V(x) = -\frac{1}{x} e^{-x^2}, \quad (A36)$$

where

$$\epsilon_\phi = \frac{m_\phi}{\alpha M}. \quad (A37)$$

Now, if $\epsilon_\phi \ll \epsilon_\nu$, the Yukawa term is always irrelevant and we revert to our previous Coulomb analysis.

However, if $\epsilon_\phi \gg \epsilon_\nu$, our analysis changes; we will use the second expression for the Sommerfeld enhancement for simplicity. The potential turns off exponentially around $x \approx 1/\epsilon_\phi$. Now, the effective momentum is

$$k_{\text{eff}}^2 = \frac{1}{x} e^{-x^2} + \epsilon_\nu^2 \quad (A38)$$

and the quantity

$$\left| \frac{k_{\text{eff}}'}{k_{\text{eff}}^2} \right| \quad (A39)$$

determines the length scale the potential is varying over relative to the wavelength; so long as it is small, the WKB approximation is good. Let us now take the arbitrarily low-velocity limit, where $\epsilon_\nu \to 0$. Then in the neighborhood of $x \approx 1/\epsilon_\phi$ we have $k_{\text{eff}}^2 \sim \epsilon_\phi e^{-x^2}$, and

$$\left| \frac{k_{\text{eff}}'}{k_{\text{eff}}^2} \right| \sim \sqrt{\epsilon_\phi} e^{(1/2)x^2} - \frac{\epsilon_\phi}{k_{\text{eff}}} \quad (A40)$$

so the WKB approximation breaks down when $k_{\text{eff}} \sim \epsilon_\phi$, where the WKB amplitude is $\sim e^{-1/2}$. The potential then varies more sharply than the wavelength, and we have a reflection/transmission problem, with an O(1) fraction of the amplitude escaping to infinity. The enhancement is then

$$S \sim \frac{1}{\epsilon_\nu} \sim \frac{\alpha M}{m_\phi}. \quad (A41)$$

We did this analysis for $\epsilon_\nu \to 0$, but clearly it will hold for larger $\epsilon_\nu$, till $\epsilon_\nu \sim \epsilon_\phi$, at which point it matches smoothly to the $1/\epsilon_\nu$ enhancement we get for the Coulomb problem. The crossover with $\epsilon_\nu \sim \epsilon_\phi$ is equivalent to $M\nu \sim m_\phi$, when the deBroglie wavelength of the particle is comparable to the range of the interaction. This is intuitive—as the particle velocity drops and the deBroglie wavelength becomes larger than the range of the attractive force, the enhancement saturates. Of course if $\epsilon_\phi$ is close to the values that make the Yukawa potential have zero-energy bound states, then the enhancement is much larger; we can get an additional enhancement $\sim \epsilon_\phi/\epsilon_\nu^2$ up to the point where it gets cut off by finite width effects.

In this simple theory it is of course also straightforward to solve for the Sommerfeld enhancement numerically. We show the enhancement as a function of $\epsilon_\phi$ and $\epsilon_\nu$ in Figs. 6 and 7.

![FIG. 6. Contour plot of $S$ as a function of $\epsilon_\phi$ and $\epsilon_\nu$. The lower right triangle corresponds to the zero-mass limit, whereas the upper left triangle is the resonance region.](image)

![FIG. 7. As in Fig. 6, showing the resonance region in more detail.](image)
4. Two-particle annihilation

Let us finally consider our real case of interest, involving two-particle annihilation. To keep things simple, let us imagine that the two particles are not identical, for instance they could be Majorana fermions with opposite spins; we can restrict to this case because none of the interactions we consider depend on spin, and the annihilation channels we imagine can all proceed from this spin configuration. Let us imagine that there are a number of states \( \{A \} \) of (nearly) equal mass, with the label \( A \) running from \( A = 1, \ldots, N \). The two-particle Hilbert space is labeled by states \( | \vec{x}, A; \vec{y}, B \rangle \) and a general wave function is \( \langle \psi | \vec{x}, A; \vec{y}, B \rangle \equiv \psi_{AB}(\vec{x}, \vec{y}) \). There is some short-range annihilation Hamiltonian \( U \delta^3(\vec{x}_1 - \vec{x}_2) \) into decay products \( | \text{final} \rangle \); where \( U \) is an operator

\[
\langle \text{final} | U | AB \rangle = M_{AB}^{\text{ann}}. \tag{A42}
\]

Now, suppose there is also a long-range interaction between the two particles with a potential. The general Schrödinger equation is of the form

\[
-\frac{1}{2M} \left( \nabla_x^2 + \nabla_y^2 \right) \psi_{AB}(x, y) + V_{ABCD}(x - y) \psi_{CD}(x, y) = E \psi_{AB}(x, y). \tag{A43}
\]

As usual we factor out the center-of-mass motion by writing \( \psi_{AB}(\vec{x}, \vec{y}) \equiv e^{iP(\vec{x} + \vec{y})/M} \phi_{AB}(\vec{x} - \vec{y}) \), and we have

\[
-\frac{1}{M} \nabla^2 \phi_{AB}(\vec{r}) + V_{ABCD}(\vec{r}) \phi_{CD}(\vec{r}) = E_{CM} \phi_{AB}(\vec{r}), \tag{A44}
\]

where \( E_{CM} \) is the energy in the center-of-mass frame.

We have an initial state with some definite \( A_+, B_+ \), and we take as an unperturbed solution

\[
\phi^{(A^+B^+)}(0)_{AB} = \phi_{A+}^B \delta_{B+}^e e^{ikz}. \tag{A45}
\]

The annihilation cross section without the interaction \( V \) is proportional to

\[
\sigma_{\text{ann}}^{(0)} \propto | M_{A^+B^+}^{\text{ann}} |^2. \tag{A46}
\]

However with the new interaction, the annihilation cross section is

\[
\sigma_{\text{ann}} \propto | \phi_{CD}^{(A^+B^+)}(0) M_{CD} |^2. \tag{A47}
\]

So we can write

\[
\sigma_{\text{ann}} = \sigma_{\text{ann}}^{(0)} \times S_k^{A^+B^+}, \tag{A48}
\]

where

\[
S_k^{A^+B^+} = \left( \frac{| \phi_{CD}^{A^+B^+}(0) M_{CD}^{\text{ann}} |^2}{| \phi_{CD}^{A^+B^+}(\infty) M_{CD}^{\text{ann}} |^2} \right). \tag{A49}
\]

Just as above, in reducing the problem to an \( S \)-wave computation, we can replace \( \phi_{CD}^{A^+B^+}(0) \) with \( \chi'(r = 0)_{CD}^{A^+B^+} \) in the obvious way.

Of course one contribution to \( V_{ABCD} \) comes from the small mass splittings between the states. If we write the (almost equal) common mass term for the DM states as \( (M + \Delta M_A) \chi_A \chi_A \), the \( \Delta M \)'s show up in the potential as

\[
V_{ABCD}^{\text{split}} = (\Delta M_A + \Delta M_B) \delta_{AC} \delta_{BD}. \tag{A50}
\]

For the Sommerfeld enhancement, we also need some long-range attractive interaction. As we have discussed, vectors are possibly the most promising candidate. The leading coupling to spin-1 particles \( a_{\mu} \) is

\[
g \tilde{\chi}_A \sigma^\mu \chi_B T^i_{AB} a_{\mu}, \tag{A51}
\]

and ignoring the mass of the gauge boson this gives us a \( 1/r \) contribution to the effective potential

\[
V_{ABCD}^{\text{gauge}}(\vec{r}) = -\frac{1}{r} T^i_{AC} T^i_{BD} \tag{A52}
\]

while taking the vector masses into account gives both Yukawa exponential factors and a more complicated tensor structure. In total,

\[
V_{ABCD} = V_{ABCD}^{\text{split}} + V_{ABCD}^{\text{gauge}} \tag{A53}
\]

Now, it is obvious that in our basis, the \( T^i_{AB} \) should be antisymmetric

\[
T^i_{AB} = -T^i_{BA} \tag{A54}
\]

since the gauge symmetry must be a subgroup of the \( SO(N) \) global symmetry preserved by the large common mass term \( M_{\chi_A \chi_A} \), and the \( SO(N) \) generators are antisymmetric. Thus, the coupling to vectors in this basis is necessarily off-diagonal. Let us look at a simple example, where \( N = 2 \) and we have a single Abelian gauge field. The \( \phi_{AB} \) span a four-dimensional Hilbert space, with \([11],[12],[21],[22]\) as a basis. Since the gauge boson exchange necessarily changes \( 1 \leftrightarrow 2 \), \( V_{ABCD} \) is block diagonal, operating in two separate Hilbert spaces, spanned by \([11],[22]\) and \([12],[21]\). Since we are ultimately interested in scattering with \( 11 \) initial states, let us look at the first one, where we have

\[
V = \begin{pmatrix} 2 \Delta M & -a \frac{2}{r} & 0 \\ -a \frac{2}{r} & 0 & \sqrt{r} \\ 0 & \sqrt{r} & 0 \end{pmatrix}. \tag{A55}
\]

Clearly, if \( \Delta M \) is enormous, we will not have any interesting Sommerfeld enhancement in \([11]\) scattering, since in this case there is no long-range interaction between \( 11 \) at all, so let us assume that \( \Delta M \) is smaller than the kinetic energy of the collision. Now it is clear that as \( r \to \infty \), the mass splitting dominates the potential, and obviously particle 1 is the lightest state. However, at smaller distances, the gauge exchange term dominates. This is not diagonal in the same basis, and has “attractive” and “repulsive” eigenstates with energies \( \pm \alpha/r \). Note that the asymptotic
A THEORY OF DARK MATTER

PHYSICAL REVIEW D 79, 015014 (2009)

[11] state is an equal linear combination of the attractive and repulsive channels. While the repulsive channels suffer a Sommerfeld suppression, the attractive channel is Sommerfeld enhanced. Note that as long as $\Delta M$ is parametrically smaller than the kinetic energy, its only role in this discussion was to split the two asymptotic states, and therefore determine what the natural initial states are. Note also that if $\Delta M$ is large but not infinite, the mixing with 2 generates an attractive potential between 11 of the form $V_{\text{eff}}(r) = -\alpha^2/(\Delta M r)$. It would be interesting to understand these limits of the multistate Sommerfeld effect in parametric detail; we defer this to future work.

It is very easy to see that our conclusion about the presence of a Sommerfeld effect is general for any gauge interaction. We think of $V^{\text{gauge}}_{(AB)(CD)}$ as a matrix in the Hilbert space spanned by $(AB)$. Note that since the $T^i$ are antisymmetric, they are also traceless, and as a consequence, the matrix $V^{\text{gauge}}_{(AB)(CD)}$ is also traceless and so has both positive and negative eigenvalues, reflecting the obvious fact that gauge exchange gives us both attractive and repulsive potentials. Let us go to a basis in $(AB)$ space

where $V^{\text{gauge}}$ is diagonal, and denote eigenvectors with negative (attractive) eigenvalues as $f^{\text{at}}_{AB}$ and repulsive ones as $f^{\text{rep}}_{AB}$. We can think of the initial wave function in $AB$ space $\delta_{AB}^{AB'}$ as a state in $(AB)$ space and expand it in terms of these eigenvectors as

$$\delta_{AB}^{AB'} = C_{\text{at}}^{AB'} f^{\text{at}}_{AB} + C_{\text{rep}}^{AB'} f^{\text{rep}}_{AB}.$$  

(A56)

We can determine the coefficients by dotting the left-hand side and right-hand side into the eigenvectors, so that

$$\delta_{AB}^{AB'} = f^{\text{at}}_{A'B'} f^{\text{at}}_{AB} + f^{\text{rep}}_{A'B'} f^{\text{rep}}_{AB}.$$  

(A57)

Then, since the repulsive components are exponentially suppressed at the origin while the attractive components are enhanced, we get a Sommerfeld enhancement as long as $f^{\text{at}}_{A'B'} \neq 0$. In particular, for scattering the same species, this is true so long as $f^{\text{at}}_{A'A} \neq 0$. Said more colloquially, these Majorana states are linear combinations of positive and negative charged states; so long as they have any component which would mutually attract, there is a Sommerfeld enhancement from that component alone.

[18] Although, it should be noted that such an explanation seems to fail because the spectrum would not be sufficiently hard; see Fig. 6 of [11].
[33] The importance of this effect in the context of multi-TeV scale dark matter interacting via W and Z bosons was first discussed by [34], and more recently emphasized with regards to PAMELA in the context of "minimal dark matter," with similar masses by [35,36].
Another possibility for sufficiently light bosons would be radiative capture [38].

[47] Recently, [48] explored the possibility that PAMELA could distinguish the spin of the dark matter, which could be relevant here in annihilations to vector bosons.

[60] Note that in the early universe, all these states will be populated at freeze-out and will participate in maintaining thermal equilibrium. However, unlike coannihilation in the MSSM, which typically occurs between a bino and a slepton, there is not expected to be a large effect, on the connection between the present annihilation rate and that at freeze-out. This is because the self-annihilation and coannihilation cross sections are similar or even equal here, while in the MSSM the coannihilation cross section is much larger.

[62] Although larger annihilation rates into W^+ W^- or other standard model states are possible, the cross section must be lower than the limits of [27,63] arising from antiprotons. Moreover, strong limits from final state radiation [64] can also arise, although these depend more sensitively on the nature of the halo profile.
